This ring is kept in contact with the carbon rings by a coiled wire and spring. The spring is so formed that the possibilities of breakage are very remote.

Each packing unit is enclosed in a chamber ring Z of L section. The relative positions are made definite by stops.

The joints of the sections of all the rings are staggered to ensure steam tightness.

The coned circumferences of the packing rings produce radial and axial contact pressures between the carbon rings X, X, and the metal ring Y.

---

* *Steam Turbines—their Theory and Construction*, H. M. Martin.

† See also pp. 1263, 1805, and 1949.

The radial components give the necessary contact pressures between the packing rings and he shaft, while the axial components produce contact pressures between the packing rings and he sides of the chambers. The side pressures serve two purposes—viz. they produce surface

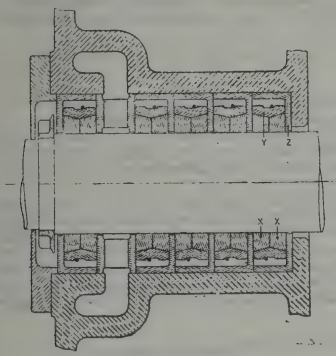

FIG. 12A.

friction which supports the weight of the packing units, and they also ensure steam-tight joints between the packings and walls of the chambers. As the shaft is relieved of the weight of the packing it is subjected only to uniform radial contact pressures, with the result that the wear on both the shaft and packings is reduced to a minimum. Means for adjusting the contact pressures are provided on the coiled wire.

Dummy Loss.

In the majority of single-flow Parsons turbines the axial thrust on the blades and drum is balanced by dummy pistons. A labyrinth packing is formed on the periphery of the dummy pistons to reduce the leakage of steam which would otherwise take place across the dummy piston to the exhaust to which they are connected on one side.

The loss of steam through the dummy clearances can be calculated in precisely the same way as the loss through a labyrinth packing.

The double-flow type of turbine obviating the necessity of balance pistons eliminates this loss.

Disc Friction.

A considerable amount of work may be absorbed in rotating the discs of impulse turbines in the dense steam present in the first stages of a pressure-compounded (disc) turbine.

Professor Stodola * has given the following formula for the disc friction loss :

$$\text{B.H.P.} = \frac{6.1}{10^8} D^2 U^3 \gamma,$$

where,

D = mean diameter of blades in feet ; U = mean peripheral velocity feet per sec. ; γ = density of steam in lbs. per cu. ft.

The experiments upon which this formula is based were performed either in air, superheated steam, or in steam whose exact condition as regards wetness was unknown.

Professor Lewicki has demonstrated that the combined work of disc friction and windage falls off with superheat, some of his experiments showing a reduction of 10 per cent. in the work done for an increase of superheat of 100° C. As the total loss due to disc friction is usually of the order of a few per cent. of the output of the turbine, the reduction with superheat is of little importance.

On the other hand, it seems probable that the disc friction would increase rapidly with the wetness of the steam, but there are at present no data for estimating this increase. For these reasons, the disc friction loss for any given turbine cannot be calculated with certainty.

* *Die Dampfturbinen*, 4th Ed., Prof. A. Stodola.

Windage.

In addition to the disc friction, loss results from the fanning action of the blades as th rotate.

The laws governing this action cannot be regarded as established, the range of experime has been limited, and results by the same experimenters are discordant. Professor Stodola* gi the following formula :

$$\text{B.H.P.} = \frac{4.6}{10^7} \cdot D \cdot l^{1.6} \cdot U^3 \cdot \gamma,$$

where,

l = blade length in inches ; D = mean diameter of blades in ft. ; U = mean periphe velocity in ft. per sec. ; γ = density of steam in lbs. per cubic ft.

Mr. W. Kerr carried out some careful tests on this subject, and by comparing his o results with those of Professor Stodola and Dr. Lasche, suggests that for wheels carrying t rows of blades the work calculated by the above formula must be multiplied by 1·23, for thr rows by 1·8, and for four rows by 2·9.†

When mixed pressure turbines are working with low-pressure steam the high-pressure end rotating idly in an atmosphere of steam, and with disc turbines the work done in disc fricti and windage is not negligible. With reaction turbines a windage loss alone is present, and this mainly due to the fanning action of reaction blading. Sir C. A. Parsons has stated that in the ca of a reverse element of a marine turbine rotating in a vacuum the loss is of the order of 1 p cent., so that the loss due to the rotation of the high-pressure element of a mixed-pressure Parso turbine rotating in steam twelve times as dense as a 28-in. vacuum may be considerable.

Water Glands.

An interesting feature in the development of turbine design consists in the introduction the water gland.

In this type, an air-seal is produced by a paddle-wheel acting as a centrifugal pump. Th

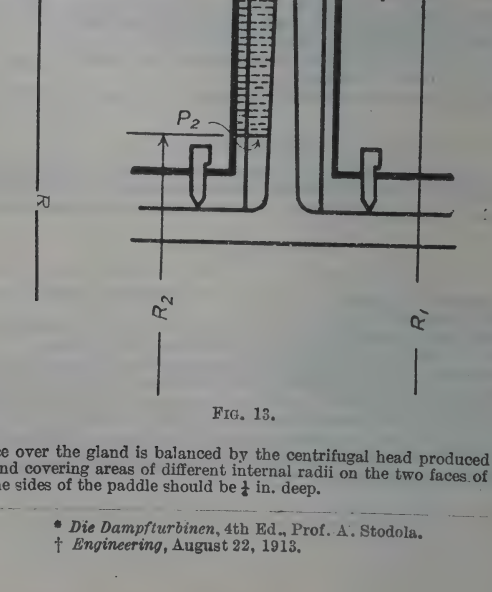

FIG. 13.

pressure difference over the gland is balanced by the centrifugal head produced in the water a it is whirled around covering areas of different internal radii on the two faces of the paddle.

The ribs on the sides of the paddle should be ¼ in. deep.

* *Die Dampfturbinen*, 4th Ed., Prof. A. Stodola.
† *Engineering*, August 22, 1913.

If P_1 (fig. 13) = the pressure on the high-pressure side in lbs. per square ft.; P_2 = the pressure on the low-pressure side in lbs. per square ft.; R_1 = inner radius in ft. of the whirling water on the H.P. face; R_2 = inner radius in ft. of the whirling water on the L.P. face; ρ = density of water = 62·3; ω = angular velocity of paddle in radians per second.

Then

$$P_2 - P_1 = \frac{\omega^2 \rho}{240\,A}(R_1^2 - R_2^2) \text{ and } P_3 - P_1 = \frac{\omega^2 \rho}{240\,A}(R_3^2 - R_1^2)$$

The value of A varies from 0·9 to 1·10″.

Although the water gland when first introduced gave rise to troubles, it has proved successful when used in conjunction with a labyrinth packing, for the purpose of preventing air leaking into the turbine casing.

Since a sufficient centrifugal head to form a seal is not developed until the turbine is running at some speed near the normal, it is necessary to steam-seal the glands as the turbine is started up.

The gland must be supplied with a constant stream of water to make up the loss which takes place by evaporation on the vacuum side of the seal. The water is admitted at the periphery of the gland, and should be supplied from a head of about 15 ft. This will, of course, be equal to $(P_3 - P_1)$.

A water gland cannot be used to seal against steam at a pressure above atmospheric, because the water boils and the seal is destroyed.

Tip Clearance Loss.

As has already been pointed out, there is always a difference of pressure over both the fixed and rotating blades of a reaction turbine. In consequence of this there is always a leakage of steam

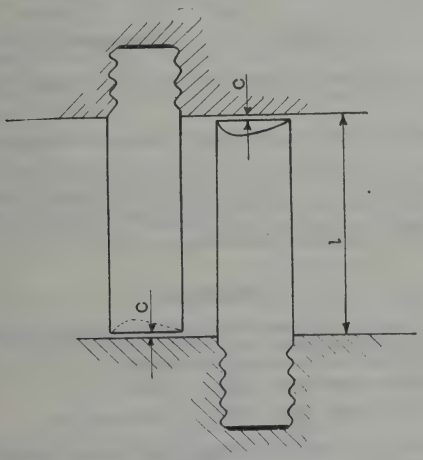

FIG. 14.

at the tips of the blades through the working clearances which have to be provided. In parallel flow reaction turbines there are two principal ways of providing these clearances:

(1) By means of radial clearance reaction blading (see fig. 14).

(2) By means of axial clearance or ' end tightened ' reaction blading (see fig. 15).

The clearance C usually allowed in design varies approximately between the following limit for radial blading, all dimensions being in inches :

$$c = 0{\cdot}0008\,d \text{ to } c = 0{\cdot}0008\,d + 0{\cdot}004\,l + 0{\cdot}015,$$

where,

d = mean diameter of blades ;

l = blade height.

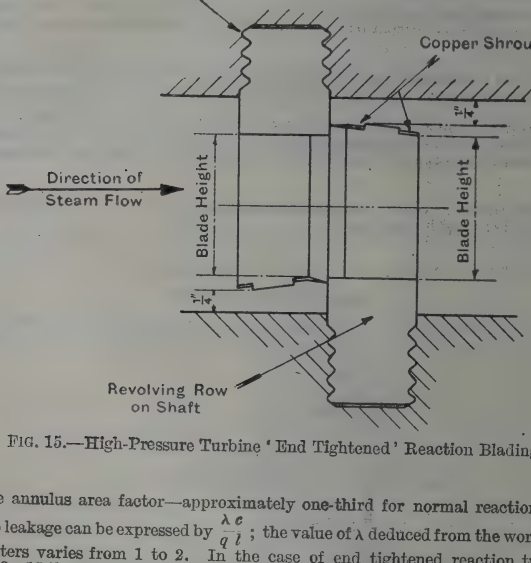

FIG. 15.—High-Pressure Turbine ' End Tightened ' Reaction Blading.

If q is the annulus area factor—approximately one-third for normal reaction blading—the loss due to tip leakage can be expressed by $\frac{\lambda c}{q l}$; the value of λ deduced from the work of a number of experimenters varies from 1 to 2. In the case of end tightened reaction turbine blading illustrated in fig. 15 the fine clearances are arranged in an axial instead of a radial direction. This type of blading is usually confined to the high-pressure end of the turbine, and an adjustable thrust block is provided to enable this clearance to be adjusted.

Bearings.

l = the length of a bearing in inches ; d = diameter of journal in inches ; p = pressure on bearing per square inch projected area ; N = speed of turbine in R.P.M. ; μ = coefficient of friction ; v = peripheral speed of journal in feet per second.

Then the work done in overcoming the bearing friction is

$$\text{Friction work} = \frac{\mu \pi l d^2 p N}{720} \text{ ft. lbs. per sec.}$$

The heat equivalent of this work must be carried away from each bearing if they are to remain at a constant temperature.

According to Lasche's experiments, if $t°$ F. is the final steady temperature of the bearing, the coefficient of friction is given by the following relation :

$$\mu \,.\, p \,.\, (t° - 32°) = 51{\cdot}2.$$

For turbine bearings $t°$ should be from 120° F. to 150° F.

Assuming a temperature of 140° F., which is about an average value, these expressions can be reduced to:

$$\text{Work done in friction} = 3{\cdot}75\left(\frac{l}{10}\right)\left(\frac{d^2}{100}\right)\left(\frac{N}{1{,}000}\right) \text{ b.h.p.}$$

With average bearings bedded in the normal way, it is found that the work done exceeds the amount just given, being usually about twice as great.

One of the striking features of the recent developments in steam turbines has been the successive increases in the specific loadings and rubbing speeds on bearings.

This rating up of bearings has been accompanied by uniform success in all cases where the natural requirements of good lubrication have been safeguarded.

The oil supplied to the bearing has two functions to perform: it must sustain the oil film, and it must flush the bearing copiously to carry away the heat generated in shearing the oil film.

The quantity of oil required by the latter consideration is by far the greater of the two: the necessary amount of oil can readily be estimated from the relation that for ordinary turbine oils—

1·0 b.h.p. in oil friction raises 1·0 gallon of oil per minute by 10° F.

In the average case the temperature of the oil passing through the bearings is such that its temperature rise in passing through the bearing is from 20° to 40° F.; therefore, for 40° F. rise in temperature the oil quantity which should be supplied to a bearing is given by oil which

$$\text{should be supplied} = 2 \times \frac{3{\cdot}75ld^2N}{40 \times 10^5} \text{ gals. per min., or, approximately, } = \frac{2ld^2N}{10^5} \text{ gals. per min.}$$

This represents the minimum quantity required, and may be increased up to double this amount with advantage.

The lengths of turbine bearings vary from $l = 2{\cdot}5d$ to $l = d$, the former value being usual for lightly loaded slow-speed bearings of older design, and the latter being approached with modern high-speed high-rated bearings.

At the present state of the art it is impossible to state the upper limits for permissible loading and rubbing velocity. Bearings are now quite common with loadings up to 110 lbs. per sq. in. and with rubbing velocities up to 130 ft. per sec.

According to modern ideas and practice, the old rules of the form pv = constant are quite unsound—in fact, when p is increased, v can and should be increased.

After leaving the bearings the oil is passed through an oil cooler, where it is cooled to some temperature usually below 110° F., although, of course, the actual temperature depends upon that of the cooling water available.

Turbine bearings give remarkably little trouble, provided the oil is kept clean and there is no tendency to emulsify.

In very small turbines the bearings are sometimes ring-lubricated, and in such cases the peripheral speed should not exceed 40 ft. per sec.; at higher speeds the oil tends to be thrown to the outside of the ring by centrifugal force.

Even in very small turbines there is now a tendency to fit a forced lubrication system provided with an oil cooler.

Centrifugal Stresses in Drums and Discs.

Stresses in thin Ring or Drum.

$$\text{Mean tangential stress} = 2\,(D)^2\left(\frac{N}{1000}\right)^2 \text{lbs./sq. ins.}$$

Solid Parallel-sided Disc.

If U_2 = peripheral velocity at the outside diam. in ft./sec.,

then radial stress at any radius x is $\sigma_r = \frac{4{\cdot}36U_2^2}{100}\left[1 - \frac{x^2}{x_2^2}\right]$ lbs./sq. ins.

and the tangential stress $\sigma_t = \frac{U_2^2}{100}\left[4{\cdot}36 - 2{\cdot}51\,\frac{x^2}{x_2^2}\right]$ lbs./sq. ins.

The maximum stress at the centre is given by

$$\sigma_{r\,max} = \sigma_{t\,max} = \frac{4{\cdot}36\,U_2^2}{100} \text{ lbs./sq. ins.}$$

If the diameter of the disc = D inches, this can be written

$$\sigma_{t\,max} = 0{\cdot}835\,(D)^2\left(\frac{N}{1000}\right)^2 \text{ lbs./sq. ins.}$$

Parallel-sided Disc with Hole in Centre.

At any radius x

Radial stress $\sigma_r = \frac{4{\cdot}36}{100}U_2^2\left[1 + \frac{(x_1^2 - x^2)}{x_2^2} - \frac{x_1^2}{x^2}\right]$ lbs./sq. ins.

Tangential stress $\sigma_t = \frac{U_2^2}{100}\left[4{\cdot}36\left(1 + \frac{x_1^2}{x_2^2} + \frac{x_1^2}{x^2}\right) - 2{\cdot}51\,\frac{x^2}{x_2^2}\right]$ lbs./sq. ins.

Dimensional symbols as shown in fig. 16.

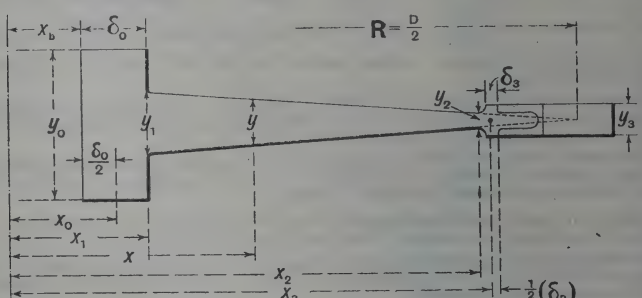

FIG. 16.

Disc with Hyperbolic Profile.

If the profile can be expressed as a hyperbolic function of the form $y = \frac{(\text{constant})}{x^a}$, the following analysis can be used :

Let

ω = angular velocity in radians/sec. $= \frac{N \times 2\pi}{60}$;

E = Young's modulus of elasticity = 30×10^6 lbs./sq. in. for steel;

ν = Poisson's ratio = 0·3 for steel;

σ_3 = load on outer edge of disc due to blade loading in lbs./sq. in. ;

σ_0 = stress at bore due to pinch fit;

μ = mass per unit volume ;

then $$a = \frac{\log\left(\frac{y_2}{y_1}\right)}{\log\left(\frac{x_1}{x_2}\right)}.$$

f $$\psi_1 = \frac{a}{2} + \sqrt{\frac{a^2}{4} + a\nu + 1}, \quad \psi_2 = \frac{a}{2} - \sqrt{\frac{a^2}{4} + a\nu + 1}.$$

and $$a = -\frac{(1-\nu^2)\mu\omega^2}{E[8-(3+\nu)a]},$$

hen radial stress at any point

$$\sigma_r = \frac{E}{(1-\nu^2)}\left[(3+\nu)a x^2 + (\psi_1+\nu)b_1 x^{\psi_1 - 1} + (\psi_2+\nu)b_2 x^{\psi_2 - 1}\right] \quad \ldots.(1)$$

nd tangential stress

$$\sigma_t = \frac{E}{(1-\nu^2)}\left[(1+3\nu)a x^2 + (1+\psi_1\nu)b_1 x^{\psi_1 - 1} + (1+\psi_2\nu)b_2 x^{\psi_2 - 1}\right] \ldots.(2)$$

In order to calculate constants b_1 and b_2, make use of the boundary conditions:—

Extension at outside, where $x = x_2$

$$\xi_2 = \frac{x_3^2}{E\delta_3 y_3}\left(\sigma_3 y_3 + \mu\omega^2\delta_3 y_3 x_3 - \sigma r_2 \frac{x_2 y_2}{x_3}\right) \quad \ldots.(3)$$

Extension at inside, where $x = x_1$

$$\xi_1 = \left(\frac{x_0^2}{E\delta_0 y_0}\sigma_0 y_0 + \mu\omega^2\delta_0 y_0 x_0 + \sigma r_1 \frac{x_1 y_1}{x_0}\right) \quad \ldots.(4)$$

But $$\xi_1 \text{ also} = a x_1^3 + b_1 x_1^{\psi_1} + b_2 x_1^{\psi_2} \ldots\ldots\ldots\ldots\ldots\ldots(5)$$

and $$\xi_2 = a x_2^3 + b_1 x_2^{\psi_1} + b_2 x_2^{\psi_2} \ldots\ldots\ldots\ldots\ldots\ldots(6)$$

By equating (3) and (6), also (4) and (5), the two resulting equations can be solved for b_1 and b_2.

When these values are put in (1) and (2) the radial and tangential stresses at any point in the disc can be obtained.

Disc with Straight-sided Taper Profile.

Treating a disc as having a conical profile, Mr. H. M. Martin * has derived a means of arriving at the stresses, which, together with the amendment to incorporate the effect of the hub, as suggested by Mr. B. Hodkinson,† provides a useful method.

The stresses throughout a conical disc are:

$$\text{Radial} = \sigma_r = Tp_c + Ap_1 + Bp_2 \ldots\ldots\ldots\ldots\ldots\ldots(1)$$

$$\text{Tangential} = \sigma_t = Tq_c + Aq_1 + Bq_2 \ldots\ldots\ldots\ldots\ldots\ldots(2)$$

where T = stress in a thin ring

$$= 2D^2\left(\frac{N}{1{,}000}\right)^2 \text{ lbs./sq. in. for steel.}$$

D = diameter of completed cone.

$p_c, p_1, p_2, q_c, q_1, q_2$, are given in the curves, fig. 17, p. 1852, co-ordinated with the ratio $\frac{x}{R}$.

The constants A and B have always to be found by writing 'boundary conditions.' Thus at the inner limit of the conical portion where it joins the hub:

$$\sigma t_1 = \left\{\sigma_4 \frac{2x_b^2}{x_1^2 - x_b^2} + 2\left(\frac{N}{500}\right)^2 (0{\cdot}175 x_1^2 + 0{\cdot}825 x_b^2)\right\}$$

$$+ \sigma_{r_1}\left\{\frac{y_1}{y_0}\left[\frac{x_1^2 + x_b^2}{x_1^2 - x_b^2} - 0{\cdot}3\right] + 0{\cdot}3\right\} \ldots\ldots\ldots\ldots\ldots(3)$$

FIG. 17.

here σ_1 is the 'pinch' pressure inside the bore in lbs./sq. in. At the rim

$$\sigma_{t_2} = \left\{ \frac{\text{Total centrifugal force of blades}}{2\pi\delta_2 y_3} + 2x_3^2\left(\frac{N}{500}\right)^2 \right\} - \sigma_{r_2}\left\{\frac{x_2 y_2}{\delta_2 y_3} - 0{\cdot}3\right\} \quad \ldots (4)$$

Putting in equations (1) and (2) the values of p_0, p_1, p_2, q_0, q_1, q_2, at the inner radius of the me, and using the resulting expressions as σ_{r_1} and σ_{t_1} in equation (3), an equation involving only and B is obtained. Writing similarly for the outer radius of the cone a second equation volving A and B, these constants can be calculated, whence the stresses anywhere in the disc e known.

The stresses throughout the hub then are:

$$\sigma_r = \sigma_{r_1}\frac{y_1(x^2-x_b^2)x_1^2}{y_0 x_1^2 - x^2 x^2} - \sigma_4\frac{x_b^2}{x^2}\frac{(x_1^2-x^2)}{(x_1^2-x_b^2)} + 0{\cdot}825\left(\frac{N}{500}\right)^2\left(x_1^2 + x_b^2 - x^2 - \frac{x_b^2 x_1^2}{x^2}\right).$$

$$\sigma t = \sigma_{r_1}\frac{y_1(x^2+x_b^2)x_1^2}{y_0(x_1^2-x_b^2)x^2} + \sigma_4\frac{x_b^2}{x^2}\frac{(x_1^2+x^2)}{(x_1^2-x_b^2)} + 0{\cdot}825\left(\frac{N}{500}\right)^2\left(x_1^2 + x_b^2 - 0{\cdot}575\,x^2 + \frac{x_b^2 x_1^2}{x^2}\right).$$

Pinch fit for Discs and Drums.

In order to ensure that the wheels shall be tight on the shaft at normal speed, they must be ressed on the shafts with an interference fit at least equal to the elastic expansion of the bore ue to centrifugal stresses.

This condition can be fulfilled without the maximum stresses in the wheel being greater hen the shaft is at rest than the centrifugal stress at normal speed, because in wheels of normal roportions the wheel bore expands during pressing on by only about two-thirds of the pinch llowance, the shaft diameter compressing by the remaining one-third.

Lubrication System.

In all cases except where ring lubrication is employed for small turbines, an oil pump is rovided to maintain a pressure of about 10 lbs. per sq. in. in the lubricating system. It should e emphasised that the actual oil pressure is of secondary importance, the prime object being to ush the bearings with a copious flood of oil, and that for this purpose 2 lbs. per sq. in. may be ufficient in a properly designed system. The oil on leaving the pump passes through a cooler f sufficient capacity to maintain the temperature of the oil leaving the bearings at about 0–68° F. above that of the inlet cooling water, bearing temperatures of 150° F. being quite ermissible. The main oil pump is usually driven by gearing from the turbine shaft, and the ormal pressure is reached when the turbine motor is running at about one-third the normal peed. A hand pump is usually provided to supply oil under pressure during starting up or hutting down, when the speed of the set is less than one-third the normal. An oil strainer hould be placed on the suction side of the pumps to prevent grit being circulated. Two to three allons of oil should be taken out of the tank daily and carefully filtered, the level of the tank eing kept constant by making up with freshly filtered oil or, when necessary, new oil. Once n each twelve months the oil tank and all accessible portions of the lubricating system should e emptied and cleaned; the tank should then be filled sufficiently with paraffin oil to enable the whole system to be flushed by operating the hand pump. The paraffin oil dissolves any gummy natter which may have deposited from the lubricating oil and thoroughly flushes away all dirt o the oil tank; the paraffin can then be removed and new or freshly filtered oil put in. These imple precautions will result in a real economy in oil consumption and a freedom from troubles nd maintenance charges which will amply repay the trouble involved.

There is a large number of lubricating oils supplied by makers of standing, all of which vill give satisfactory results in operation. For turbines driving geared installations an oil to the ollowing specification has been found to give satisfactory results:

Heavy turbine oil.

The specific gravity at 60° F. should be from 0·89 minimum to 0·91 maximum.
The flash point taken by a closed test should not be less than 390° F.
The viscosity measured with a Redwood viscometer should be within the following limits:

At 68° F.	Minimum 650 seconds.	Maximum 800 seconds.
At 140° F.	„ 90 „	„ 100 „

The acidity expressed as SO_3 should not exceed 0·005 per cent.

One of the most important properties lies in the freedom of a suitable oil from a tendency to form an emulsion. Suitable oils should satisfactorily pass the following test:

When steam is passed into 100 c.c. of oil until the total volume of the condensate and oil measures 200 c.c., the whole of the oil shall separate out within ten minutes, leaving the water clear.

The sludge value of the oil carried out, according to Dr. Michie's test, should not exceed 1·2 per cent.

The following specification would apply to oils suitable for steam turbines driving generators, etc., direct:

Light turbine oil.

The specific gravity at 60° F. shall be 0·87 minimum to 0·89 maximum.
The flash point of the oil measured by a closed test shall not be less than 365° F.
The viscosity measured with a Redwood viscometer shall conform to the following :

At 68° F.	Minimum 300 seconds.	Maximum 400 seconds.
At 140° F.	,, 60 ,,	,, 75 ,,

The acidity expressed as SO_3 shall not exceed 0·005 per cent.
When steam is passed into 100 c.c. of oil until the total volume of condensate and oil measures 200 c.c., the whole of the oil shall separate out within five minutes, leaving the water clear.
The sludge value, measured by Dr. Michie's test, shall not exceed 1·2 per cent.

See also ' Lubrication,' p. 1062.

Critical Speeds of Turbine Shafts.

At the critical speed of a loaded shaft, a small disturbance sets up vibrations which may reach a dangerous magnitude. For a uniform shaft, when the obliquity of the loading masses may be neglected, the critical speed coincides with the natural frequency of transverse vibration.
Although turbines have been run for considerable periods at their critical speeds without failure, this is a very dangerous proceeding and should be carefully avoided. It follows, therefore, that the critical speed should always be estimated, and should be at least 30 per cent. removed from the running speed.
This particularly applies to turbines of the disc type, and the calculation can be made with some degree of certainty. In drum turbines, the calculation is much more difficult, but in such cases as usually arise the critical speed is much above the running speed.
Table V. gives the formula for calculating the critical speeds of shafts of uniform diameter in certain standard cases.
Dunkerley has evolved theoretically, and demonstrated experimentally, a law from which can be determined the critical speed of a loaded system which corresponds to any combination of the standard cases.
By means of Table V. in conjunction with Dunkerley's formula, the first critical speeds of sensibly uniform shafts can be approximately calculated for any combination of loading, and any method of fixing the shaft at the bearings.
Thus if a rotor consists of a uniform shaft loaded with weights $W_2 W_3$ etc. as external loads,

n_1 = the critical speed of the shaft without the external loads ;

n_2, n_3, etc. = the critical speed of a massless shaft loaded with weights $W_2 W_3$ etc. ;

then the critical speed N of the system is given by

$$\frac{1}{N^2} = \frac{1}{n_1^2} + \frac{1}{n_2^2} + \frac{1}{n_3^2} + \ldots$$

In those cases of rotors having shafts stepped in diameter, as is usually the case in practice, the method already given is only a rough approximation, owing to the difficulty of judging the diameter of the equivalent uniform shaft.
Such cases may be dealt with by obtaining the maximum static deflection y of the shaft under various loads, by the graphical methods due to Mohr.
Then if

N = critical speed in R.P.M. ;

$N^2 y = C$, where C is constant.

For impulse turbine shafts supported in bearings which do not fix the direction of the shaft Mr. K. Baumann* has found that the value of C varies from 37,700 to 38,000 if y is in inches.

See also p. 1079.

MATERIALS FOR TURBINE CONSTRUCTION.

The use of such high peripheral speeds as are common in turbine practice introduced a new consideration into machine design ; because, unlike the conditions existing in reciprocating engine parts, the stresses in the various members are in the main due to centrifugal forces resulting from their own rotation. The stresses in a given turbine will, therefore, be proportional to the square of the numbers of revolutions per minute, and to the density of the material.

With an increase in the possible speed of rotation of a given turbine, the efficiency will in general be improved, since the average ratio $\frac{U}{C_0}$ in the various stages will be increased, or a greater heat drop can be utilised with the original efficiency.

d = Diam. of Shaft in ins.

Note Units employed.

On the other hand, the available heat drop per stage might be increased, so that the required number of stages for a given efficiency can be correspondingly reduced, or with the same number of stages the mean diameter of the blades can be reduced inversely as the revolutions per minute, both of which alternatives would result in a cheaper turbine.

Hence, it will be seen that in turbine work it is eminently desirable to use the highest possible peripheral speeds, the limit of which will be determined by the ultimate strength of the material employed.

British Electrical and Allied Manufacturers Association's Specifications for Turbine Forgings, Etc.

The following particulars have been extracted from the Association's specifications for forgings for turbine discs, shafts, and general forgings for use on land turbines.

The following table gives the minimum physical properties acceptable for each of four grades of materials:

Grade	I.			II.			III.			IV.		
*	L.	T.	R.	L.	T.	R.	L.	T	R.	L.	T.	R.
Minimum u.t. tensile tons per sq. in.	30	30	30	35	35	35	40	40	40	48	48	48
Yield point	15	15	15	17½	17½	17½	20	20	20	30	30	30
Minimum elongation per cent.	30	23	20	25	20	18	22	18	16	17	14	12
Minimum reduction in area, per cent.	45	40	38	40	35	32	35	32	30	40	35	30
Bending Angle	180°	160°	150°	180°	150°	135°	180°	150°	120°	180°	130°	100°
Test radius	⅜″	⅜″	⅜″	½″	½″	½″	¾″	¾″	¾″	¾″	¾″	¾″

* L.=Longitudinal. T.=Tangential. R.=Radial.

Grades Nos. I, II, and III are for carbon steels, whereas grade IV applies to an alloy steel. A margin of 3 per cent. below the reductions in area given in the above table is allowed to the steel maker providing this is compensated by a corresponding increase of 3 per cent. on the elongation.

Bend Tests.

A cold bend test is made upon test pieces having a rectangular section of ¾ in. by ¾ in. These test pieces shall be machined and the edges rounded to a radius of $\frac{1}{16}$nd. The test pieces shall be bent over the thinner section, and the bending shall be done by pressure or by blows. The test pieces must withstand being bent around the radii and through the angles given in the table without fracture.

Additional Test before Rejection.

If either tensile or bending test fail to fulfil the test requirements, and the inspector agrees that the test piece does not clearly represent the quality of the material, two duplicate specimens may, if the maker wishes, be tested, and if the results from both are satisfactory the quality of the material shall be judged therefrom, and not from the original test which failed. If, however, either of the duplicate tests fail the material represented will not be approved, and the manufacturer shall have the option of retreating and again presenting for test.

Table VI. gives the physical properties of steels used for steam turbine blading, the data for which have been supplied by the courtesy of Messrs. Thomas Firth & Sons, of Sheffield.

The blades of Parsons turbines are commonly of brass, the usual mixture being alloy of 63 per cent. copper to 37 per cent. zinc, having an ultimate strength of 20 tons per sq. in., an elastic limit of 12 tons per sq. in., and an elongation of 40–50 per cent.

The blades of impulse turbines are usually made of 5 per cent. nickel steel, although bronze blades are sometimes called for.

The physical properties of a bronze are greatly dependent on the treatment to which it may have been subjected, cold working having the effect of raising the ultimate strength and reducing the ductility.

Such an increase in the ultimate strength is to a large extent artificial, the material returning to its virgin state under the influence of high temperature or vibration.

The importance of this effect will be emphasised by the figures published by M. Breuil† and reproduced in Table VII. respecting the effect of temperature on some materials used for blading.

† *Engineering*, July 5, 1912.

TABLE VI.—PHYSICAL PROPERTIES OF STEELS USED IN STEAM TURBINE CONSTRUCTION.

Nature of Material.	Yield Point, Tons per sq. in.	Ultimate Strength, Tons per sq. in.	Elongation on 2-in. Gauge Points.	Purpose for which Material is Employed.	Remarks.
			Per Cent.		
5 per cent. nickel steel sheets	25	40	20	Turbine blades and shrouding strips supplied mild in sheets for stamping and bending	—
5 per cent. nickel steel sheets	—	35–42	20–24	Turbine blades and shrouding strips	Higher carbon content than above
5 per cent. nickel steel bars	30–35	40–45	25	To be drawn into blade sections	—

For some years so-called rustless irons and steels have been used for turbine blades. These aterials can now be regarded as of proved usefulness for turbine blading, owing not only to eir comparatively high resistance to erosion and corrosion, but to their attractive mechanical operties.

Rustless steels are a chromium alloy, usually for turbine blading of composition within the llowing limits : carbon, 0·10 to 0·40 per cent. ; chromium, 12 to 15 per cent. Ultimate strength,) to 50 tons/sq. in. ; yield point, 30 tons/sq. in ; elongation, 25 per cent. ; izod test, 25 ft./lbs.

Most non-ferrous alloys suffer under high temperatures in a loss of mechanical strength and ther desirable physical properties.

The following table illustrates the effect of temperature on some typical materials :

TABLE VII.—MATERIALS FOR TURBINES.

Nature of Material.	Elastic Limit, Tons per Sq. In.	Ultimate Strength. Tons per Sq. In.	Elongation.	Temperature.
			Per Cent.	
70 per cent. copper . 28 per cent. pure zinc .	34·9	36·2	11	Ordinary
	34·3	36·2	8·5	100° C.
	32·7	34·3	11	200°
	22·2	24·1	30	300°
	7·6	12·7	75	400°
85 per cent. copper . 15 per cent. manganese .	38·7	41·3	10·2	Ordinary
	36·8	40·0	10·5	100° C.
	37·5	41·0	11·0	200°
	32·0	36·8	21·0	300°
	21·0	24·1	68·0	400°

From this it follows that before figures relating to the strengths of alloys can be accepted as orking data the effect of temperature and the previous history of the specimens fractured in the est should be known.

Phosphor bronze has been largely employed for impulse turbine blading when conditions were uch that abnormal corrosion was expected, and gives satisfactory results with dry steam where he steam velocities are moderate and the stresses induced in the blades relatively small. The ollowing represent the average properties of this material as given by Mr. W. B. Parker.*

Maximum tensile stress . .	Not under 24 tons per sq. in.
Elastic limit	„ 12 „
Elongation on 2 ins. . .	13 per cent.
Modulus of elasticity . .	16,000,000 to 17,800,000 lbs. per sq. in. within a stress range of 0 to 10 tons per sq. in.

The average composition is as follows :

Tin	From 3 to 5 per cent.
Copper	From 94·9 to 96·9 per cent.
Phosphorus	Not less than ·1 per cent.

* *Steam Turbine Blading*, Institute of Metals, September 1915.

Nickel-copper alloys are now being used for the manufacture of turbine blading, the be known being Monel metal (*Messrs. G. & J. Weir, Ltd.*). This metal when drawn into the form turbine blading has the following properties :

	At 60° F.	At 750° F.
Ultimate stress	41·9 tons per sq. in.	36·4 tons per sq. in.
Yield point	37·7 „	31·2 „
Elongation on 2 ins.	24 per cent.	16·5 per cent.
Reduction of area	60 „	60 „

Modulus of elasticity : 22,500,000 lbs. per sq. in. over a stress range of 1 to 15 tons per sq. in.

The composition (tests by the National Physical Laboratory) is as follows :

Nickel	67%
Copper	28%
Iron	1–2%
Manganese	1–2%
Lead, tin, and antimony	Nil.
Also silicon and carbon	

See also p. 2718.

PROCEDURE IN STARTING UP LARGE TURBINES.

While the general guidance given in the following remarks is, in the main, intended apply to relatively large units (say turbines of 10,000 kw. capacity and larger), the procedu is an excellent one to follow on smaller sets.

The time intervals indicated can be reduced as the size of the set is reduced.

First operation.—Start up condensing plant and obtain 20 ins. to 24 ins. vacuum.

Second operation.—To warm up turbine, open stop valve sufficiently to start it rotating, th close it down until a steady speed of not more than 10 per cent. of the normal speed is obtaine Maintain this condition for ten to fifteen minutes during which vacuum is increased.

Third operation.—Increase the speed by gradual and steady increments at a rate of fro 5 per cent. to 10 per cent. per minute.

Fourth operation.—Synchronise set and switch on to bus bars.

Fifth operation.—Build up load on set at a steady rate of from 5 to 10 per cent. per minute

The procedure here outlined is a safe one to be recommended in normal practice ; in an em gency the time intervals can, of course, be reduced.

TURBINE TEST CORRECTIONS FOR STEAM CONDITIONS.

While it is rarely possible to make tests upon a turbine under the exact steam conditio for which it has been designed, the performance which may be expected under the design conditions can be estimated from the steam consumption actually obtained during the test.

The usual practice consists in correcting the test consumption for the difference between t steam superheat, pressure, and vacuum during the test, and that which is specified for the turbi

These 'corrections' are arranged as coefficients by which the observed consumptions mu be multiplied, and are determined for any steam conditions from consideration of the chan in available heat-drop and turbine efficiency which take place with any change in that co dition.

A very complete list of these corrections has been published by Mr. K. Baumann,* and t values he gives are incorporated in this section.

Superheat Correction.

Where the superheat is different from that specified, the following corrections should made, both for high-pressure or low-pressure turbines.

Between :—

0–100° F. superheat 1 per cent. improvement of steam consumption for every 10° F. sup heat.

100–200° F. superheat 1 per cent. improvement of steam consumption for every 12° F. sup heat.

200–300° F. superheat 1 per cent. improvement of steam consumption for every 14° F. sup heat.

Correction for Initial Wetness of Steam.

For each 1 per cent. wetness the steam consumption, if measured as condensed water, w be 2 per cent. too high.

* *Recent Developments in Steam Turbine Practice*, Inst.E.E., April 1912.

Pressure Correction.

The correction which is to be made for the pressure depends upon whether the change in ssure is before the stop valve or before the nozzles.

Thus, if in the case of a high-pressure turbine working on a constant generator load the ssure before the stop valve is raised, say 10 lbs. per sq. in., the governor valve closes slightly, the pressure before the nozzle will be very little altered, the only result being that the steam hrottled to a greater extent than formerly.

The effect of such an increase of pressure will be that the steam consumption will be improved the small amount corresponding to the superheat due to the additional throttling.

In such cases the steam consumption will be improved by 0·5 per cent. for every 10 per cent. rease of pressure.

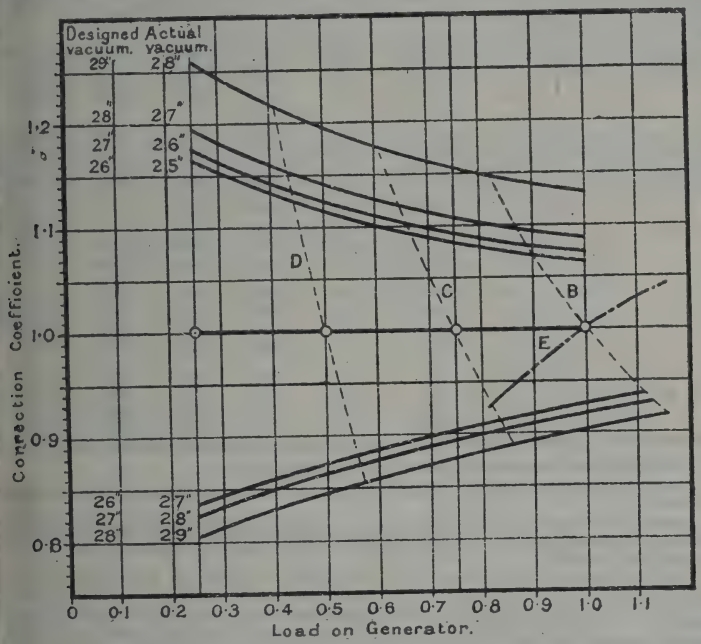

FIG. 18.—Vacuum Correction for Low-pressure Turbines.

When, on the other hand, the pressure before the nozzles is increased, the correction is of lite different magnitude and is:

For high-pressure turbines, an improvement of 1½ per cent. in steam consumption for 10 per cent. increase in pressure.

For low-pressure turbines, an improvement of 4 per cent. in steam consumption for 10 per cent. increase in pressure.

Vacuum Correction.

In any test, the correction for vacuum is usually of greater magnitude than that for pressure superheat. Although every care has been exercised in estimating these corrections, it is viously desirable that the total correction should be as small as possible, and if only for this ason every effort should be made to obtain during a test a vacuum as little different as practicable om that for which the turbine was designed.

Table VIII. gives the correction for vacuum which should be employed for various designed onditions with high-pressure turbines or mixed-pressure turbines, working with high-pressure team.

TABLE VIII.—VACUUM CORRECTION FOR HIGH-PRESSURE AND MIXED-PRESSURE TURBIN

Partial loads are expressed as fractions of the full load for which turbine is designed.

The correction is to be made when the turbine is run on a vacuum other than that for wh it was designed.

Designed Steam Conditions.			Theo. Corr. for 1 in. Vac. Variation.	Actual Correction for 1 in. Vac. Variation.								Range o Vac. Variatio Ins.

		28	9·2	6·6		7·7		9·9		12·6		26—28—2
		29	13·5	9·9		11·3		13·3		16·8		28—29

The Theoretical Correction is given for 150° F. Superheat.

The actual correction given for various loads can be used for any superheat between saturat and 300° F.

It should be noted that at any load and for the same designed steam conditions and act vacuum, the correction in the case of a mixed-pressure turbine (M.P.) is greater than for a hi pressure turbine (H.P.).

Thus, for example, the correction for a M.P. turbine at full load and working with hi pressure steam is the same as for a H.P. turbine on half load. The assumption underlying t is that the M.P. turbine is designed to give the same output on H.P. as on L.P. steam, and th therefore, the conditions in the nozzles and blading of the L.P. end of the M.P. turbine are same as that of a H.P. turbine designed for twice that output. Changes in vacuum only aff the conditions in the last few stages of a turbine, and these in a M.P. turbine on H.P. steam operating under the same conditions as those of a H.P. turbine at half load.

Vacuum corrections for low-pressure turbines or for mixed-pressure turbines working w low pressure steam are still larger than those already considered.

In fig. 18 a coefficient will be found for various loads on the generator which is the ratio :—

$$\frac{\text{(Steam consumptions for 1 in. } \begin{matrix}\text{above}\\ \text{or}\\ \text{below}\end{matrix} \text{ the designed vacuum.)}}{\text{(Steam consumption for the designed vacuum.)}}$$

While the corrections as given above can be applied to the generality of cases, special con tions may arise where corrections must be separately considered.

Thus, it is possible to obtain little or no benefit by increasing the vacuum with a turbi designed for a certain load at a certain vacuum and modified to operate on a considerably higt load and a higher vacuum; in such a case the velocity in the exhaust would be exceedingly hig and may even approximate to sound velocity.

In back pressure turbines, or the high pressure end of reducing turbines, all corrections will considerably larger than those given above, and these require separate consideration in each cas

It cannot be too strongly emphasised that every endeavour should be made to arrange t test conditions in such a way that all corrections are as small as possible.

TYPES OF TURBINES.

Turbines may be classified according to the steam conditions under which they operate. It ould be noted that the energy available in adiabatic expansion of steam from 180 lbs. per sq. g. and 100° F. superheat to 28 ins. vacuum, is about twice that available if the expansion is ried down to atmospheric pressure only. Hence the addition of condensing plant approxi- tely doubles the amount of work which can be done per lb. of coal, without necessitating any rease in boiler capacity.

High-Pressure Turbines.

High-pressure turbines take their steam directly from the boilers, and expansion takes place the turbine down to the pressure in the condenser. This may be regarded as the fundamental ss of turbine. The steam conditions are usually 350–150 lbs. per sq. in. g. pressure, 0°–300° F. perheat, and 27½ ins. to 29 ins. vacuum (30 ins. Barm.). Of course, the range of possible ditions is greater than these: for instance, in collieries and steelworks, steam pressures of)–50 lbs. per sq. in. are to be met with, while steam temperatures of 800° F. will probably adopted in the near future.

Low-Pressure Turbines.

Low-pressure turbines take their steam at about atmospheric pressure, the source almost ariably being the exhaust from non-condensing reciprocating engines. The initial steam essure is usually from 20–15 lbs. per sq. in. abs., and should in all cases be above atmospheric essure in order to eliminate the risk of air leakage into the steam pipe line. Low-pressure rbines require no governor gear if connected either mechanically or electrically to the recipro-

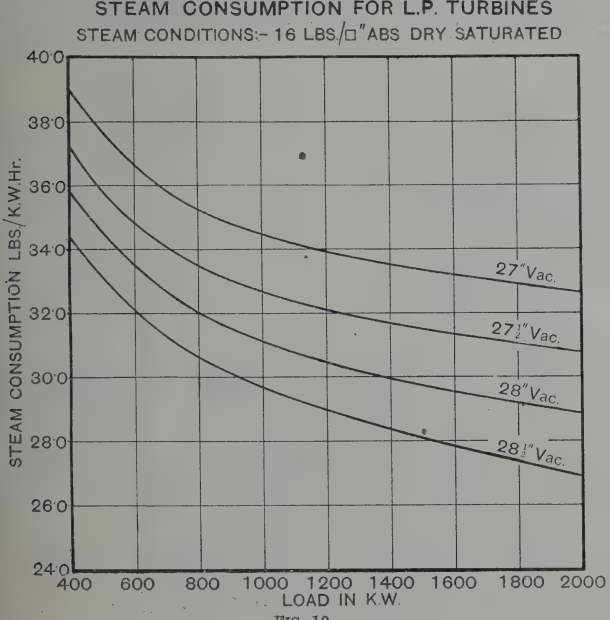

FIG. 19.

ting engine from which they obtain their steam. In the event of the engine being shut down e turbine is supplied with steam from the boilers through a reducing valve.

The efficiency with which low-pressure steam can be used naturally depends not only on the ze and speed of the plant, but also on its capacity and costliness. As an average the steam nsumption shown in fig. 19 can be used for estimating purposes when dry steam is supplied to a w-pressure turbine at a pressure of 16 lbs./sq. in. absolute.

Back-Pressure Turbines.

Back-pressure turbines take their steam directly from the boilers and exhaust at or abov atmospheric pressure. Such turbines may be used in cases where the exhaust steam is require for heating purposes, and the back pressure usually ranges from 1 to 20 lbs. per sq. in. g.

In certain cases the back pressure may be as high as 40 lbs. per sq. in. g.

Back-pressure turbines are used to a considerable extent to drive the auxiliaries, their exhau steam being utilised for feed heating ; by this means the losses in the turbine are recovered in th feed heater, and an overall efficiency for back-pressure turbine and feed heater of over 90 per cen is obtained.

Mixed-Pressure Turbines.

When L.P. steam is utilised in an L.P. turbine it is obviously desirable that the turbine set ma be operated at will independently of the reciprocating engines from which it obtains its steam, a that in the event of the engine being shut down the turbine may operate with reasonable economy This becomes possible by the addition of what is really a B.P. exhausting into the L.P. turbin and having a common casing and spindle. This combination forms a mixed-pressure turbin which can operate not only on either H.P. or L.P. steam, but if sufficient L.P. steam is not availab to carry the load, the deficit is automatically supplied by admitting H.P. steam to the H.P. en of the turbine.

The governor gear is automatic and adjusts itself so that all the L.P. steam available is us in preference to H.P. steam.

In mixed-pressure turbines the governor gear is of special importance, as for successful workin in parallel with other alternators the changes from L.P. steam to H.P. steam must be effecte without any appreciable change in speed or load of turbo-alternator.

Reducing Turbines.

With a B.P. turbine the amount of steam available for heating purposes, and the work don by the turbine, are directly connected. In most installations it is desirable to be able to vary the quantities independently of each other, and to meet this demand 'Reducing' turbines we introduced.

Power Obtained from Heating Steam.

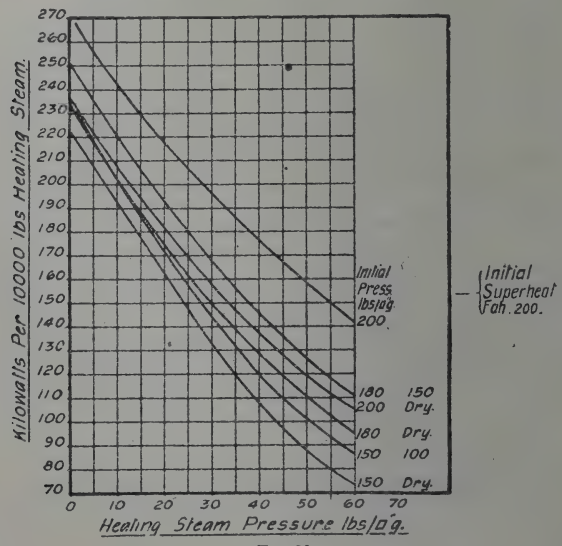

Fig. 20.

An R.P. turbine consists of a B.P. turbine to which an L.P. turbine is added. The B. turbine is designed for the maximum amount of steam required by the heaters it supplies.

As the demand for heating steam decreases, an automatic governor gear by-passes the supp to the L.P. end of the turbine, and at the same time the supply of steam to the H.P. end decreased.

In this way the load the generator can carry is independent of the amount of heating steam uired.

The governor gear should be operated in such a way that the pressure of the heating steam ains constant.

An increasing demand for this type of machine has arisen in recent years as a result of the remely economical results which can be obtained in those manufacturing works requiring h electrical power and heating steam.

In order to obtain the best result the pressure at which steam is taken from the turbine for ting purposes should be as low as possible in view of the requirements of the heating cess. The effect of back pressure on the consumption of heating steam can be seen from following table, while the variation in the power which can be obtained from back pressure reducing turbines is shown in fig. 20 for various steam conditions.

In recent years marked improvements have been made in the efficiency which can be obtained H.P. ends of steam turbines. Whereas formerly the first step in expansion was accomplished h an efficiency of from 50 to 60 per cent., efficiencies of from 70 to 80 per cent. can now be lised in turbines of reasonable size and of other than the cheapest construction. It follows that back pressure or reducing turbines of some considerable size, elaboration and costliness, the kw. tainable per 10,000 lbs. of steam per hour can, in such cases, exceed those given in fig. 20 by ne 25 per cent.

TABLE IX.

RCENTAGE CHANGE IN STEAM CONSUMPTION OR WORK CAPACITY OF HEATING STEAM FOR A CHANGE IN HEATING STEAM PRESSURE OF 5 LBS. SQ. IN. G.

Initial Pressure. lbs. sq. in.	Initial Superheat. Degrees F.				
	Dry.	50	100	150	200
200	6·85	6·5	6·15	5·8	5·45
190	7·3	6·92	6·52	6·15	5·77
180	7·75	7·35	6·9	6·5	6·1
170	8·22	7·75	7·25	6·82	6·37
160	8·7	8·15	7·6	7·15	6·65
150	9·25	8·65	8·1	7·5	6·95

ECENT DEVELOPMENTS IN STEAM CONDITIONS AND MODIFICATION IN OPERATING CYCLE.

The component elements in a modern steam turbine and boiler plant are indicated in fig. 21.*

The various parts shown of steam turbine, regenerative feed heaters A, B, C, and D, economisers,

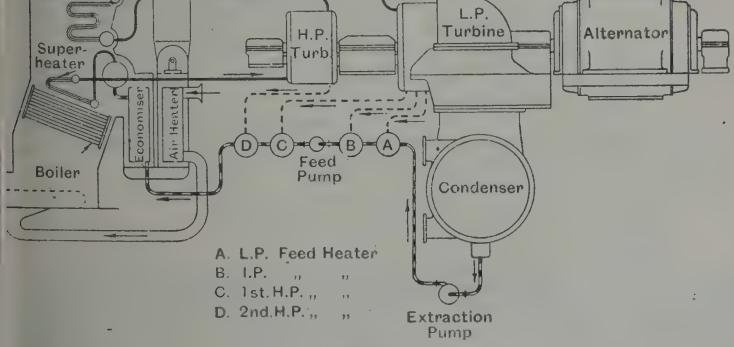

FIG. 21.

* This figure, together with the others used in this Section, is taken from *The Economic alue of Increased Steam Pressure*, by H. L. Guy. Institution of Mechanical Engineers, 1927.

boiler, superheater, resuperheater and air preheater, may be used all together, or one or othe the various elements may be omitted. For instance, the resuperheater appears desirable if ste pressures above 500 lbs./sq. in. are used, while air preheating will usually be employed if the f water is heated above 230° F. by the turbine feed heaters. In order to consider the influence these elements on plant efficiency, the influence of steam pressure, regenerative feed heating a resuperheating will be considered separately.

Increased Steam Pressure.

The influence of steam pressure on heat consumption of the steam turbine itself is shown fig. 22 by curve G; while curve M shows the corresponding gain when the effect of the turb and boiler auxiliaries is taken into account. The meaning of the remaining curves in the figu will be evident.

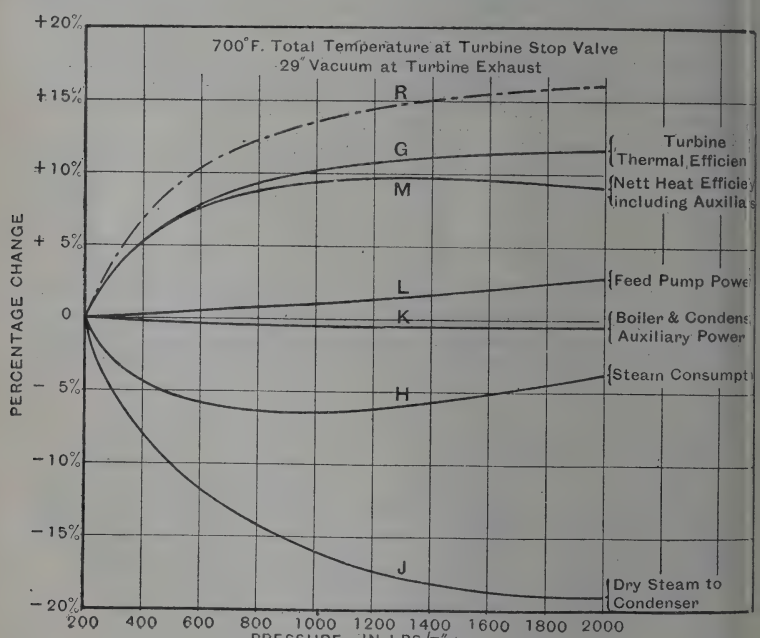

Fig. 22.

Curve R shows the way in which the gain flowing from the use of increased steam pressure increased by the use of four stages of regenerative feed heating, and therefore represents t relative gain which can be realised in a fairly elaborate modern installation of reasonable capacit The last reservation arises from the fact that the gain which can be obtained by using increas pressure depends very much on the capacity and speed of the installation. The figures giv apply to an installation of about 20,000 k.w. capacity if the speed is 3,000 r.p.m., or 40,000 k capacity if the speed is 1,500 r.p.m. For much larger installations the returns will be ver slightly increased. For sensibly smaller capacities the gains will be materially reduced. Fro curve R the following table has been deduced, showing the pressure steps and pressures whic correspond to definite gains in coal consumption of 3 per cent. each time:

INCREMENTS OF PRESSURE FOR 3 PER CENT. THERMAL GAIN.

Accumulated Thermal Gain %	Corresponding Increment in Pressure Lbs. sq. in. g.	Change in Pressure Lbs. sq. in. g.	Approximately Corresponding Pressure Lbs. sq. in. g.
3	65	200–265	250
6	95	265–360	350
9	140	360–500	500
12	255	500–755	750
15	570	755–1325	1300

The absolute values of the most important quantities entering into the calculation of the curves ig. 22 are given in Table X. The figures given in lines 21 and 22 under 'Plant Efficiency' are ed on a generator efficiency of 96 per cent. and a boiler efficiency of 84 per cent. It should be ted that all the preceding figures are based on an initial temperature of 700° F. and on a vacuum 29″. The relative position is not sensibly affected by increased steam temperature, but net gains increase as the vacuum is decreased. For instance, the gain with 28″ vacuum at 00 lbs./sq. in. is some 2 per cent. greater than that shown for 29″ vacuum.

Regenerative feed heating.

In recent years the practice of heating the feed water progressively by feed heaters supplied h steam tapped from the main turbine at various points in the expansion has developed until as become standard. From one to four feed heaters are used, depending on the size and

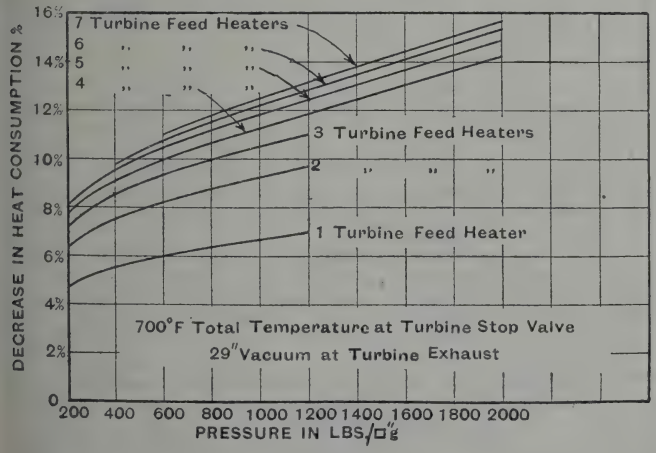

FIG. 23.

oration of the plant. The gains in coal consumption which can be expected at various steam ssures with from one to seven feed heaters are shown on fig. 23 for installations including an nomiser and air preheater. If no air preheating is done, these gains are reduced to about two- rds of those shown in this figure.

TABLE X.—VARIATION IN EFFICIENCY WITH STEAM PRESSURE.
(700° F., 29 in. Vacuum.)

Resuperheating.

If steam is taken out of the turbine after partial expansion and passed through a superheater, he thermal efficiency is improved and consequently the coal consumption reduced. This gain in fficiency varies with the points in expansion at which resuperheating takes place. The upper art of fig. 24 shows the percentages given of the total expansion which should precede resuper-

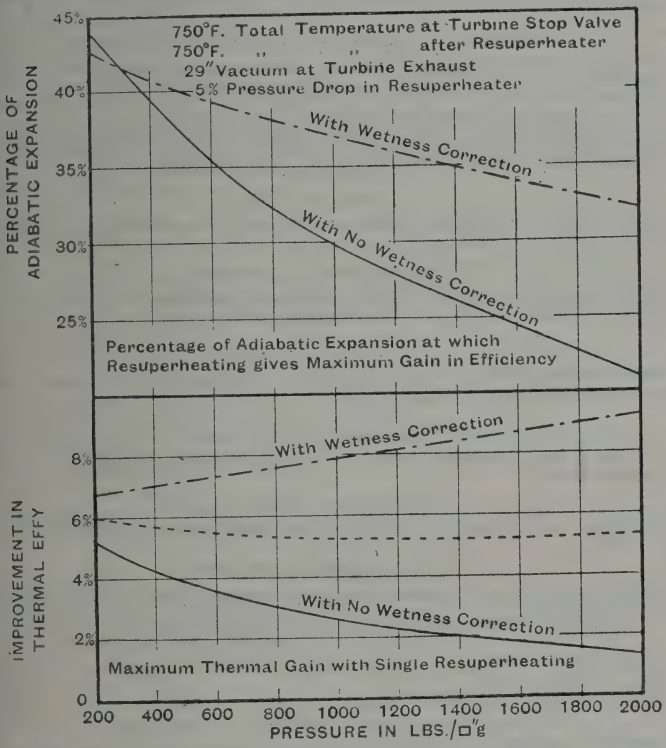

FIG. 24.

heating. The two curves shown should be treated as giving two limits. Again, in the lower portion, the two curves show the two limits for the reduction in coal consumption. The dotted curve shows the mean value and represents about the percentage which has so far been obtained by resuperheating.

BRITISH ENGINEERING STANDARDS SPECIFICATION FOR STEAM TURBINES FOR ELECTRICAL PLANT.*

No. 132–1920 (Abstract).

RATING.

The rating of the steam turbine shall be the rated output of the generator to which it is coupled. (The British Engineering Standards Committee have laid down that the rating of the generator shall be the load which it is capable of carrying continuously with a temperature rise of 40° C.)

* By permission of the British Engineering Standards Association.

Margin of Capacity of Steam Turbine.

The steam turbine shall be provided with means for developing 10 per cent. greater loa than the rated load of the generator with the specified steam conditions. This margin is provide with a view to allowing the turbine to drive the generator at its rated capacity when the stea conditions are worse than those specified, and is not provided with the object of obtainir overloads on the generator.

Output of the Turbine when Working Non-Condensing.

If the specified steam pressure is not less than 165 lbs. per sq. in. absolute, and the rated outpu of the turbine is not more than 3,000 kw., the turbine shall be capable of developing 30 per cen of its rated output when exhausting to the atmosphere. For turbines of larger capacity th output must be settled between the purchaser and the manufacturer.

Note.—It is undesirable to work high-pressure steam turbines exhausting to the atmosphe and this should only be done in cases of emergency. Even under this condition, the turbi should not operate in this way for a longer time than is absolutely necessary.

Maximum Speed.

The turbine shall be capable of withstanding for five minutes, without injury, a speed 15 pe cent. in excess of the rated speed.

Governing Characteristics.

When the rated load is taken off or on the permanent speed variation shall not exceed 3 pe cent., nor shall the momentary variation exceed 6 per cent.

Governing Adjustment.

Means shall be provided to enable the speed to be adjusted by plus or minus 5 per cent when working under synchronising conditions.

Emergency Cut-off Speed.

The emergency governor shall be set to shut off steam if the speed exceeds 9 to 11 per cen of the rated speed.

Economic Rating of the Turbine.

The turbine shall be designed to give a minimum steam consumption at 80 per cent. of i rated output.

Guarantee Steam Consumptions.

If steam consumptions are guaranteed for various outputs, the average steam consumptio shall be obtained by

Mutiplying the steam consumption at the rated output by 3,
" " " 80 per cent. of the rated output by 4,
" " " 60 " " " 3,
" " " 40 " " " 2,
and dividing the sum by 12.

Load at which Steam Consumption is Guaranteed.

The load or loads at which the steam consumption is guaranteed shall be stated in the orde Unless otherwise specified, the guaranteed steam consumptions shall be deemed to be the avera steam consumptions as defined above.

Tolerance.

For the purpose of comparing test consumptions with the guarantee performance a toleran calculated as follows shall be allowed:—

Percentage tolerance (+ or —) =

$$\frac{\text{Arithmetical sum of percentage corrections} - 5}{4} + 2\tfrac{1}{2} \text{ per cent.}$$

Hydraulic Test for Parts Exposed to Full Boiler Pressure.

All parts exposed to the rated steam pressure shall be tested with a hydraulic pressu 50 per cent. in excess of the rated pressure. The machine as a whole shall be tested with hydraulic pressure of 15 lbs. per sq. in. gauge.

Critical Speed of Shaft.

The critical speed of the turbine shaft shall not be within 30 per cent. above or 35 per cen below the rated output.

TURBINE SPEED-REDUCTION GEAR.*

The speed at which it is most desirable to run a turbine is limited only by the strengths of the aterials used in its construction. Unfortunately this limit of speed cannot be approached hen the turbine is employed for direct driving of propellers, D.C. generators of large output, lling mills, line shafting, etc., and in such cases where comparatively low speeds are essential ot only does the turbine become heavy, costly and inefficient, but direct turbine drive is often ite out of the question.

For this reason several systems of speed reduction have been introduced, and are being ccessfully applied.

Double Helical Gears.

Speed reduction by means of double helical gears was employed in the earliest days of turbine gineering by Dr. Delaval, whose turbines, running at speeds of the order of 10,000 r.p.m., uld not be directly coupled to electric generators. The gearing of these turbines gave re-arkably little trouble, and although the outputs were low it is notable that even to-day this is e most successful system of speed reduction.

Double helical gearing for large turbines was introduced by Sir C. A. Parsons, who with aracteristic courage first introduced the system in the famous case of the propelling machinery the s.s. 'Vespasian,' and the drive of a rolling mill at Calderbank Steel Works.

In the earlier installations difficulties were experienced through minute inaccuracies of the ar teeth, which gave rise to very noisy working. This was traced to errors in the gearing of e table of the gear-cutting machine by Sir C. A. Parsons, who has very materially reduced the ouble by arranging a 'Creeping' table giving the gear blank an advance of 1 per cent. latively to the main table of the machine. The improvements in modern gear-cutting machines ve eliminated the inaccuracies referred to, so that the creeping device is no longer essential.

The helix angle adopted varies from 20° to 45°, the usual angle in modern practice being 30°.

The teeth of modern double helical gears are of the standard involute type, the pressure gle adopted by different makers varying from 14½° to 20°.

If p = average pressure in lbs./inch tooth face.
L = total length of tooth face in inches.
D = diam. of pitch circle of pinion in inches.
R = revs. per minute of pinion.

V = pitch speed in feet per second $= \frac{\pi D}{12} \times \frac{R}{60} = \frac{\pi D}{720} \times R.$

Then

$$\text{Horse-power transmitted} = P = \frac{pLV \times 60}{33{,}000} = \frac{pLV}{550}.$$

Professor Stoney states that V should be kept between the limits 100 and 130 ft./sec. He so gives the maximum permissible pressure $p = 120d$ for pinions smaller than 5 inches ameter, and $p = 175\sqrt{d}$ for larger pinions.

Fig. 25 shows curves co-ordinating p and d, published by Mr. F. H. Hodgkinson *Engineering*, Jan. 10, 1919).

With pinions having two bearings where E = Young's modulus of elasticity = 30×10^6 os./sq. inch,

$$I = \text{the moment of inertia of the pinion} = \frac{\pi D^4}{64}.$$

$$\text{Transverse deflection at the centre} = \delta_1 = \frac{5}{384} \cdot \frac{pL^4}{EI}.$$

This is one of the determining factors in design, and, according to Stoney, should not exceed 0002 inch.

For pinions having three bearings, the maximum deflection on each portion of the pinion etween two bearings should not exceed 0·0002 inch, and in most cases this is not the ndition determining the diameter.

Another condition fixing the design of the pinion arises from the fact that the torsional eflection opens the teeth, thus preventing uniform distribution of pressure on them. This orsional opening, δ_2, according to Stoney, must be limited to less than 0·0001 inch, and is iven by the following expressions :

$$\text{For two or three bearing pinions } \delta_2 = \frac{OL}{10 \times 10^4} \text{ inches over one helix.}$$

In the Melville-McAlpine gear, manufactured and developed by the Westinghouse Machine o., the pinion is supported in a floating frame which permits its axis to take up a slight inclina-

* See also 'Reduction Gear for Propulsion,' p. 2369.

DOUBLE HELICAL GEAR CURVES.

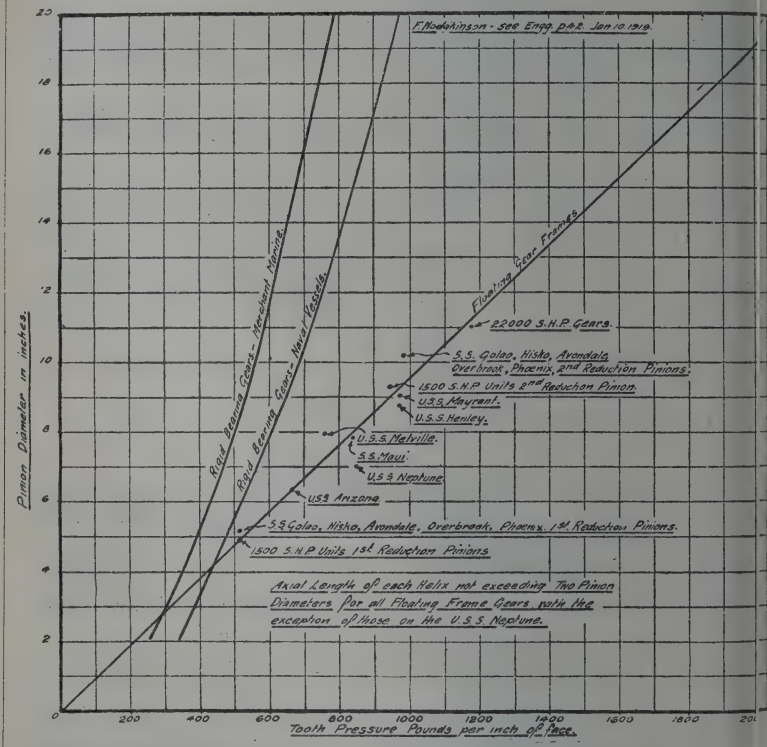

FIG. 25.

on in the vertical plane relatively to the slow speed shaft. The torque on the pinion tends to crease the helix angle of one half of the pinion and decrease that of the other half, so that if the lix angle of the pinion is the same as that of the wheel, as load comes on, the helix angles become fferent. If the axis of the pinion is inclined in a vertical plane relatively to the wheel, the ange in the helix angle with load can, it is claimed, be very largely compensated, so that ith the floating pinion larger torques can be transmitted through a given size pinion than rough a pinion supported in rigid bearings. According to the inventors, the floating frame so corrects to a certain extent errors in the teeth and in alignment of the gears.

The action of this gear is well explained, together with some authoritative notes on double lical gearing, in a series of articles by Mr. J. H. McAlpine, which appeared in *Engineering*, mmencing May 5, 1916.

In these articles Mr. McAlpine suggests the use of the 'Power Constant' for comparing fferent gears; these he defines as follows:

D = pitch diameter of pinion in ins.; L = length of tooth face in ins.; p = average essure in lbs. per in. of tooth face; R = r.p.m.; C = power constant; P = horse-power ansmitted;

Then

$$P = \frac{\pi D R p L}{33000 \times 12}.$$

For correctly designed gears, p and L vary as D, therefore

$$P = C (D^3 R),$$

d

$$C = \frac{P \times 1000}{D^3 R}.$$

For gears having the pinion supported in two rigid bearings, the power constant 'C' should t exceed 1·5.

'C' is usually from 1·2 to 3·0, for gears having three bearings on the pinion.

Gears having the pinion supported in a floating frame have worked very successfully with a wer constant of 4.

The ratio $\frac{L}{D}$ should preferably be equal to 4-in. gears having the floating frame.

For best results the pinions for all sizes should have from 26 to 30 teeth; if the number is preciably reduced interference takes place.

The efficiency in double helical gearing varies from 98·5 per cent. in large gears to 97·5 per nt. in small sets, so that from 1·5 per cent. to 2·5 per cent. of the heat equivalent of the power ansmitted has to be dissipated in the lubricating oil cooling system.

The gears are usually lubricated by spraying the oil on the teeth at the point of contact.

The success of a gear depends to a larger extent than is generally supposed on the rigidity d correct design of the gear-box and lubricating system, and where experienced engineers are sponsible for these details every confidence can be placed in a turbo-geared proposition.

Table XI, p. 1873, gives some particulars of notable installations of geared turbines.

Rapid advances have been made in the application of steam turbines to the ercantile marine, by the introduction of double reduction gearing. Single reduction gears ving ratios larger than 15 to 1 are scarcely practical for ship propulsion, but a reduction of, y, 42 to 1 can be commercially obtained by a double reduction gear having two trains of heels, the first having a reduction of, say, 6 to 1 and the second 7 to 1.

Such double reduction gears are now being used having efficiencies at full load of about per cent.

Now that such large ratios of reduction are commercially practicable, both the turbine and e propeller can be run at the speed most suitable for each respectively.

See also p. 1022, and 'Reduction Gear for Propulsion,' p. 2369.

Hydraulic Transmission.

Prof. Fottinger has invented an ingenious system of speed reduction in which the turbine rives a centrifugal pump which delivers water into a water turbine to which the propeller or enerator is coupled.

The possibilities and limitations of this type of transmission are illustrated by the follow figures given by Prof. Fottinger.*

No. of Stages.	Gear Rates.	Estimated Efficiency.
1	5 to 1	90 per cent.
2	7½ to 1	90 ,,
3	10 or 12 to 1	88 ,,

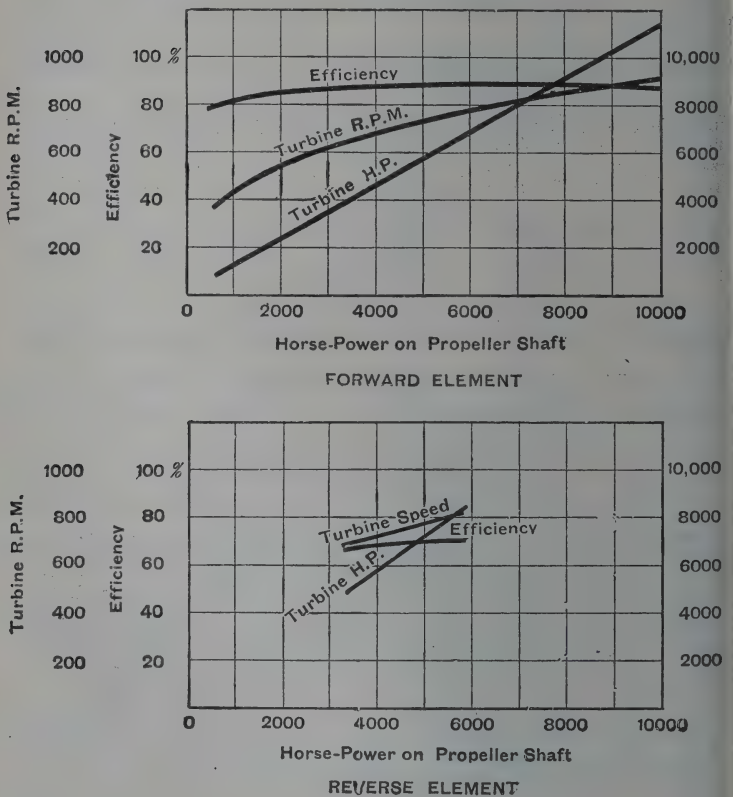

FIG. 26.

Unfortunately the ratios usually required for marine purposes are from 10 to 1 up to 20 to and as it is doubtful if more than single stage transmitters could be commercially adopted, it v be seen the field open to this type is limited. A distinct advantage lies in the fact that the d charge from the turbine pump element can be diverted to a reverse water turbine, by which mea reversal can be easily and economically effected. The water used in the transmitter is usua the boiler feed, and in this way some of the losses can be recovered in feed water heating, but is difficult to see how the gain can possibly exceed 1 per cent. measured at the driven shaft.

Fig. 26 shows the results of tests on a 10,000 B.H.P. transmitter.†

Electrical Transmission.

Various schemes of electrical reduction of speed have been suggested at various times, which an overall efficiency of from 90 to 92 per cent. is claimed.

The General Electric Company * have installed an electrical transmission of considera importance in the collier 'Jupiter' for the U.S.A. Navy, the following particulars of which of interest :—

The ship is of 20,000 tons displacement, and is driven by a six-stage Curtis turbine, in wh each wheel has two rows of blades and runs at 2,000 r.p.m., coupled to a bipolar 3 P.H. genera supplying current at 2,200 volts to two motor-driven propellers. The motors have 36 poles, that the ratio of synchronous speed reduction is 18 to 1. The efficiency of the motors is 95 per ce

At the designed speed of 14 knots the propeller speed is 110 r.p.m., and the output at propellers 5,600 s.h.p.

Under these conditions the consumption on test was 12 lbs. per s.h.p., with a steam press of 190 lbs. per sq. in., dry saturated steam, and exhausting into vacuum of 28½ ins. Hg. 30 i Baro. Thus the thermal efficiency of the turbine generator and motors is 19 per cent., but t does not include any loss in switchgear or cables.

Variations in speed are obtained by varying the speed of the turbine, the gear ratio remain constant, and in the process of reversal water-cooled resistances are put in circuit with the rot of the motors.

A system which is virtually an electrical speed reduction has been introduced where dir current is desired with steam turbines as the prime movers, in which the turbine drives an alt nator which is electrically coupled to a rotary converter. As compared with direct-curr generators driven by double helical gearing, it appears that in plants of over 1,500 kw. capac the pure electrical scheme may be the more advantageous. Other considerations peculiar a particular installation often arise demanding the electrical scheme for smaller outputs th 1,500 kw.

Very large installations of electrically driven ships have been completed for the Uni States Navy, and this system may possess certain advantages for such ships as oper for a large proportion of their time at speeds very much less than the maximum which they able to develop. In such cases the turbines can run at their normal speed independently of t speed of the propeller. Further, the main turbines can be disposed in any convenient posit in the ship without reference to the position of the propeller. These conditions are important in the case of the majority of ships in the mercantile marine.

SECTION XXX

PART V

STEAM CONDENSERS—HEAT TRANSMISSION IN SURFACE CONDENSERS—AIR PUMPS—ROTARY AIR PUMPS—STEAM JET EJECTOR AIR PUMPS—FEED PUMPS—COOLING TOWERS—STEAM ACCUMULATORS.

(Revised by T. B. Morley, D.Sc., M.I.Mech.E.)

STEAM CONDENSERS.

The principal types of condenser are:—

(1) Jet condensers, in which the condensing water mixes with the steam.

(2) Surface condensers, in which the cooling water and the steam are kept separate.

The jet type involves much less initial cost than surface condensing plant, and requires less attention and cleaning, but requires more power to operate it. The choice of type depends to a very large extent on the nature and cost of the water available for cooling and for boiler feed.

Jet condensers are preferred to surface if the cooling water is fit for boiler feed or if a suitable boiler feed, other than the condensed steam, is available.

If ample water is available, but not suitable for boiler feed, the surface condenser is advisable. In some cases the water may be too bad even for use in surface condensers, causing choking of tubes or serious corrosion; jet condensers may then be used and boiler feed obtained from a limited supply of good water, even though the price of the good water is high.

Jet Condensers.

With low-level jet plants it is necessary that the cooling water should be drawn in by virtue of the vacuum, and an efficient vacuum breaker be fitted whereby, in the event of the pumps connected to the condenser suddenly shutting down, the vacuum will be broken, thus stopping the flow of the injection water, and preventing it from entering the L.P cylinder.

The mixture of cooling water and condensed steam is preferably withdrawn at the bottom of the condenser, and the air is taken off near the top. This involves separate air and water pumps, but in the case of engines of moderate power having their own jet condenser one pump for both air and water is commonly used. In the barometric or elevated type of jet condenser no water extraction pump is required, as the condenser being fixed at the barometric height is self-draining. Usually, however, an injection pump is required to lift the water partly up to the condenser, as the vacuum can be utilised to a certain extent for drawing the water into the condenser the same as in the low-level plant. These condensers are more expensive than the low-level type, and, due to a long exhaust pipe being necessary, require to maintain a slightly higher vacuum for an equivalent exhaust pressure at the turbine or engine exhaust flange.

The capacity of a contra-flow jet condenser should not, according to *Sim*, be less than one-quarter of the volume of the cylinder or cylinders exhausting to it, and need not be more than one-half. For quick-running engines one-third is generally sufficient. For turbine work or continuous steam flow, 0·008 to 0·011 cub. ft. per lb. of steam per hour is reasonable.

Surface Condensers.

Cooling water should be arranged to pass through the tubes and steam to flow over the tubes. It is usual to divide the tube element in two, three, or four passes according to the design of the plant, the passes being arranged so that the hottest water meets the hottest steam.

Large spaces should be allowed between the tubes at the condenser inlet to obtain a good flow of steam into the heart of the condenser. The steam flow should always be as direct as possible, changing the direction of flow should be avoided, and to ensure an evenly distributed flow over the top of the tubes a dome should be formed on the top of the condenser body.

Internal guide plates are used by some makers, in order to distribute the entering steam uniformly over the tubes.

It is important that the drop of pressure across he groups of tubes should be reduced to a minimum. Baffles in the tube space are not recommended, as their total effect is harmful.

The pitch of the tubes should be such that they will allow sufficient area for the flow of steam without an excessive pressure drop through the condenser.

The number of tubes which can be fixed in a square foot of plate is,

$$N = \frac{166}{p^2};$$

where,

N = number of tubes per sq. ft. of plate; p = pitch of tubes in ins.

Air in the condenser must not be allowed to remain stagnant round the tubes.

Frequently a section of the condenser next the air pump suction branches is partitioned off to act as a cooler for the air passing to the air pump. The first water pass takes place through the tubes in this section. The cooling of the air reduces the volume to be dealt with by the air pump.

Mr. Allen has used a short overflow pipe upstanding in the condenser so as to keep immersed the lower tubes which serve to cool the water going to the air-pump and so improve the vacuum.

Tube Plates.

These are usually of rolled brass alloy of copper 62 per cent., zinc 37 per cent., and tin 1 per cent., and are generally made of a thickness equal to tube diameter + 0·25 in.

Tubes.

These are of solid drawn brass alloy, of copper 67 per cent., zinc 32 per cent., tin 1 per cent., or where salt or corrosive water is used, of Admiralty mixture alloy, of copper 70 per cent., zinc 29 per cent., tin 1 per cent. A still better tube to use where corrosion is liable to occur is copper of 99·5 per cent. purity, but the initial cost of these is often found prohibitive. Tinned tubes should be avoided, since unless the tinning is absolutely perfect, serious pitting is liable to occur. The Admiralty practice is to adopt untinned tubes of the alloy referred to.

The unsupported length of tubes should not exceed 100 times the diameter, and where the length of the condenser exceeds this dimension, tube-supporting plates should be fixed. The tubes should be secured in the tube plates by tape packing and ferrules, the latter having an internal lip to prevent 'creeping' of the tubes.

Ferrules should allow a space for free movement of the tube ends, and should be rounded, so as to reduce to a minimum the loss of head of the water at its entry into the tubes.

According to Stanton, in a condenser of a given surface for maximum efficiency, the tube length should be as great as possible. As regards tube diameter he says that condensers will be equally efficient in which the ratio $\frac{l^{n-1}}{d}$ = constant, where l = length in feet, n = number of tubes, d = external diameter of tube in feet. Tube diameters should be chosen which offer the least aggregate resistance to flow. Resistance is, he finds, proportional to l^{4-2n}, and is therefore least when the tubes are the smallest practical diameter. He considers the best position for tubes is vertical and the water movement downward.

Tube diameters may vary from $\frac{1}{2}$ in. to 1 in., but are usually $\frac{5}{8}$ in. or $\frac{3}{4}$ in., in fact $\frac{3}{4}$ in. diameter and 18 S.W.G. (0·048 in.) thickness are practically standard.

Unannealed hard-drawn condenser tubes tend to become corroded more readily than tubes that have been annealed.

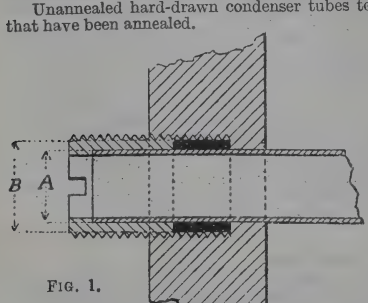

Fig. 1.

Tube Packing.

'Compressed Asbestos Fibre Tube Gromets' (*Turner Brothers Asbestos Co., Ltd., Rochdale*) are illustrated in fig. 1. The Gromets are essentially for packing the tube ends of surface condensers, feed-water heaters, etc.; they are a sliding fit between the tube and the tube plate, making a perfectly tight joint with a few turns of the screw, after which no 'following up' is necessary.

When ordering, the dimensions at 'A' (the outside diameter of tube) and at 'B' (the apex of thread in socket), together with the length of Gromet required, should be given; the necessary clearance is allowed for in manufacture.

British Standard Specification for Condenser Tubes and Screwed Glands for Condensers for Marine Purposes.

(No. 3000-1921).*

(*Abstract.*)

1. The material of the shells from which the tubes for condensers and for screwed glands are drawn shall be an alloy of copper and zinc as follows:—

* By permission of the British Engineering Standards Association.

For Condenser Tubes: 70/30 Alloy.—Containing not less than 70 per cent. of metallic copper nd not more than a total of 0·75 per cent. of materials other than copper and zinc (except that, if so specified, it may contain 1 per cent. of tin or 1½ to 2 per cent. of lead).

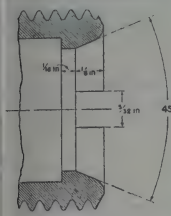

FIG. 2.
iew of Outer End of crewed Glands for ⅝ in. nd ¾ in. External Dia- eter Condenser Tubes.

For Screwed Glands: 60/40 Alloy.—Containing not less than 60 per cent. of metallic copper and not more than a total of 0·75 per cent. of materials other than copper and zinc (except that, if so specified, it may contain 1 per cent. of tin or 1½ to 2 per cent. of lead).

3. The condenser tubes shall be of ⅝ in. or ¾ in. external diameter as may be specified—and they shall not be larger than, nor more than 1½ per cent. smaller than, the specified external diameter. The tubes shall be of uniform diameter throughout and the thickness shall be 18 S.W.G. within the usual manufacturing margins.

5. For ⅝ in. external diameter condenser tubes the average weight per 100 ft. run shall be not more than 32¾ lbs. and not less than 31½ lbs. and for ¾ in. external diameter condenser tubes the average weight per 100 ft. run shall be not more than 40 lbs. and not less than 83 lbs., *i.e.* 2½ per cent. above or below the theoretical weight.

6. Each condenser tube shall be tested internally by water pressure to 600 lbs. per square inch.

Heat Transmission in Surface Condensers.

Let K = coefficient of heat transmission from steam to cooling water, i.e. the number of B.Th.U. transmitted per hour per sq. ft. of cooling surface per degree F. of mean temperature difference.

$\frac{1}{K}$ represents the resistance to the flow of heat. This resistance is made up of:—

(1) The resistance to the flow of heat from the steam to the external surface of the condenser tube, $\frac{1}{k_1}$ say;

(2) resistance to conduction through the tube = $\frac{t}{k_2}$ where t = thickness of tube in inches and k_2 = conductivity of metal in B.Th.U. per hour per sq. ft. per temperature gradient of 1° F. per inch; and

(3) the resistance to flow of heat from the tube to the water = $\frac{1}{k_3}$ say.

The total resistance $\frac{1}{K} = \frac{1}{k_1} + \frac{t}{k_2} + \frac{1}{k_3}$.

For brass tubes, 18 S.W.G. thick, the middle term $\frac{t}{k_2}$ is negligible in comparison with the thers.

k_1, the coefficient for flow from steam to metal, depends on the velocity with which the steam ows over the tubes, the presence of air in the condenser, and the cleanliness of the tubes.

k_3, the coefficient for transmission from tube to water, is the most important term. It epends upon the water velocity, the diameter of the tube, cleanliness of tube surface, and also n the mean temperature, there being evidence that the heat transmitted is greater at higher emperatures even though the temperature *difference* is the same.

For the usual tube sizes and usual temperatures, it will be seen that the chief variable factor nfluencing the overall transmission rate is the water velocity.

Data for k_1 and k_3 are not yet thoroughly established, and the data given by various experi- nenters for the coefficient K also vary widely. This is due not only to experimental error, but o the fact that frequently some of the factors influencing the transmission rate are not taken nto account at all.

For high-class condensers, with clean tubes and small air leakage, the following transmission ates are probable:—

Water velocity, ft. per sec.	3	4	5	6	7	8	9	10
K, B.Th.U. per hour per sq. ft. per deg. F.	470	570	660	740	820	890	960	1,020

(*Weir* '*Trans. Inst. E. and S.*,' 1912–13.)

The increased transmission rate—and consequently reduced cooling surface necessary—du to high water velocities is not all gain, however, for high velocity means increased power to circu late the water. The final design must be decided with reference to cost of pumping as well a initial cost of plant.

Fig. 3 shows the head lost in friction per 10 foot of tube element for $\frac{5}{8}$ in., $\frac{3}{4}$ in., and 1 in external diam. by 18 S.W.G. smooth brass tubes. For application it is necessary to take th total length of the tube element (the length of the tubes multiplied by the number of water passes and add the 'loss at entry (including loss at exit also) per pass,' values for which are given o the bottom curve.

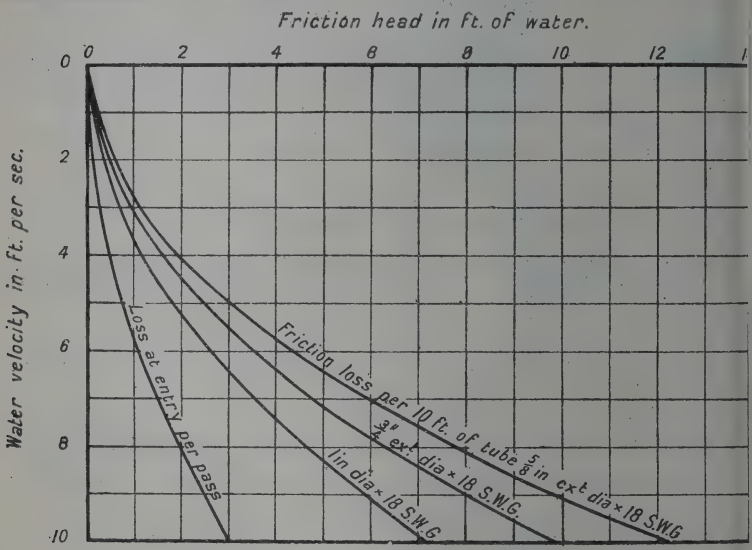

FIG. 3.

MEAN TEMPERATURE DIFFERENCE.

The true mean temperature difference for condensers, heaters, coolers, etc., in which heat i transmitted between two fluids separated by a metallic wall is not the difference of the arithmeti mean temperatures.

If one of the fluids is cooled from T_1 to T_2 and the other heated from t_1 to t_2, then,

$$\text{mean temperature } t_m = \frac{(T_1 - t_1) - (T_2 - t_2)}{\log_e \frac{T_1 - t_1}{T_2 - t_2}}$$

Fig. 4 enables t_m to be readily determined from the maximum and minimum temperatur differences $T_1 - t_1$ and $T_2 - t_2$.

COOLING SURFACE.

If

t_m = mean temperature difference between steam and water; t_1 = inlet water tempera ture; t_2 = outlet water temperature; T = steam temperature in condenser; K = heat transmis sion B.Th.U. per hour per sq. ft. per F.°; then,

$$\text{Cooling surface per lb. steam per hour} = \frac{1{,}050}{K \times t_m}$$

(1,050 is the number of B.Th.U. given up by 1 lb. steam in the condenser, under usual conditions)

FIG. 4.

For rough approximations, surface condenser cooling surface may be based on 6 lbs. of steam per square foot of surface; 10 pounds is sometimes adopted, but is too severe unless the temperature of the cooling water is low, say 60° F., or less. For tropical countries the lower rate of condensation should be taken, and even less when very hot condensing water is anticipated.

Quantity of Cooling Water.

If T_1 = temperature of cooling water at inlet to condenser; T_2 = temperature of cooling water at outlet of condenser; T_3 = temperature of steam at inlet, corresponding to the vacuum; T_4 = temperature of the condensed water at outlet; h_3 = sensible heat at inlet; h_4 = sensible heat of the condensed water at outlet; L = latent heat in B.Th.U. per lb. of steam; W = steam weight; Q = water weight; R = ratio of water and steam quantity; x = dryness fraction then,

Heat (in B.Th.U.) given up by exhaust steam = $W\left\{xL + (h_3 - h_4)\right\}$;

Heat (in B.Th.U.) gained by cooling water = $Q(T_2 - T_1)$.

In practice h_3—h_4 may be neglected, therefore

$$WxL = Q(T_2 - T_1), \quad \text{and,} \quad \frac{Q}{W} = R = \frac{x\,L}{T_2 - T_1}.$$

To allow a small margin, x—which generally varies between 0·8 and 1·0—can be neglected and as L only varies slightly with the vacuum, it is generally assumed to be a constant for all vacua at 1,050 B.Th.U. per lb. of steam. Therefore the general equation for all vacua can be taken as

$$R = \frac{Q}{W} = \frac{1050}{T_2 - T_1}.$$

For surface plants, T_2—T_1 ranges from 8° to 20° F., and for jet plants, 4° to 8° F.

The ratio of the amount of cooling water to that of the steam to be condensed usually varies from 35 to 40 for jet, and from 60 to 70 for surface condensers.

It is important that the condensed steam should be at as high a temperature as possible, since this water is usually returned to the boilers, therefore it is essential that all the heat possible should be recovered.

Every 8°–10° F. difference in the hot-well temperature means approximately 1 per cent difference in fuel consumption. The gain obtained with an increase in hot-well temperature can be calculated as follows:—

$$\text{Percentage gain in B.Th.U.} = \left(\frac{100\,T}{H_T + T - T_4 + 32}\right) \times \frac{100}{B_p}$$

where,

T = difference in hot-well temperature (F.°); T_4 = final hot-well temperature (F.°); H_T = total heat of steam at boiler pressure (B.Th.U. per lb.), reckoned from 32° F.; B_p = percentage boiler efficiency.

In surface condensers for turbines, $(T_3 - T_4)$ is about 5° to 8°, and for reciprocating engines about 10° to 15°.

Vacuum Efficiency may be expressed as the ratio of the vacuum at the condenser inlet to vacuum corresponding to the temperature of the condensed steam; it is dependent both upon the design of the condenser and the air pump.

The *Efficiency of a Condenser* is best stated as a 'Coefficient of Performance,' which measures the extent to which the two conditions are fulfilled that (1) the condensate should be cooled as little as possible below the steam temperature, and (2) the quantity of cooling water should be a minimum, and hence its rise of temperature a maximum.

Sim takes as 'Coefficient of Performance' the ratio $(T_2 - T_1) \div (T_3 - T_4 + 10)$, and states that it should be 1·0 to 1·2 for good surface condensers.

Degree of Vacuum.—The maximum vacuum obtainable is dependent upon the inlet circulating water temperature. For engine work 26 ins. to 27 ins. is the maximum vacuum desirable, owing to the limitations in size of the low-pressure cylinder and ports, etc. For turbine work high vacua are necessary. The most economical vacuum depends upon individual installations, and is generally decided by the power required to be expended by pumping the cooling water, price of coal, available water supply, etc.

The following may be taken under average conditions to be the maximum commercial vacua.

Temp. of inlet water, F.°	55	60	65	70	75	80	85

AIR IN CONDENSERS

Air enters the condenser in the following manner :—

1. With the steam entering from the boiler having been dissolved in the feed water ; this is usually a small amount in the nature of 1 to 3 per cent. of the total volume of feed water.

2 Air leakage from the atmosphere through the glands of the prime mover or other sources ; this cannot easily be measured, and an allowance has to be made accordingly to cover contingencies.

3. In jet condensers air in solution with the cooling water which is released when in the vacuu space; this varies from 1 to 5 per cent. of the total volume of water.

Due to air contained in the cooling water in the case of a jet condenser, a much larger a pump is required than for a surface plant of similar duty.

For turbine work to cover cases (1) and (2) it is usual to allow for 6 to 8, and, in the cas of low-pressure turbines, up to 11 lbs. of air per 10,000 lbs. of steam.

For engines, about two or three times this amount is required according to the type of engin

These figures are for one unit only; if two or more turbines or engines exhaust to the on condenser an extra margin of 10 or 15 per cent. per extra turbine or engine, respectively, shoul be allowed.

(See also page 897.)

The Ejector Condenser.

This condenser is at once an air-pump and a condenser. It acts on the principle that steam will flow into a vacuum at a velocity of many hundred feet per second. The water supply to th ejector should flow to it under a head of several feet. The steam condenses in the jet of water and the combined jet has a velocity which is a mean of the velocity of the steam and of th water. Thus let the water approach at a velocity 30 feet per second and the steam at 1,200 fee per second. Let the combined jet be assumed to have a temperature of 100° F. and the water t be supplied at 60° F. The water gains 40° F. The steam loses say 1,100 B.Th.U. Ther 1,100 ÷ 40 = 27 = ratio of water weight to weight of steam. The total weight of combined jet is 28 The velocity difference is 1,200 − 30 = 1,170, to be divided over a mass of 28, or $\frac{1,170}{28} = 42$ feet pe second nearly. Add the initial velocity of the water 30, and the final velocity is 72 feet per secon

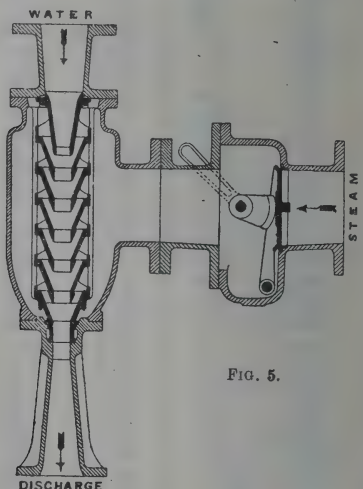

Fig. 5.

This corresponds with a head of H = (72 ÷ 8)² = 81 feet; and since 1 foot of water column equals 0·43 pounds, 83 feet will represent 36 pounds nearly. Since a perfect vacuum is only 14·7 pounds, it follows that with ordinary ratios of water and steam an efficiency of less than 50 per cent. should give an excellent vacuum.

The apparatus (fig. 5) consists of a converging water nozzle into which water is directed from a centrifugal pump or other pressure source, or from an overhead source of 15 to 20 feet head. This jet flows downwards through a series of steam cones to which the exhaust steam has admission at their upper wide portion. The steam flows down each of these short cones and imparts further velocity to the jet as it condenses, and finally the jet flows into a divergent discharge cone at a velocity as above indicated, carrying with it any air that has come in with the steam, and discharging it. The degree of vacuum is of course that proper to the jet temperature, and the proportion of water can, as seen, be sufficiently great to admit of a moderate final

jet temperature and therefore a good vacuum. The ejector condenser occupies very little space and for jet condensing is very simple. The centrifugal water supply pump is conveniently direct driven by an electric motor. While the jet final temperature is amply low for good vacua, the velocity of the combined jet is still more than sufficient to run freely against atmospheric external pressure; but it is always desirable to give the water a fair initial velocity, and there is nothing lost by giving the discharged jet a good fall in a long tail pipe.

The Barometric Condenser is a simpler form of ejector condenser, in which the water enters the head of the apparatus as a spray about the steam entrance, and the vacuum is produced by the fall of the water down a tail pipe of at least 30 feet in vertical drop. By suitable formation of the head the air which enters with the steam is entrained with the water, or, by means of a special surface condenser at the side of the head the air is drawn over cold tubes and carried down to a lower point in the draught tube, whereby it is withdrawn from the head at a minimum temperature, with the object of securing a maximum degree of vacuum.

Mirrlees-Delas-Ginabat Surface Condenser.

(Patented.)

(The Mirrlees Watson Co., Ltd., 45 Scotland St., Glasgow.)

In this condenser it is claimed that every tube does its equal share of work. The tube area opposed to the inlet steam is very large and the steam path through the tubes very short ; the tubes are particularly free from air or water blanketing, and the kinetic energy in the steam and

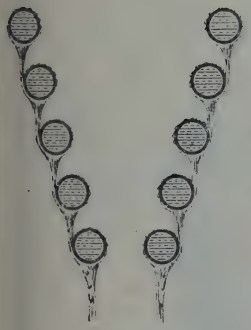

FIG. 6.

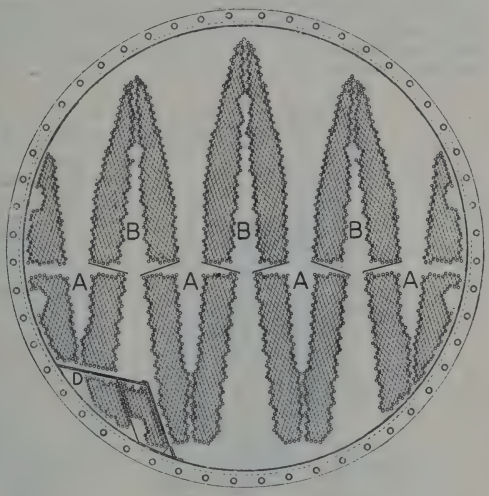

FIG. 7.

condensate passing through the condenser is fully used in reheating the condensate, and to such an extent that the condensate may be removed at a temperature several degrees higher than the inlet steam temperature, and an absolute pressure at the bottom of the condenser slightly higher than the absolute pressure at the condenser inlet ; this is a distinctive feature of the arrangement.

Fig. 6 shows the pitching of the tubes. By the arrangement the water of condensation falling from any one tube meets the tube immediately below tangentially to its surface, and thus flows over only $\frac{1}{4}$ of its circumference, leaving the other $\frac{3}{4}$ dry as far as falling water is concerned. Also the water of condensation may be made to travel to the right or left, according as to whether the lower tube is arranged to the right or left of the higher tube.

The method of grouping the tubes is shown in fig. 7. The tubes are arranged in shallow banks, leaving very deep V-shaped openings for entry of steam, thus giving maximum area of contact ; the V-shaped openings being carried almost to the bottom of the condenser, all tubes are equally effective. There are also correspondingly deep inverted V openings on the under side.

As stated, the condensate can be made to traverse a tube path into this centre inverted space, and, doing so, passes over a very small number of tubes and then over only ¼ of the circumference.

As there is very little resistance to the steam and incondensible vapours passing through thes shallow banks of tubes, the kinetic energy is used in giving a compression effect to the incondensibl gases at the bottom of the condenser, and an increment of heat to the condensate: the com pression effect is enhanced by the unrestricted fall of condensate through the inverted V-shape openings.

The heat transmission of the condenser is very much higher than anything previously recorde in practice; in several installations a transmission of 1,000 B.T.U.'s per sq. ft. per deg. temperatur difference has been attained.

A recent test gave the following results:

Steam condensed in lbs. per hour	442,000
Steam condensed per sq. ft. cooling surface	16·3 lbs.
Absolute pressure at condenser inlet	0·81 in. Hg.
Temperature of inlet circulating water	45·5° F.
Temperature of outlet circulating water	55·9° F.
Heat transmission B.Th.U./sq. ft./deg. Fah. temp. diff./hr. =	756

The 'Weir' Regenerative Surface Condenser.

(G. & J. Weir, Ltd., Cathcart, Glasgow.)

This condenser has been introduced to eliminate the temperature loss which exists in the con densate from the vacuum temperature in normal type condensers, and also to give a condense which delivers its condensate practically air or oxygen free, consequently, although this con denser is suitable for any feed system, it is pre-eminently suitable for fitting to a closed circui feed water system.

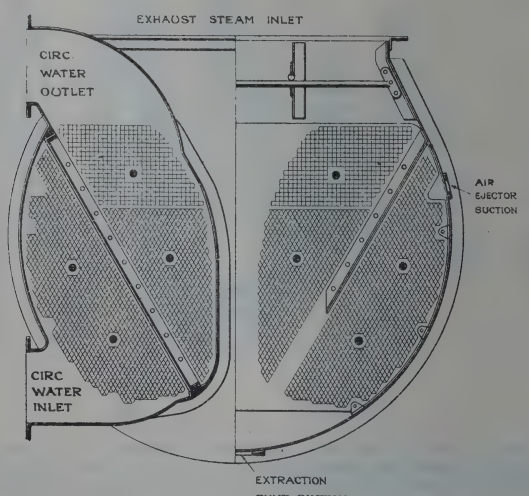

FIG. 8.

The design is the result of a series of researches carried out by Messrs. G. & J. Weir, and in its present form is shown in fig. 8.

It will be seen that a large lane is provided down the middle of the condenser, so that steam can penetrate right down to the bottom; this steam re-heats the condensate dropping from the lowest row of tubes to practically steam temperature. Tests from actual plants show that the difference between the condensate temperature and the vacuum temperature does not vary by

ıore than 2° F. This result is independent of the air leakage present. These tests also show ıat the oxygen contained in the condensate can reach as low as zero oxygen, 0·015 c.c. per litre ·eing quite a normal figure.

A hood plate is fitted on each side of the condenser, thus giving two reflex flows on the steam ide; this arrangement permits a large surface to act as an air cooler if large air quantities are resent, while if the latter are small the air cooling surface will be small. This action is automatic, ne surface acting as an air cooler, automatically adjusting itself to the air quantity. This property esults in the air being drawn off by the air-pump at a minimum temperature for the conditions nd resulting in an enhanced condenser performance. The double arrangement shown lends :self to the twin water box design favoured by many present-day land engineers, the idea being hat one-half can be shut down for cleaning or tube plugging while the other half is working, so hat the main turbine need not be shut down.

The shape of the centre lane, together with the position and length of the hood plate, permit f a large entrance area being presented to the entering steam, with a gradually reducing area to he air suction, so that all the surface is equally effective and a minimum of pressure drop is ttained.

The 'Weir' Water Extraction Pump and Air Ejector.

(G. & J. Weir, Ltd., Cathcart, Glasgow.)

To work in conjunction with their 'Regenerative Condenser,' Messrs. G. & J. Weir manufacture ı water extraction pump and air ejector. The water extraction pump is of the vertical spindle ype, driven by a steam turbine of the velocity stage type having three rows of moving blades nounted in a single wheel and two rows of stationary blades mounted in a guide segment; the ıump is shown in fig. 9. To maintain the speed constant under variations of load a speed governor

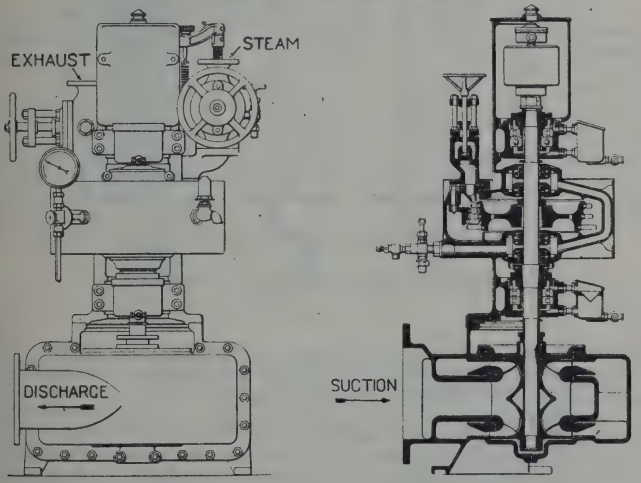

Fig. 9.—Arrangement of Weir Vertical Turbine Extraction Pump Turbine.

is fitted, while in addition a safety governor is fitted which shuts off the steam completely in the event of the pump overspeeding. Auxiliary nozzles under control of the auxiliary stop valves are provided, so that by regulating these the pump may deal economically with large variations in load.

The impellers are located low down at the base of the pump to enable the pump to work satisfactorily under the minimum suction head; the impellers are of the twin type operating in parallel and having the suction placed between the impellers; whirlpool chambers of the diverging

type are employed, and no stuffing gland is fitted at the lower impeller, while a large clearance provided between the top impeller and the stuffing gland, so that the full discharge pressu reaches the stuffing box, thus preventing air leakage into the pump suction.

The weight of the impellers, turbine wheel, shaft, etc., is carried on a ball thrust bearing, wh the shaft is centred by two roller bearings ; both thrust and journal bearings run in an oil ba

The pump end is made of gun-metal, while the framing is of cast iron. The framing and pur end are divided down the centre line, so that the shaft with impellers and turbine wheel can removed for overhaul without disturbing any of the pipe connections.

The most modern type of ejector as developed by Messrs. Weir is shown by fig. 10. It h three stages and can attain the highest vacua. On dry air tests these ejectors have attain vacua within 0·02 in. of the barometer; such extreme vacua, however, is seldom called commercially, but this property enables them to reduce the partial air pressure in normal plan down to the very lowest limits. The saving in steam consumption of the three-stage type ov

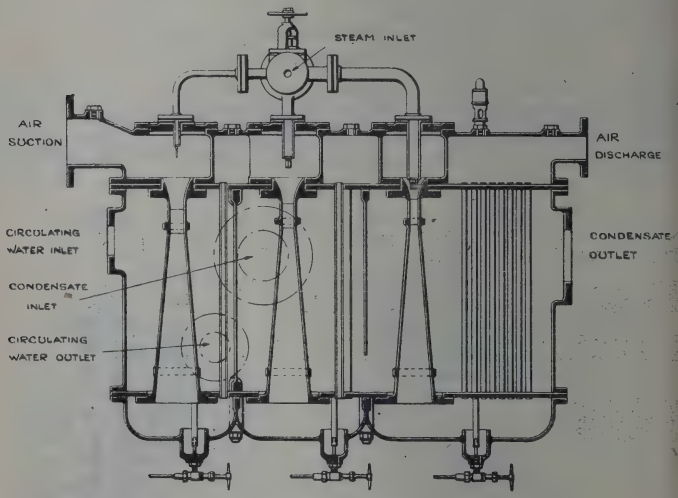

FIG. 10.

the two-stage type is about 30 per cent. at 29 in. vacuum, and increases with higher vacuum The three stages are generally similar in design, but are proportioned to suit the actual a steam, and vapour volumes reigning at the respective stages. The steam nozzles are normal co vergent, divergent steam ones, wherein the pressure energy of the steam is converted into kinet energy ; the steam issuing from the nozzles at high velocity (over 3,000 ft. per sec.) is deliver into a convergent, divergent diffuser nozzle ; entrainment of the air and vapour takes place the convergent portion of the diffuser, and the pressure rise takes place in the diverging portio the combined mass of operating steam and entrained air and vapour pass to first intercooler, whi is of the surface type and is arranged alongside and partly embraces the diffuser ; the operati steam and vapour are condensed out in this cooler, while the air and its associated vapour pa on to the second stage, where the action is repeated, and so on to the third stage, the air bei finally discharged to atmosphere.

The steam nozzles are of Monel metal to resist erosion, while the diffusers are of hard gun-met

On board ship the first and second intercoolers are circulated with sea-water, while the thi or after-cooler is circulated with condensate. On land power stations only the first intercool is circulated with cold circulating water, the second and third coolers being circulated with co densate. On board ship it is imperative that a full vacuum be maintained during manœuvrin

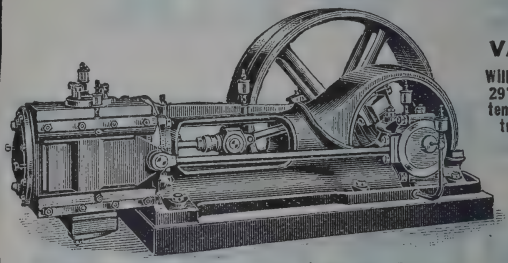
BAILEY'S PUMPS
AND VALVES



Belt-driven Slide Valve 'Dry' Vacuum Pump.

'K' 'DRY'
VACUUM PUMPS

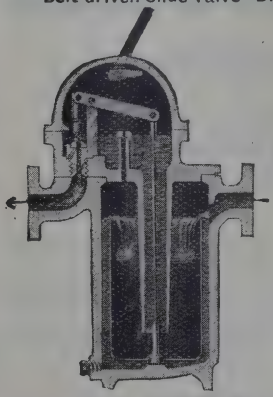
Will maintain a vacuum of over 29·8 ins. of mercury at normal temperature and with a Barometric pressure of 30 ins.

Remarkable for high Efficiency.

No delicate parts to wear out.

SIMPLE AND COMPOUND.

Steam, Belt, or Electric Driven



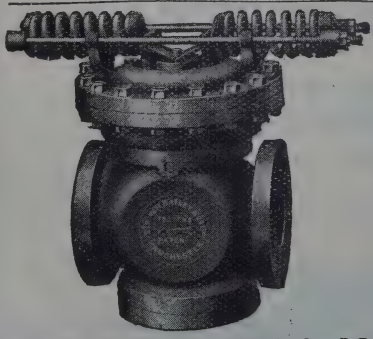
BAILEY'S VACUUM PUMPS are particularly suitable to work as Air Pumps for Condensers for Steam Engines, Central Condensation Plants, Cooling Towers, Condensers for Evaporating Plants, Vacuum Drying Plants, Distillers, etc.

BAILEY'S
'SCAVENGER' STEAM TRAPS
FOR PRESSURES TO 200 LBS.

LARGE CAPACITY, HAND BLOW THROUGH WORKS WITHOUT ADJUSTMENT AT ANY PRESSURE. WORKING PARTS EASILY EXAMINED WITHOUT BREAKING PIPE JOINTS.

'POP' ACTION, NO DRIBBLING. RENEWABLE VALVE AND SEAT.

SAVES TIME IN 'STARTING UP' AS LONG PIPES CAN BE QUICKLY DISCHARGED OF COLD AIR AND WATER.



BAILEY'S 'FOSTER CLASS W'
REDUCING VALVE

FOR SATURATED AND SUPERHEATED STEAM PRESSURE REGULATION.

MAINTAINS CONSTANT DELIVERY PRESSURE IRRESPECTIVE OF VOLUME DEMANDED.

MOST SENSITIVE, DURABLE, AND EFFICIENT OF ALL REDUCING VALVES.

MADE IN ALL SIZES ½ In. to 24 ins.

and to enable the air ejector to do this the first and second stage coolers are circulated with sea-water, while the third stage is arranged that when insufficient condensate is circulating the operating steam simply blows through the after-cooler to a sea-water circulated ejector condenser wherein the steam is condensed. This arrangement is automatic, requires no attention from the ship's engineers, and has been found to work well in practice. On land power stations the above arrangement is not called for, but, owing to the condensate being delivered from regenerative condensers at approximately vacuum temperature, it is imperative to circulate the first inter-cooler with cold circulating water to keep down the surface in the intercooler. With this arrangement the heat in the operating steam of the first stage is lost in the cooling water; but since the steam used in this stage is less than 10 per cent. of the total steam used by the ejector, the actual heat lost is very small indeed.

The vertical design of intercoolers allows of the maximum air cooling and devaporising effect, so that the air is cooled and dried to a maximum for the conditions before it passes on to the next stage.

Between the discharge of the second stage and the inlet to the third stage a light plate non-return valve is fitted. This valve has the effect of stabilising the vacuum produced by the third stage should the steam pressure fall below the designed figure. It also allows of the full vacuum being retained should the ejector steam valve require to be shut for any reason whatever; each intercooler is drained separately to the main condenser, the after-cooler drain passing through a trap.

For land work and mercantile marine work these ejectors are manufactured with cast-iron bodies, steel or brass tube plates, copper tubes, gun-metal diffusers, Monel metal nozzles, while for fast naval craft the bodies can be aluminium alloy, brass tubeplates, Monel metal tubes, gun-metal diffusers, Monel metal nozzles.

Air Pumps.

The essential feature of a plant having a high vacuum efficiency is an air-pump capable of operating without cooling the condensed steam. Excepting in small plants where the heat loss is not so appreciable, all surface condensers should be arranged with two pumps working on the vacuum side, *i.e.* an air-pump capable of dealing with all the air entering the condenser and a water-pump capable of dealing with all the condensed steam. This is what is known as a 'dry' system. Cases where only one pump is employed for the combined duty are known as a 'wet' system. In order to cut down the size of the air-pump in the latter system to reasonable proportions, the condensed steam is usually cooled by means of the last few rows of tubes in the condenser being arranged so that they are always flooded, or by an intercooler.

Capacity of Air-Pump in order to Remove given Amount of Air.

The diagram (fig. 11, p. 1888) shows the properties of mixtures of air and steam such as exist at the air-pump suction. Thus, if the temperature is 100° F., and the vacuum 26 ins., the volume of 1 lb. of air (together with the associated vapour) is 204 cu. ft. and the weight of air per lb. of steam is 1·75, *i.e.* 204 cu. ft. of the mixture contains 1 lb. of air and 0·57 lb. vapour.

The scale on the right provides a basis for calculating the air-pump capacity if the air leakage and the temperature and vacuum are known. For example, assume a surface condenser installation for a reciprocating engine in which allowance is to be made for 16 lbs. air per 10,000 lbs. steam, vacuum 27 ins., temperature at air-pump suction 100° F. From the right-hand scale the volume of air per lb. of condensate, measured at the conditions of the air-pump suction, is 0·395 cu. ft. for an air proportion of 10 lbs. per 10,000 lbs. steam. Thus in the present case the volume is

$$0{\cdot}395 \times \frac{16}{10} = 0{\cdot}63 \text{ cu. ft. per lb. steam.}$$

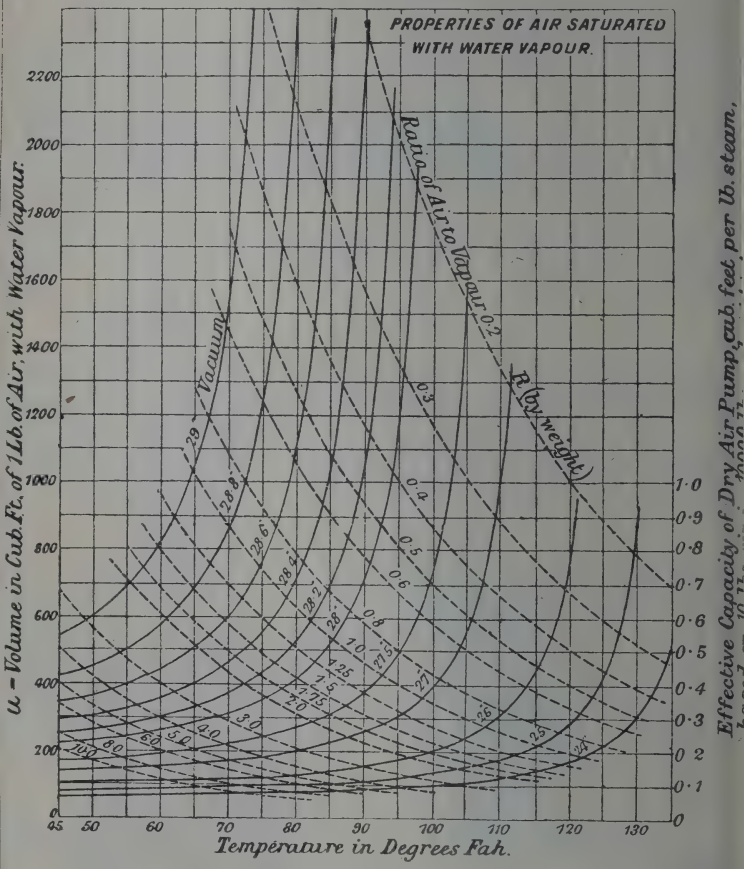
If the steam condensed is 15,000 lbs. per hour, the *effective* capacity of the 'dry' air-pump will then be

$$\frac{15{,}000}{60} \times 0{\cdot}63 = 157 \text{ cu. ft. per minute.}$$

For a 'wet' air-pump the volume of the condensate must be added. The actual capacity of the pump must be greater than the capacity thus found, on account of losses of volumetric efficiency due to clearance, slip, leakage, and valve or port resistance.

The diagram shows the reduction in volume due to cooling of the air-steam mixture before it passes to the air-pump.

DIAGRAM SHOWING THE PROPERTIES OF MIXTURES OF AIR AND STEAM, SUCH AS EXIST AT THE AIR PUMP SUCTION.



(Morley)

FIG. 11

In a jet condensing plant the air introduced by the injection water must also be allowed for.

Leakage of air into the exhaust pipe and condenser should be reduced to a minimum by xercising the greatest care to keep all joints, etc., in good condition.

The amount of air entering the exhaust pipe due to leakage at joints and glands is obviously ot proportional to the amount of exhaust steam, nevertheless air-pumps are frequently designed o give an effective displacement proportional to the amount of exhaust steam, and in fact air- umps for piston engines are frequently proportioned upon the low-pressure cylinder.

Vertical air-pumps are usually single-acting, and low-pressure engine cylinders double-acting. n this basis for ordinary bucket pumps the piston displacement of the low-pressure cylinder is bout 6·5 times that of the pump for jet condensing compound engines in this country and 5·5 imes for India and hot tropical climates. For surface condensers this air-pump ratio varies rom 10 to 12, the lower figure for the smaller and less efficient engines.

Wet-air pumps for jet condensers are frequently proportioned so that their effective displace- ent is about five times the volume of the water (injection plus condensed steam) which they ave to discharge.

Horizontal air-pumps are double-acting, and their volume is therefore one-half that of single- cting pumps.

Air-pumps of the Edwards type usually have about 75 or 80 per cent. as much capacity as he ordinary pumps.

It is tacitly assumed that the vacuum aimed at is about 26 ins., and that considerably greater apacity is necessary for higher vacua.

Air-pump bucket speeds rarely exceed 200 ft. per minute unless the buckets are of the solid lunger type. A usual value is 180 ft. per minute.

The vacuum in a condenser ought to maintain itself an hour with a drop of only 2 lbs.

The smallest air-pump found practicable by Mr. R. W. Allen had 0·5 cu. ft. of displacement er pound of steam condensed.

With circulation water at 65° to 70° F. a vacuum of 28½ ins. at full load with a single-stage ir-pump can be maintained without special accessories. It is not advisable to allow less than ·75 cu. ft. of air-pump volume per 1 lb. of steam condensed, and it ought to be possible to naintain a 98½ per cent. vacuum.

Circulating Pump.

The pump for delivering the required water quantity to the condenser is nearly always of he centrifugal type. The head against which this pump has to deliver is made up of the static lifference in water levels between the inlet and discharge points, plus the pipe and condenser riction. In cases where water is drawn from and returned to a river or canal, the discharge ipe end can be sealed, thus forming a closed or syphon system. In arranging syphon systems are should be taken to ensure that the highest point in the system is never above a vertical listance of 25 ft. from the water level, otherwise the air contained in solution with the water s liable to be released and accumulate, thus breaking the syphon and throwing extra head on he pump.

The Edwards Patent Air-Pump.

In the Edwards Patent Air-Pump, fig. 12, foot and bucket valves are entirely dispensed with. The only valves used are those which in the old type of pump are known as 'the head valves,' but which in the Edwards pump are simply called 'the valves,' as there is no need to distinguish hem in any way.

The condensed steam flows continuously *by gravity* from the condenser into the base of the pump, and is there *dealt with mechanically* by the conical bucket working in connection with a base of similar shape. Upon the descent of the bucket the water is projected *silently and without shock* at a high velocity through the ports into the working barrel, as shown in fig. 13. The rising water is followed by the rising bucket, which closes the ports, and sweeping the air and water before it discharges them through the valves at the top of the barrel.

The essential feature of the Edwards pump is that the water is dealt with *mechanically*, and is in no way dependent on *pressure* in the condenser to drive it up into the pump; consequently,

increase of speed does not impair its efficiency. The speed of the water must correspond with the speed of the bucket, and the pump thus having a regular quantity of water to deal with at each revolution is particularly well suited to work at high speeds.

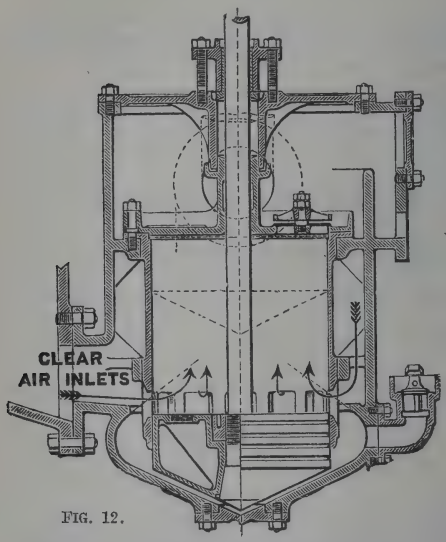


FIG. 12.

Another point of considerable importance in the design of the pump is that *clear air inlets are maintained*. As the bucket descends and the ports open there is absolutely no obstruction between the condenser and the pump. The air has a perfectly free entrance into the barrel, as indicated by the arrow in fig. 13, while immediately afterwards the water is injected at a high velocity; thus, instead of obstructing the entrance of the air, the water tends to compress that already in the barrel, and to carry more air in with it.

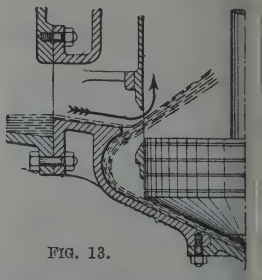

FIG. 13.

Before any air-pump can discharge, all the air in the barrel must be compressed to slightly in excess of the atmospheric pressure, and consequently the greater the amount of air remaining in the clearance water the more inefficient the pump becomes. By reducing the top clearance to a minimum, as is done in the Edwards pump, the efficiency is considerably increased.

SIZE, SPEEDS, AND APPROXIMATE OVER-ALL DIMENSIONS OF THREE-THROW EDWARDS AIR PUMPS WHEN WORKING IN CONNECTION WITH SURFACE CONDENSERS FOR VARIOUS AMOUNTS OF STEAM.

Lbs. of Steam per Hour.	Number of Pump Barrels.	Dia.	Str.	Revs. per Min.	Approximate Dimensions.

55,000 to 60,000	3	16 ins.	12 ins.	145 to 160	7 ft. 0 ins.	7 ft. 6 ins.	2 ft. 8 ins

By means of the door at the top of the pump the only valves used can be readily examined cleaned, and, if necessary, renewed while the pump is at work.

The door also allows the engineer-in-charge to estimate the air duty of the pump, and after a little experience to tell whether there is any serious leakage into the system.

For marine pumps a weir is arranged between the door and the valves (see fig. 13); this enables the door to be taken off while the pump is at work, without loss of water even when there is a heavy list on the ship.

The table on page 1890 gives the dimensions of 3-throw pumps suitable for electrical and other land installations, and for dealing with the stated quantities of steam, when working in connection with *surface* condensers of the ordinary type.

(*The Edwards Air-Pump Syndicate, Ltd.*)

The Leblanc Air-Pump, Simple Jet Type.

In the Leblanc Simple Jet Condenser and Air-pump, water is jetted across the exhaust pipe from the engine by means of a reversed turbine wheel which rotates in a closed casing alongside the pipe, there being an opening into the pipe at a portion of the turbine periphery. There are thus a series of flat sheets of water traversing down the vertical pipe, and serving both to condense and to draw off the steam and air. The water can be used over again if not too hot, and the pump is thus intended for use as a wet and dry air-pump. As there are quite a number of water vanes acting together and moving with great energy down the eduction pipe, there is only a small pressure difference between adjacent vanes, and there is quite a mass of water always acting. The vanes of water practically act like an extension of the metal vanes of the central fan, so that this fan is in a sense an absolute fit in the casing like a scoop wheel, and air is withdrawn between each such vane and the next following. The fan or turbine is practically a water-packed radial-bladed wheel which scoops out the air as it rotates.

The Leblanc Rotary Air-Pump.

In the Leblanc type of Rotary Air-pump, a section of which is given in fig. 14, the air from the condenser is trapped between thin sheets of water thrown out by a series of turbine vanes, which rotate at a high speed in an enclosed casing. The discharge opening in the casing uncovers a certain portion of the turbine periphery where the sealing water, drawn in at centre and passing through the distributor nozzle, gets shot out in sheets from the revolving blade wheel, down the narrowing part of collecting cone discharge pipe, at a high velocity, trapping on its way a certain volume of air between the water sheets discharged.

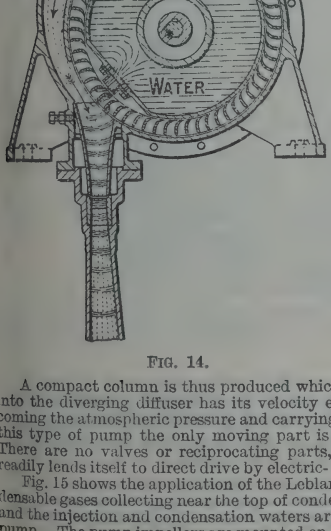

Fig. 14.

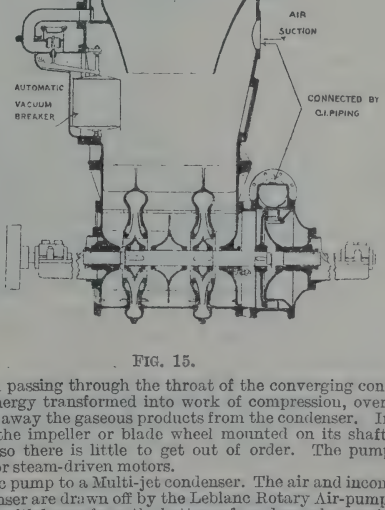

Fig. 15.

A compact column is thus produced which passing through the throat of the converging cone into the diverging diffuser has its velocity energy transformed into work of compression, overcoming the atmospheric pressure and carrying away the gaseous products from the condenser. In this type of pump the only moving part is the impeller or blade wheel mounted on its shaft. There are no valves or reciprocating parts, so there is little to get out of order. The pump readily lends itself to direct drive by electric- or steam-driven motors.

Fig. 15 shows the application of the Leblanc pump to a Multi-jet condenser. The air and incondensable gases collecting near the top of condenser are drawn off by the Leblanc Rotary Air-pump, and the injection and condensation waters are withdrawn from the bottom of condenser by special pump. The pump impellers are mounted on a common shaft and driven by one motor.

Jet or Ejector Air Pumps.

Of recent years great developments have taken place in the design and application of air-pumps in which the vacuum is produced entirely by means of a jet or jets of fluid, which may be water or steam. The air from the condenser mixes with the jet, and the mixture, which just after mixing is at high velocity and low pressure, passes through a 'diffusor' tube of increasing area in which its kinetic energy is as far as possible transformed into pressure energy, so that the mixture may be finally discharged against atmospheric pressure.

Such types of air-pump have the advantage that there are no moving parts in the complete condensing plant, with the exception of a pump for removing the condensate; also they occupy very little space, have little weight, can be located in any convenient situation, and require little attention and maintenance.

The types using steam jets appear to be superseding those with water jets.

It is found advantageous not to carry out the compression of the air from vacuum to atmospheric pressure in one stage, but in two. In order to reduce the work in the second stage, and hence to reduce steam consumption, frequently an auxiliary condenser is used between the first and second stage ejectors.

Under certain circumstances, the flow through the diffusor becomes unstable, causing a drop in the vacuum. To overcome this, some makers provide auxiliary air inlets by which atmospheric air can enter at the throat of the diffusor when required; one firm uses a water jacket round the combining nozzle, and at least one other uses neither of these means, but relies entirely upon the proportions of the nozzles. These forms of the apparatus are described below.

A further recent development is the introduction of an ejector with three stages and two intermediate condensers.

Condensing Plant with Hick-Breguet Ejectair.

(Hick, Hargreaves & Co., Ltd., Bolton.)

The surface condenser is so designed that the whole of the steam comes into intimate contact with the tubes, and the tubes are disposed so as to reduce to a minimum the resistance to the passage of steam.

To ensure the air being withdrawn at maximum density, it is drawn through a 'de-vapourising' chamber formed in the lower pass of the condenser by steel plates enclosing about 8 per cent. of the total number of condenser tubes. The reduction of volume of the air adds to the efficiency of the air-extracting apparatus.

The condenser inlet is usually connected to the turbine exhaust by means of a galvanised wrought-steel bellows pipe which permits of relative expansion between turbine and condenser. The condenser may be mounted on springs, and the bellows pipe dispensed with, but in this case expansion joints are required for all piping connected to the condenser

The jet condenser is of the multiple jet type, the number of nozzles being proportionate to the duty of the plant. The upper portion is designed to eliminate, almost entirely, resistance to the passage of steam on to the finely divided water sprays, condensation thus being immediate and complete.

The air and water are extracted at different points entirely independent of one another, the former being extracted by a steam-jet air pump and the latter withdrawn by a pump of the centrifugal type.

The water extraction pump is single-stage, designed for efficient continuous running under all load variations, and is driven through a flexible coupling by an electric motor or by a steam turbine as required.

The air is extracted from the condenser by the patented 'Hick-Breguet' Ejectair, combining the advantages of a high degree of air extraction with low steam consumption. To meet varying requirements the apparatus is manufactured in the following types:—

Duplex Ejectair with intermediate condenser of the jet or direct-contact type.
Duplex Ejectair with combined intermediate surface condenser and feed heater.
Three-stage Ejectair with combined surface condenser and heater.

In the first-mentioned type, as shown by fig. 16, the first ejector withdraws the air from the condenser, compressing it slightly and discharging it into the intermediate condenser, where the steam from the first ejector is condensed and the air reduced in volume, thereby increasing the volumetric efficiency of the secondary ejector.

The water from the intermediate condenser along with the condensate of the first ejector is delivered by means of a balance pipe direct to the extraction-pump suction, in this way raising the temperature of the condensate from the main condenser, and conserving the heat in the first jet.

The steam from the second jet, along with the air, is discharged preferably into a surface heater, through which the discharge water from the extraction pump passes; by this means the heat from the second jet is conserved and the temperature of the condensate further raised.

The apparatus is fitted with a patent stabilising valve which automatically regulates the working of the two ejectors at light loads, and prevents them from becoming unstable. Under ordinary conditions of working the stabilising valve is not in operation, the whole energy of the team operating the Ejectair being used for extracting the air from the condenser.

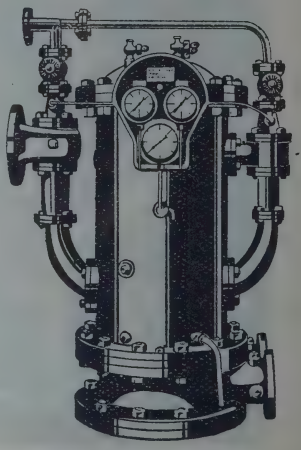
STEAM EJECTOR AIR PUMP

with

Intermediate Surface Condenser

This is our most modern type of Ejector which we have just placed on the market.



Advantages

Combined air pump and feed water heater in one compact unit. The condensate does not come into contact with the highly aerated steam.

The MIRRLEES WATSON COMPANY LIMITED

ENGINEERS, SCOTLAND ST., GLASGOW

LONDON: Mirrlees House, 7 Grosvenor Gds., S.W.1.

314*

F. 1893

The plant is very simple in construction and requires no attention when put into service, the only moving parts being the extraction pump spindle and impeller. It is put into operation by simply opening the steam valve to the two jets, and closing the switches controlling the circulating pump and extraction pump motors.

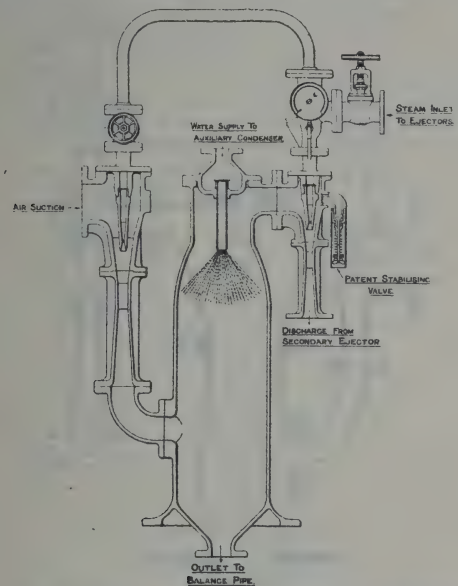


FIG. 16.—Sectional Arrangement of Hick-Breguet Ejectair.

THE MIRRLEES EJECTOR AIR PUMP.

(*The Mirrlees-Watson Co. Ltd.*)

The earlier types of Mirrlees air ejector were provided with groups of small steam nozzles in each stage. Also an auxiliary air inlet was provided at the throat of the second stage ejector. To hasten the production of vacuum when starting, the throat was made larger than necessary for normal working. When the air from the condenser became less than that required to fill the throat, the auxiliary ports admitted atmospheric air and the working of the ejector thus became stable. The latest type of Mirrlees ejector is shown in fig. 17 (p. 1894).

In this design there is a single steam nozzle in each stage instead of a group, the auxiliary air inlet is eliminated, and the consumption of operating steam reduced.

Steam enters at G, the air from the condenser at B. The steam from the first ejector is condensed by injection water entering at F, which also cools the partially compressed air delivered by the first ejector. This cooled air and incondensible gases are led to the second ejector, and discharged at L along with the steam used in the second ejector.

The condenser is self-draining through a U-sealing pipe to the condensate pump suction branch.

The Mirrlees-Watson Co. state that their experiments with water-jacketed ejectors show that the additional complications involved by the water jacket are unnecessary.

In the Mirrlees ejector the convergent cone is cool, and the discharged air and gases do not attain a temperature higher than 215° F.

A standard works test chart for one size of the latest Mirrlees ejector is shown in fig. 18 (page 1894).

The chart shows that there is a great reduction in steam consumption as the air leakage falls below 85 lbs. per hour. In large installations advantage is taken of this by arranging the extractors in batteries working in parallel.

THE MIRRLEES EJECTOR PUMP.
(The Mirrlees-Watson Co. Ltd.)

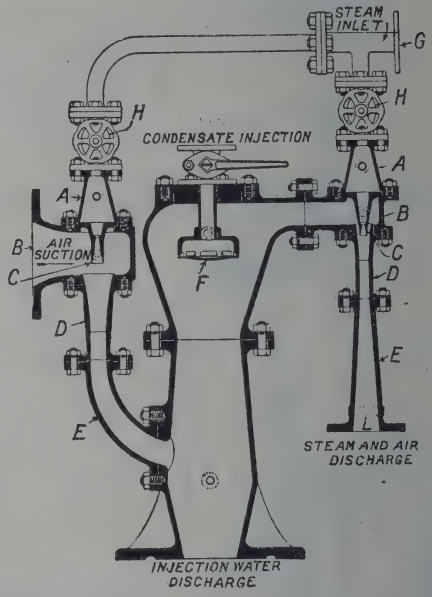

FIG. 17.

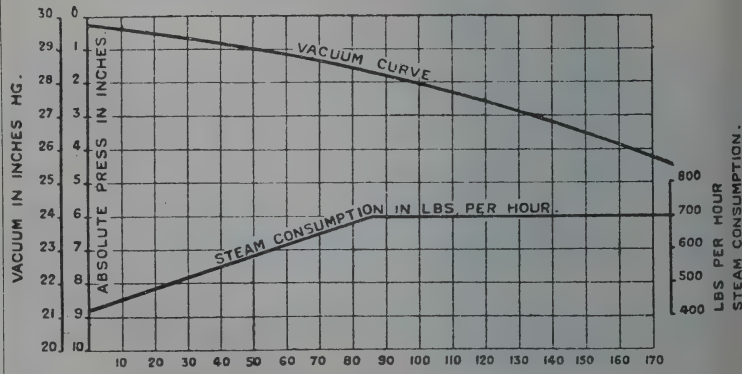

FIG. 18.

Condensing Plant with Radojet Air-Pump.

The construction of the 'straight' type air-pump is illustrated by fig. 19. The arrangement comprises, essentially, two steam ejectors working in series. The first-stage ejector consists of a number of specially designed and arranged tubular nozzles, whilst the second-stage ejector comprises a specially designed radial nozzle with an adjustable nozzle point, so arranged that the steam passing from the nozzle to the diffuser does so in the form of a radial jet and offers a large surface area of steam for the entrainment of the air.

Steam is supplied to the second stage of the 'Radojet' through a steam strainer, and a branch pipe with valve from this strainer controls the supply of steam to the first stage. The steam issues from the first stage nozzles at high velocity, entrains the air withdrawn from the condenser, or other vessel in which it is required to maintain a vacuum, and compresses the air and vapour to a pressure several inches above that at the entrance to the 'Radojet.' The mixture of air

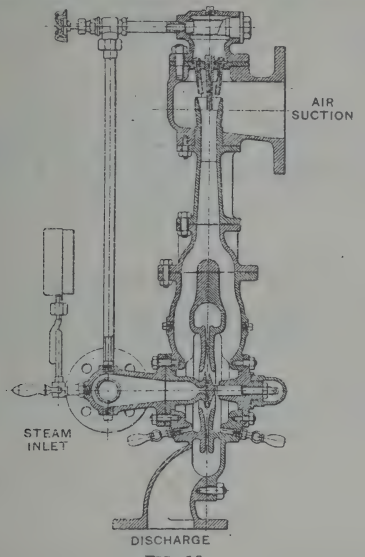

FIG. 19.

and steam then passes through the body of the ejector to the second stage, where it is entrained by the second-stage steam and compressed to atmospheric pressure in an annular diffuser. The whole then passes through the discharge branch to atmosphere, or to some place where the heat of the steam can be utilised.

It will be noted that the second-stage steam compresses not only the air but also the steam coming from the first stage. The air-pump may, however, be arranged with a surface or jet type intercondenser, fitted between the stages, so as to condense the steam used in the first stage, and leave only the air and vapour to be dealt with by the second stage. For equal air handling capacity, this arrangement reduces the steam consumption by about 50 per cent. as compared with an ordinary 'straight' type 'Radojet.' Where it is desired to recover the heat in the steam discharged from the ejector, the discharge pipe may be led direct into the feed tank, or the steam may be led to a feed heater of the direct-contact or surface type.

The 'Radojet' air-pump has been adopted in a great many land installations, and has also been widely applied to marine service. For closed feed systems the first stage discharges into a surface intercondenser, and the second stage into a surface type aftercondenser—both units being incorporated, if desired, in one casing. The air-pump has also been fitted in conjunction with the maker's surface and jet type main condensers for turbine installations up to large sizes, and for uniflow, steam extraction, and slow-speed reciprocating steam-engines. For turbine installations the water extraction and circulating pumps are usually driven by electric motors

or small turbines, and this drive may also be adopted in the case of reciprocating engines, or th pumps may be driven through ropes or belts from pulleys on the engine shaft. Where the vacuum obtainable with existing reciprocating or other type air-pumps is unsatisfactory due to age o any other cause, an improvement may be effected by the substitution of a 'Radojet' equipment Such conversions have frequently been carried out in connection with large reciprocating steam engines, and have been accompanied by an increase in the power and efficiency of the prim mover. If desired, the air-pump may be arranged in the 'Duplex' form, which provides tw complete ejector units with common inter- and after-condensers, and thus affords a spare uni capable of dealing with abnormal loads or air leakages.

The application of the 'Radojet' is not confined to condenser installations, but embraces a processes in which the creation of a vacuum is required, *e.g.* vacuum drying, filtering, and pape making, sugar making and refining, evaporative and chemical processes. In such cases th total absence of moving parts is an important advantage, and the exhaust heat from the air-pump may frequently be used for heating the liquor or other material used in the process. The principl of the radial jet has also been applied to the design of a 'Radojet' Vacuum Augmenter, operate by steam from the auxiliary exhaust range at a pressure of 2 to 5 lbs. gauge. This augmenter i intended for use in conjunction with existing air-pumps where it is desired to increase the vacuum without entailing additional work on the existing pumps.

THE WEIR EJECTOR AIR-PUMP.

(*G. & J. Weir, Ltd., Cathcart, Glasgow.*)

The most modern Weir Ejector Air-Pump is the three-stage type, totally enclosed, eac stage being fitted with after coolers. These three-stage air ejectors have a greater air-handlin capacity than the two-stage types, the ratio of increase naturally varying with the quantity of ai being handled. At normal duties the ratio is roughly 3 to 2 on the same steam consumption.

THE BAILEY AIR-PUMP.

(See p. 1264).

Measurement of Condensed Steam.

The condensate may be measured by passing over a V-notch in a suitably arranged tan the height of the water surface above the apex of the notch being measured at a point at suc a distance from the notch that the water is nearly still.

If h is the height in inches, Q the flow in cub. ft. per minute, and the angle of the notch 90°, then $Q = ch^2\sqrt{h}$, where c is approximately 0·305, but, more accurately, varies from 0·3 at $h = 2$ ins., to 0·301 at $h = 9$ ins. or over. Less heads than 2 ins. should not be used, it bein better to increase the head by using a notch of narrower angle; the discharge is approximatel proportional to the tangent of half the notch angle.

For the 90° notch th ecubic feet of flow per minute$=0{\cdot}305h^2\sqrt{h}$, where h is the depth fro the water level in the still pond above the notch measured down to the point of the V.

If one notch will not pass the water, two may be used, and the reading of the instrume doubled.

In the 'close feed' systems, which are now frequently adopted in power stations, the co densate and the make-up feed-water may be measured by means of Venturi meters included i the pipe system.

Measurement of Air-Pump Water.

THE LEA AUTOMATIC WATER RECORDER FOR MEASURING CONDENSED STEAM.

This instrument, made by *The Lea Recorder Co., Ltd.*, of Manchester, measures the condensa from surface condensers by means of 90°, or smaller, 'V' notches.

A float in a chamber, connected to a measuring tank, which is fitted with 'V' notch plat rises and falls in accordance with the level of water flowing over the 'V' notch.

On the float rod is a toothed rack which turns a pinion on a drum spindle. The pen of th recording mechanism is moved across the record paper (which is clock-driven) by means of th spiral groove cut in the drum. This spiral has an increasing pitch, starting at 0 when the wat is down to zero level, or the apex of the 'V' notch, and increasing in the ratio $h^2\sqrt{h}$, so th the pen movement is always proportional to the volume of water flowing. (See p. 1503.)

An important feature of these recorders is that when measuring hot water they possess a com pensative action, owing to the fact that when the temperature increases, the density of the wat is reduced, and consequently the float sinks slightly, and thus the instrument records a less weigh which is correct. On the other hand, when the temperature falls the float rises, owing to th increased density of the water, and the instrument records a slightly greater weight, which is als correct. The instrument, therefore, remains accurate for changes of water temperature withi wide limits.

By means of this recorder the steam consumption of an engine or turbine can be noted at any time, whilst a chart record is secured of the total discharge over a given period.

Any small changes in the running of the plant can be instantly noted on referring to the diagram produced.

TABLE OF FLOWS THROUGH 90° V NOTCHES.

Depth in Notch in Ins.	Flow per Hour.		Depth in Notch in Ins.	Flow per Hour.	
	Galls.	Lbs.		Galls.	Lbs.
2	654	6,540	9	27,300	273,000
3	1,785	17,850	10	35,600	356,000

8	20,300	203,000	15	79,900	979,000

(*Barr.*)

The position of the 'V' notch tank varies with the type of plant, *e.g.* sometimes it is placed in the condenser pit, alongside the extraction pump, and the condensed steam flows from it by gravity to a hot-well, or, alternatively, it is inserted between the extraction pump and a lift pump, the latter drawing water from the end compartment of the notch tank, and delivering to an overhead hot-well or storage tank.

In cases where the 'closed feed' system is in operation the recorder tank can be sealed, and the same degree of vacuum maintained as exists in the condenser, in which case the tank is placed immediately underneath the condenser outlet, and between this and the extraction pump.

This apparatus is also extensively used for the measurement of boiler feed-water, in which case the measuring tank is usually inserted on the suction side of the boiler feed pumps, so that water is drawn from it; the supply of water flowing through the recorder tank being controlled by means of an equilibrium float valve.

These recorders can be obtained in two patterns, *i.e.* the 'Indicating and Recording' type, and the combined 'Indicating, Recording, and Integrating' type. With the latter the total quantity can be read off directly on large dials of the Harding type.

Injection Cocks

Are usually of the hollow plug type, in gunmetal. One per condenser is sufficient. Two or three standard sizes are generally available to choose from. The minimum size can be checked, as in the following example:—

Maximum load under normal conditions	1,000 i.h.p.
Steam per i.h.p. hour	15 lbs.
Steam per second	4·17 lbs.
Condensing water per pound of steam	40 lbs.
" " per second	167 lbs.
" " "	2·67 cub. ft.
Vacuum in condenser, worst	24 ins.
" " in feet of water	27 ft.
Vertical height water level to injection cock	11 ft.
Head of water on injection service, 27-11	16 ft.
Assume spent in friction	50 per cent.
Net head at injection cock	8 ft.
Velocity of water at cock $= 8\sqrt{8}$	22·6 ft. sec.
Hence area of opening	0·118 sq. ft.
" "	17 sq. ins.

If in doubt add a margin of 25 to 30 per cent. It is, of course, understood that the above level, steam consumption, etc., must be modified to suit the actual conditions. Thus in tropical countries 60 should be substituted for 40 lbs. of condensing water per lb. of steam.

Force or Feed Pumps.

When the boiler feed-pump is driven off the engine it is usual to allow sufficient capacity for other works purposes.

The following are frequently adopted :

Textile spinning mills	25 lbs. water per i.h.p. hour
Textile weaving sheds	40 ,, ,, ,,
Mixed spinning and weaving	30 ,, ,, ,,
Flour mills	35 ,, ,, ,,
Bleach works	50 ,, ,, ,,

It will be seen that an ample allowance is made, and for economical superheated-steam engines a reduction of about 5 lbs. can be made. The above are based on actual pump displacement. The plunger speed should not exceed about 200 ft. per minute.

Pump Openings.

The velocity of water in pump openings should not exceed 500 ft. per minute.

Cooling Ponds.

Where the supply of water for condensing purposes is limited, it is necessary to cool the condensing water and use it again and again. One method of cooling is to pass the hot water into an open pond and draw off water for condensing from the opposite side of the pond, the water being cooled simply by evaporation from the surface.

Spray Ponds.

An improvement upon the simple pond is to lay a system of piping over the pond and let the water issue from nozzles in a fine spray. A large amount of water is, however, carried away by the wind and lost.

A spray pond should have 2½ sq. ft. of area per gallon of water to be cooled per minute. This includes the marginal straps necessary for windage, etc.

Water-Cooling Towers.

Water-cooling towers are of two principal types—chimney type and open type. Both act by bringing the water into intimate contact with air currents, and to expose as large a surface of water to the air as possible the water is either broken up by splash bars into fine drops, or made to run down in thin films. In chimney type towers air is admitted at or near the bottom only, and passes up inside the casing usually by natural draught, though sometimes forced draught is used. Forced-draught towers are smaller than natural-draught for the same duty, but require a large expenditure of power in the fans.

Open type coolers have water-distributing arrangements similar to those in the chimney type, but have no external closed casing, the flow of air across the water is dependent upon the action of the wind. To prevent excessive loss of water, the stack is usually surrounded by louvre boarding, but even then the loss of water is large compared with that in the chimney type.

In chimney type towers the water is usually pumped to distribution troughs at a height of 16 to 25 ft.; the height of the chimney is about 60 to 70 ft. if of timber, 100 to 120 ft. if of steel (which is less usual). The width of the tower should not exceed 25 ft. at most, as the difficulty of getting cool air to the centre increases as the width is increased; nor should the tower be narrower than about 15 ft., in order that it may have an adequate margin of stability.

In all cooling towers the heat is extracted from the water partly by (1) direct heating of the air, partly by (2) evaporation of part of the water. Under typical atmospheric conditions in this country evaporation accounts for about 75 to 85 per cent. of the cooling.

The amount of evaporation possible depends upon the amount of moisture already contained in the air entering the tower and its temperatures at inlet and outlet.

PREMIER

PREMIER
COOLING TOWERS

have been erected by us for many of the important engineering firms.
Combining strength with efficiency, absolutely weatherproof, Premier plant cools over 85,000,000 gallons per hour.

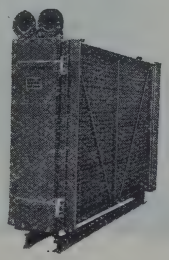
The name that means absolute efficiency —and low— maintenance cost

ADHESIC AIR FILTERS

With its low resistance to air flow, uniform surface and adhesive coating, the "Premier" filtering system is far superior to any other.
Guarantees to remove 98% of all solid impurities.

CLOSED CIRCUIT
AIR COOLER

For alternator ventilation, to be found in practically every engineering plant of importance throughout the world. Installations to date exceed 400,000 kw.



HASTE PATENT VALVES

No springs, hinges, corners, angles or pockets; the only working part is the valve itself. For a given size, more water can pass through this valve than any other type.

UNIC
STEAM TRAP

Simple design ensures constant flow of liquid. Works satisfactorily with superheated steam.

OIL SEPARATORS

Simple to install—needs very little attention, no filtering materials required. Guaranteed to separate all oil up to ·33 grains per gallon of steam condensed.

We shall be pleased to supply details of other Premier products upon request.

Film Cooling Towers (1925) Ltd

124 CHANCERY LANE
LONDON, W.C.2

Telephone: HOLBORN 5877 *Telegrams:* "ALOOF," FLEET, LOND

F. 189

It is important, in specifying or judging the capacity of cooling towers, to take into account the humidity or the wet and dry bulb readings.

The 'relative humidity' of the atmosphere is the ratio of the weight of water vapour contained in a certain volume of air to the weight required to saturate this volume at the same temperature, or it may be expressed as the ratio of the vapour pressure at the dew-point to that at the actual air temperature, the dew-point being the temperature to which the air must be cooled in order that it may just become saturated, so that further cooling would cause condensation to begin. The greater the humidity of the atmosphere, the less, of course, is its capacity for taking up moisture by evaporation. The humidity is ascertained by reading wet and dry bulb thermometers and referring to humidity tables.

The quantity of fresh 'make-up' water required to compensate losses by evaporation, etc., in cooling plants is about 3 to 5 per cent. of that in circulation.

It is stated that the loss by evaporation only in natural draught chimney type cooling-towers is approximately 1 per cent. for each 12° F by which the water is cooled in the tower.

(*I. V. Robinson*, '*B.E.A.M.A. Journal*,' *March* 1921.)

The amount of air for which the cooling tower should be proportioned may be calculated as in the following example :—

Let the atmospheric temperature and humidity be 65° F. and 60 per cent. respectively, the atmospheric pressure 14·7 lbs. per sq. in., and let the air leave the tower at 85° F. (saturated with vapour).

From steam tables, the vapour pressure at 65° F. is 0·31 lb. per sq. in., thus the air pressure is 14·7—0·31 = 14·39 lb. per sq. in.; 1 lb. air at this pressure and at 65° F. occupies 13·45 cu. ft ; 1 lb. vapour at 85° F. occupies 990 cu. ft.

$$\therefore \text{weight of vapour per lb. air if saturated} = \frac{13{\cdot}45}{990} = 0{\cdot}0136 \text{ lb.}$$

$$\therefore \text{weight of vapour at 60 per cent. humidity} = 0{\cdot}0136 \times 0{\cdot}6 = 0{\cdot}00816 \text{ lb.}$$

At 85° F. the vapour pressure = 0·6 and air pressure 14·1 lb. per sq. in.; 1 lb. air at these conditions occupies 14·3 cu. ft.; 1 lb. vapour at 85° occupies 541 cu. ft.

$$\therefore \text{vapour per lb. air} = \frac{14{\cdot}3}{541} = 0{\cdot}0264 \text{ lb.}$$

Hence, for each lb. of air passing through the cooling tower, 0·0264—0·00816 = 0·0182 lb. water is evaporated.

Heat to evaporate 1 lb. water from water at 65° F. to vapour at 85° F. = 20 + latent heat = 1,061 B.Th.U.

$\therefore$ heat to evaporate 0·0182 lb. = 0·0182 × 1 061 = 19·3 B.Th.U.
Heat absorbed in heating air = 0·237 × 20 = 4·74 B.Th.U.
Total heat taken from water per lb. air = 19·3 + 4·74=24·04 B.Th.U.

Ratio of cooling by evaporation to total cooling

$$= \frac{19{\cdot}3}{24{\cdot}04} = 0{\cdot}8 \text{ or } 80 \text{ per cent.}$$

If the water is cooled, say 30°, the weight of water cooled per lb. air = $\frac{24{\cdot}04}{30} = 0{\cdot}801$ lb.

Percentage of water lost by evaporation

$$= \frac{0{\cdot}0182}{0{\cdot}0182 + 0{\cdot}801} \times 100 = 2{\cdot}22 \text{ per cent.}$$

Weight of air to pass through cooler per lb. water

$$= \frac{1}{0{\cdot}801} = 1{\cdot}25.$$

Premier Water-Cooling Towers.

(The Premier Cooler and Engineering Co. Ltd., Station Works, Shalford, Surrey.)

'Premier' Cooling Towers, although primarily designed for cooling the water used for condensing purposes in, or in conjunction with, steam engines or turbines, also for cooling the jacket water for internal combustion engines, are equally useful to a degree for other industrial purposes, such as: (1) The liberation of gases in liquids, (2) the evaporation of water in solutions containing certain solids it is desired to concentrate as far as possible by this process.

The Chimney Type Tower, which is almost invariably used for the larger schemes, although usually made in rectangular form with a height ranging from 70 ft. to 100 ft., can, nevertheless, be supplied with chimneys of hexagonal or octagonal construction. The latter type, a considerable number of which have been put into operation in this country, has exceptional strength owing to its shape approaching as near as possible the circular form. The chimneys are designed so as to resist the full wind pressure experienced with a good factor of safety without the assistance of the internal filling or irrigation. The materials used for this class of tower are generally pitch pine and red deal, if of timber construction, but towers can be supplied with steel, concrete, or brick chimneys. In the wooden construction all the bolts, fishplates, grappling irons, etc., are heavily galvanised.

The irrigation system is designed to give the largest area possible for the uprising air, which is brought into contact with the water or other liquid to be cooled or evaporated, in the finest possible form. The towers operate on the splash and film principle, which extensive experience has proved gives the best results. The distributing troughs and gutters are of the open top type, thus allowing the quick removal of solids and foreign matter which invariably accumulate, due to the continuous process of evaporation. The distributing tubes are of 'Venturi' type executed *in acid-resisting earthenware, as also are the splash plates.* The water is thoroughly atomised before falling into the irrigation or lath system. The laths are fixed without the use of nails, being held in place in machined-notched bearers. The design provides for keeping the air in contact as long as possible whilst allowing the maximum amount of air to be circulated through the plant.

The Open type construction, such as is usually employed for dealing with the jacket water for internal combustion engines, is constructed on somewhat similar lines, but the outside faces are louvred to prevent splashing out. Since this type of tower is not fitted with a chimney, the air circulation is much slower, and consequently the space occupied for a given duty is much more than with the natural draught Chimney type construction. In cases where the water volume is comparatively small, and it is desired to reduce the temperature to a very low degree, this type of cooler is especially suitable.

In exceptional circumstances, where the space available is limited, Forced Draught Towers can be supplied with considerable benefit, but such plant is uneconomical from the point of view of running cost, as compared with Natural Draught Plant.

The Film Cooling Tower.

(Film Cooling Towers (1925), *Ltd.*, 124 *Chancery Lane, W.C.* 2.)

The object in view of the 'Film Cooling Tower' is to enable the user effectively to cool larger quantities of water on the same area than has been possible with the older types of cooling towers. In the latter case the water is delivered into a system of troughs, and in its descent to the tank below it is broken up into drops, the rising air cooling the water. Owing to the density of this 'rainfall' a very large resistance is set up against the incoming air, and this had to be taken into account when designing this type of tower. In the 'Film' tower the water is broken up into a thin, flat stream running along the laths inclined in the direction of their length, the bottom end of each lath being cut in such a way so as to allow the water to be delivered into the centre of the next lath, and so on. Owing to surface tension the water will completely envelop each lath and run along the underside as well as along the upperside, whilst the formation of the lath is such as to provide natural passages for the air, thus providing even the centre portions of the cooling tower with an efficient air supply.

In actual practice it has been found that a 'Film' tower of the same capacity when built of the same height as a 'Splash Type Tower' would occupy a ground space about 27 per cent. smaller. The discharge from the troughs takes place through syphonic earthenware tubes on to specially designed splash cups; these tubes, as well as the film lath, are covered by Letters Patent.

Steam Accumulators.

Where, as in the case particularly of rolling mill engines and winding engines, large quantities of steam are exhausted intermittently, this steam may be profitably utilised in exhaust steam turbines. In order to give a steady supply of steam to the turbine, the exhaust from the high pressure is first passed into a storage vessel or heat accumulator, which consists essentially of a large container in which a large mass of material is placed which can absorb the heat of the engine exhaust during its working periods and redeliver it to the turbine during the 'bridge' periods, i.e. when the reciprocating engine is not exhausting any steam.

An exhaust steam turbine working with steam at, say, 16 lbs. per sq. in. abs., and a vacuum of 27·5 ins., will require, with allowance for auxiliaries, about 40 lbs. steam per kw. hour, so that for every 1,000 lbs. exhaust steam per hour available, and deducting 16 per cent. for wetness and leakage, $\frac{1{,}000 - 160}{40} = 21$ kw. can be obtained.

The proportions of the accumulator depend on the bridge period or time of regeneration, the range of temperature allowable, and the material used to store the heat, as well as on the steam rate. Early accumulators were made up of old boilers packed with old rails, etc., but water is a much more efficient material, for iron has a specific heat of about 0·11 and a specific gravity of about 7, so that its volumetric specific heat is only about 0·77.

The range of temperature to be allowed in the accumulator must be decided upon, and from these figures the mass of water to be employed must be calculated. If the accumulator becomes too hot it will reduce the power of the engines which feed it. If it becomes too cold this proves that the turbine is doing more work than can be supplied by the waste steam. It is considered that usually the stops to be bridged by the accumulator are 60 secs. in colliery work and 30 to 45 in rolling mills. The admission to a steam turbine is assumed to be 16·5 lbs. absolute, the range being 15 to 18 lbs., or 10° F. In some plants, pressure rises more than ½ lb. above atmosphere, and it may fall to 12 lbs. absolute or 5½ ins. of vacuum. A reflux valve is arranged in that case to prevent the vacuum getting back to the engine—an important safeguard for a winding engine.

In calculating accumulators,

$$\mathrm{WTL} = wt,$$

where,

W = lb. of steam supply per sec.; T = time of regeneration in secs.;
w = lb. of water in accumulator; L = latent heat of steam per lb.;
t = range of mean water temperature in accumulator.

It should be noted that if the circulation is not perfect, the range of mean temperature (t) of the water will be less than that corresponding to the change of steam pressure. This should be allowed for in using the formula.

It is essential that the steam should mix with the water or this will be locally heated only. Shallow dishes of water piled in tiers with narrow spaces for steam admission between them have been used, or the water may be kept in continuous circulation by a pump which delivers it in a shower through an upper steam space.

In the Rateau-Morison type of steam accumulator, great attention has been paid to efficient circulation. This has been attained by means of a number of vertical open-ended cylinders, each containing a nozzle with upturned star-shaped opening. This is placed 9 ins. below water-level, and sets up a powerful up-flow through the cylinder, which draws from the base of the accumulator and discharges the heated water at the surface.

As many as 30 such circulators are hung on curved branch pipes from each side of the exhaust main which runs along the crown of the accumulator boiler. Below the main is a third row. The accumulator is a plain cylinder laid horizontally with about 6 ft. of water depth. Circulation is so rapid that a difference of only 2° F. occurs between top and bottom of the water. The circulation cylinders have their discharge openings all turned to one end of the accumulator, and all oil is then drifted that way and collected behind two vertical plates and blown off periodically.

Accumulators may be made of old Lancashire boiler shells, or built up of cast-iron segments, or may be of ferro-concrete.

An increase of vacuum from 26 to 28½ ins. will reduce the steam consumption of a turbine by 25 per cent. With this vacuum the condensate will be about 80° F., and if there is any spare steam it should be applied to feed heating. In this case by heating the feed to 200° an economy of 12 per cent. is secured.

The Galloway Steam Accumulator.

This accumulator (figs. 20 and 21) is intended for receiving the exhaust steam at a few lbs. per

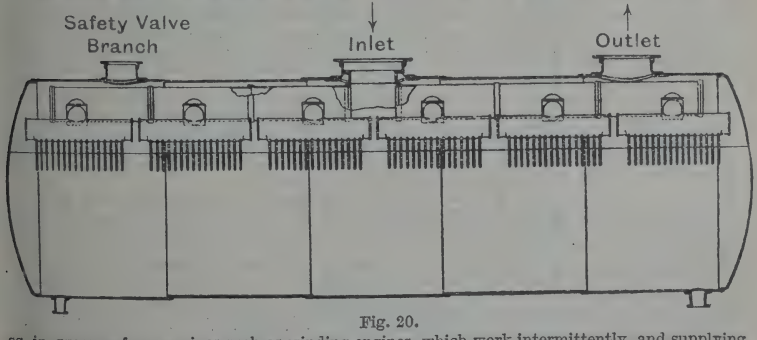

Fig. 20.

sq. in. pressure from engines such as winding engines, which work intermittently, and supplying steam at a steady rate to mixed pressure turbines.

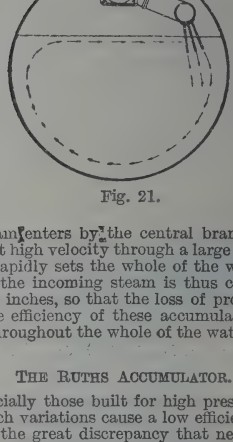

Fig. 21.

As shown in the figs., the steam enters by the central branch through internal distributing boxes, and is led into the water at high velocity through a large number of simple nozzles of small bore, so placed that the steam rapidly sets the whole of the water in the accumulator into circulation. The condensation of the incoming steam is thus carried out very effectively. The nozzles are submerged only a few inches, so that the loss of pressure between incoming and outgoing steam is very slight. The efficiency of these accumulators in operation is evidenced by the uniformity of temperature throughout the whole of the water, the maximum difference being about 1° Fah.

The Ruths Accumulator.

Ordinary steam boilers, especially those built for high pressures, are not well suited to cope with quickly varying loads. Such variations cause a low efficiency in the operation of the boiler plant, which manifests itself in the great discrepancy that nearly always exists between boiler test results obtained at constant load and those obtained under normal practical working conditions. More serious, however, is the detrimental influence which the limited rate of steam supply from the boilers has on the magnitude of the *output of the works* where the boilers are installed. It also happens very often that variations in steam pressure, caused by variable loads, have a serious influence on the quality of the products manufactured.

Investigations made in a great number of different industries show that the actual variations which occur in the steam consumption are usually larger than conceived. Moreover, if the limiting effect on the steam consumption that is exercised by the boilers did not exist, the variations in the steam consumption would be even still larger, as a more intensified work is possible in the factory when steam is always available in sufficient quantities.

By means of the new steam accumulation system of Dr. J. Ruths of Stockholm, all such variations in the steam demand for process and for power purposes, which are detrimental to the work of the manufacturing plant or the boilers, can be completely ' equalised ' and prevented from reaching the boilers. This system will also prevent inevitable unevenness in the quality of fuel or in the fuel supply to adversely affect the operation of the boilers, the overall efficiency of which can thus be materially increased.

The scope of application of the Ruths Accumulator is thus a much larger one than that of earlier steam accumulators as, *e.g.*, the exhaust steam accumulators of Rateau and others. As in these accumulators, the Ruths Accumulator utilises the well-known ability of hot water to accumulate steam at a rising temperature and pressure and to release it again through re-evaporation by the internal heat of the water at falling temperature and pressure. The pressure ranges applied in Ruths Accumulators are much wider than those used in earlier steam accumulators, and although the Ruths Accumulators co-operate with the boilers, the pressure of the latter is under normal circumstances unaffected by the accumulator pressure. The maximum working pressure in a Ruths Accumulator is usually much greater than the minimum pressure. Ranges like 150–40 50–10 lbs. gauge are common. On account of the use of these wide pressure ranges at comparatively low level on the pressure scale, great steam quantities are stored per unit of volume. The practical heat storing capacity or ' steam reserve ' of Ruths Accumulators is as an average 5 to 50 times larger than the maximum ' steam reserve ' that can be obtained at a permissible pressure drop in the steam boilers with which they co-operate.

The Ruths Accumulator is usually built in the form of a large cylindrical steel tank, with hemispherical ends. It is constructed like a steam boiler of riveted steel plates to withstand a certain maximum steam pressure. It contains the hot steam-storing water, and is equipped with arrangements for an even distribution of the charging steam into the water, and for re-discharging steam in a safe way. The accumulator is not directly attached to the boilers, but is usually erected out of doors in a factory yard, etc., in order to be out of the way. By means of a single steam pipe and a few control valves of special type and action the accumulator is connected to the steam system, including the boilers, steam engines, or turbines, and other consumers, in such a way that a *complete and positive equalisation* of all the flow of heat energy in the whole works in question is accomplished. All surplus steam that may occur is absorbed by the accumulator, and any shortage of steam that may arise in the supply to the consumers is

THE RUTHS STEAM ACCUMULATOR.

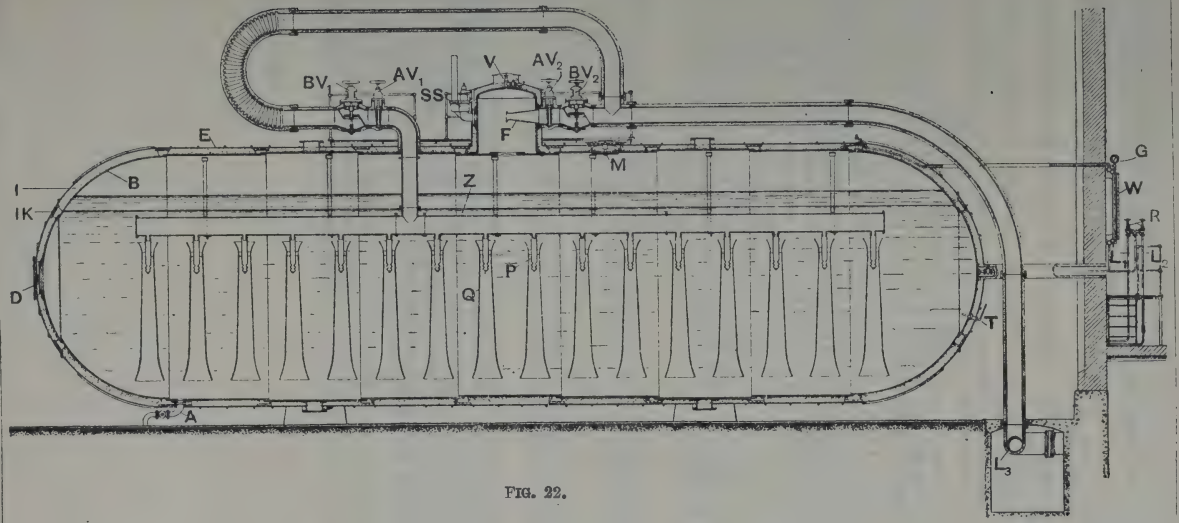

FIG. 22.

automatically made up from the accumulator; the boiler plant can therefore be worked und practically constant load and the boiler pressure remains steady at the set maximum level. Th following are the advantages obtained as a result of this 'thermo-fly-wheel effect' of th accumulator:

1. Steady supply and practically unlimited reserve of steam at constant pressure for a power or process purposes.

2. Maximum economy in the operation of the whole manufacturing plant, as the same ca be intensively utilised.

3. Maximum efficiency in the boiler plant, as ideal load conditions prevail.

4. Reduction in the numbers of boilers in operation, as only so much heating surface is require as corresponds to the average steam requirements of the factory.

The firing of the boilers is guided by a pressure gauge, put up in the boiler-house, which show the accumulator pressure. As long as this pressure is swinging within the limits of the set rang of the accumulator (which is clearly marked on the dial), the firing rate is kept constant.

Fig. 22 shows a section of a Ruths Accumulator. The accumulator is charged through stea entering the check valve BV_1 and passing into the water through the distribution pipe Z, th special nozzles P and the circulation pipes Q. The check valve BV_1 in the steam inlet preven the water flowing backwards out into the steam pipe. When discharging, the steam is passed ou from the steam dome through a 'safety nozzle' F and a cheek valve BV_2, which prevents th charging steam passing this way. Usual boiler mountings are fitted, including a water-gauge W made extra long on account of the great variations in level that are a result of the wide pressu range. No regular supply of feed-water is necessary, but only occasional adjustments of th level in order to make it correspond to the pressure. The accumulator does not require dai attendance. The steam passes in and out (according to the requirements of the factory) witho any noise or vibrations. The vessel is covered all over by a thick cover I of first-class insulatio material, whereby the heat losses are sufficiently reduced as to be negligible. On accumulato erected out of doors the insulation is protected by roofing material E.

The control valves, which govern the proper action of the whole plant, including the co-operatio of the accumulator and the boilers according to the variations in the steam demand, are automat in action and operate on the relay principle with oil as a pressure medium.

The pressure impulses that govern the work of the valves are taken from the various stea pipes, and by suitable combinations of these valves, relays, and impulses, all variations tha occur in the steam system are kept away from the boilers and made to fall on the accumulato This action goes on automatically and accurately without attendance.

Numerous Ruths Accumulators have been working for years with marked success in man different industries and also in purely power stations, especially in Scandinavia and on th Continent. The accumulators are particularly useful in the increasing number of factori where back pressure, pass-out, or mixed pressure steam turbines or engines are employed f producing cheap steam power. In such schemes they work as a very valuable 'clearin department' for handling all the fluctuating requirements of heat and power that are inte linked by means of the steam machinery.

Under the steadying influence which the accumulator exercises on the load and steam pressur it is usually found, in such schemes, that a great deal more power can be produced out of the heatin steam than when the variations in the steam and power demand are left unequalised.

1 kilowatt=1·34 British horse-power.
Absolute temperature °F. (T)=460 + ord. temp. °F.
" °C. =273 + ord. temp. °C.

The volume of 1 lb. of a gas varies with its pressure and temperature and for purposes of comparison a definite pressure and temperature are selected. If normal pressure and temperature be one atmosphere and 32°F., this may conveniently be denoted by N.T.P.

Mass and Bulk of some Gases and Vapours at N.T.P.

Air is by *weight*, composed of 77 per cent. nitrogen and 23 per cent. oxygen.
By *volume* its composition is 79 per cent. nitrogen and 21 per cent. oxygen.
One pound of oxygen is contained in $\frac{100}{23}=4{\cdot}35$ lbs. of air.
One cubic foot of oxygen is contained in $\frac{100}{21}=4{\cdot}8$ cub. ft. of air.
One pound of dry air at N.T.P. occupies 12·387 cub. ft.
One cubic foot of dry air at N.T.P. weighs 0·08073 lb.
The following table gives data relating to the heaviness and bulkiness of the more usual gases:—

HEAVINESS AND BULKINESS OF SOME GASES, ETC., AT N.T.P.

Gas.	Symbol.	Specific Gravity; Hydrogen = 1.	Heaviness of 1 Cubic Foot at N.T.P.; Lbs.	Bulkiness of 1 lb. in Cubic Feet at N.T.P.
Column:—	1	2	3	4
Hydrogen	H_2	1	0·00559	178·89
Methane (marsh gas)	CH_4	8	0·04472	22·36

Oxygen	O_2	16	0·08944	11·18
Carbon dioxide	CO_2	22	0·12298	8·13
Normal benzene	C_6H_6	39	0·21801	4·59

p=abs. pressure, in lbs. per sq. foot
=144 {14·7 + pressure in lbs. per sq. in. above atm.}
v=volume of 1 lb. of gas, in cubic feet;
T=absolute temperature in °F.;
=460 + ord. temp. °F.

Then for a perfect gas:—

$$pv = c\,T, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where c is constant for any, the same, gas.

For dry air at N.T.P.:—

p=14·7 × 144=2116·8 lbs. per sq. ft.
v=12·387 cu. ft. (Table, col. 4.)
T=460 + 32=492°F. (abs.).

Whence, by Eq. (1), we have $c=53{\cdot}29$. Thus the characteristic equation for dry air regarded perfect gas, is :—

$$pv = 53{\cdot}29\ \mathrm{T}. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Equations (1) and (2) show that in a perfect gas the value of the product pv is proportional he absolute temperature. If the pressure remains **constant,** the volume and absolute tempera- are mutually proportional. So also, if the volume remain constant, the pressure and absolute perature are mutually proportional.

The specific heat of dry air at constant pressure, k_p, is 0·2374 B.Th.U. per lb.

The specific heat at constant volume, k_v, is less than k_p by the heat equivalent of the external k of expansion under constant pressure.

If Eq. (1) be differentiated at constant pressure we have :—

$$p\ dv = c\ d\mathrm{T};$$

s, putting $d\mathrm{T}=1°\mathrm{F}.$, we have $c=p\ dv$; so that c expresses the external work of ex- sion under constant pressure in foot-lbs. As Joule's equivalent, J, is 778 foot-lbs. per Th.U., we have for dry air :—

$$k_v = 0{\cdot}2374 - \frac{53{\cdot}29}{778} = 0{\cdot}1689.$$

The ratio of k_p to k_v is important in the theory of gas engines, and is usually denoted by γ: s for dry air :—

$$\gamma = \frac{k}{k_v} = 1{\cdot}4056.$$

Isothermal and Adiabatic Expansion.

The two fundamentally important modes of expansion of gases are :—

(1) Isothermal expansion.
(2) Adiabatic expansion.

(1) *Isothermal Expansion.*—When a mass of gas changes volume at constant temperature, change is described as 'isothermal.' In the case of perfect gases, Eq. (1) shows that in this e the value of the product pv remains constant. If p_o v_o T_o be respectively the initial values pressure, volume, and (abs.) temperature, and pv any subsequent simultaneous values, we ve in isothermal expansion :—

$$pv = p_o\ v_o = c\ \mathrm{T}_o \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

The external work W done in expanding from volume v_o to volume v, is expressed by :—

$$\mathrm{W} = \int_{v_o}^{v} p\ dv \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

, in isothermal expansion, $pv = p_o\ v_o$, we have $p = \dfrac{p_o\ v_o}{v}$; hence (4) becomes for this case :—

$$\mathrm{W} = p_o\ v_o \int_{v_o}^{v} \frac{dv}{v} = p_o\ v_o\ \mathrm{Log}_e \frac{v}{v_o} \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

is the volume ratio of expansion, and may be denoted by ρ; thus, from (5), we have in othermal expansion :—

$$\mathrm{W} = p_o\ v_o\ \mathrm{Log}_e \rho = c\ \mathrm{T}_o\ \mathrm{Log}_e \rho \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

As the internal energy of a perfect gas depends only on its temperature, it follows that isothermal change the internal energy of the gas remains constant. Hence, in isotherm expansion of a perfect gas the heat given to the expanding gas is the exact equivalent of t

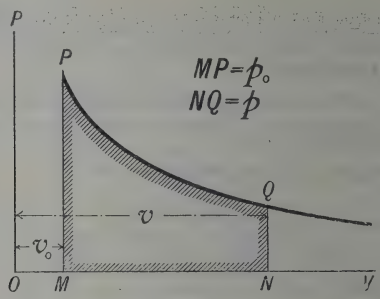

FIG. 1.

external work performed by the gas. And, conversely, in isothermal compression of a perfe gas, the heat that flows from the gas during compression is the exact equivalent of the wo done on the gas in compressing it.

Frequently in engineering thermodynamics it is found that actual expansion and compressi curves of diagrams can be closely represented by an equation of the form :—

$$pv^n = p_0 v_0^n, \text{ a constant} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

where the index n is constant in value.

When $n=1$ we have the particular case of isothermal change, which has just been consider For all other values of n, the external work done during expansion from volume v_0 to volume v represented by the hatched area MNQP of fig. 1—is given by :—

$$W = \int_{v_0}^{v} p \, dv = p_0 v \int_{v_0}^{v} v^{-n} \, dv, \text{ by Eq. (7)}$$

That is,

$$W = \frac{1}{n-1}\left\{p_0 v_0 - pv\right\} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

The expanding substance being assumed a perfect gas, we have $p_0 v_0 = cT_0$, and $pv = cT$ hence, in expansion of this type Eq. (8) may also be written :—

$$W = \frac{c}{n-1}\left\{T_0 - T\right\} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

Thus if n be greater than unity, expansion is accompanied by a falling temperature. If be equal to unity the temperature remains constant during expansion. While if n be less th unity expansion is accompanied by a rising temperature. Equation (9) shows further that expansion of this type the external work done is proportional to the change of temperature the expanding gas.

Again, the heat expended, H, is equal to the sum of the external work and change of inter energy of the gas ; thus we have :—

$$H = \frac{c}{n-1}(T_0 - T) + k_v(T - T_0)$$

$c = k_p - k_v$, this becomes on reduction :—

$$H = \frac{n\,k_v - k_p}{n-1}(T - T_o) \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

which shows that the heat expended is also proportional to the change of temperature of the expanding gas ; and that the gas expands with an apparent specific heat which is constant, and expressed by $\frac{nk_v - k_p}{n-1}$ B.Th.U. per lb.

(2) *Adiabatic Expansion.*—When a mass of gas changes its volume without any heat communication from without, the changes are said to be adiabatic.

Thus in adiabatic expansion the external work is done wholly at the expense of the internal energy of the expanding gas ; its temperature, and consequently its pressure, rapidly fall during expansion. And contrariwise, in adiabatic compression, the work done in compressing the gas appears as an increase of the internal energy of the gas ; hence, the temperature and consequently the pressure rapidly rise during adiabatic compression.

The adiabatic equation for a perfect gas is at once obtained from Eq. (10). For as, by supposition, there is in this case no heat communication with outside bodies, we have only to put $H = 0$ in Eq. (10), and then deduce the corresponding value of n. But if $H = 0$ we must have $nk_v - k_p = 0$, so that $n = \frac{k_p}{k_v} = \gamma$ in this case.

Hence, the adiabatic equation of a perfect gas is

$$pv^\gamma = p_o v_o^\gamma, \text{ a constant} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (11)$$

By aid of Eq. (1) the following two equations are at once obtained from Eq. (11), giving the relation between change of temperature and volume, and change of temperature and pressure respectively, in adiabatic changes :—

$$T = T_o \times \left(\frac{v_o}{v}\right)^{\gamma - 1} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (12)$$

$$T = T_o \times \left(\frac{p}{p_o}\right)^{1 - \frac{1}{\gamma}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (13)$$

For dry air, as $\gamma = 1{\cdot}4056$, we have accordingly from Eqs. (11) (12) and (13) :—

$$pv^{1{\cdot}4056} = \text{constant} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (14)$$

$$T = T_o \times \left(\frac{v_o}{v}\right)^{0{\cdot}4056} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (15)$$

$$T = T_o \times \left(\frac{p}{p_o}\right)^{0{\cdot}2886} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (16)$$

Thus, in Diesel engines, the ratio is commonly about 13. Assume the initial temperature of the air to be 70°F., and the pressure to be atmospheric. Then $T_o = 460 + 70 = 530$; and $p = 14{\cdot}7$ lbs. per sq. inch : hence from (15) we have : $T = 530 \times 13^{0{\cdot}4056} = 1500$°F. or $1500 - 460 = 1040$°F. by ordinary scale. This is a sufficiently high temperature to at once ignite the charge of fuel oil on injection. The corresponding pressure from Eq. (14) is 540·8 lbs. per sq. in. abs. = 526 lbs. per sq. in. above atmosphere.

Moisture in Air.

Ordinary air always contains water vapour in greater or less degree, and the presence of this vapour modifies its physical properties.

The pressure of saturated steam formed at temperatures below 212°F. is usually described as the 'vapour tension' of water. In table, page 1912, some data are given relating to the vapour tension of water from 32°F. to 212°F.

When air contains a maximum of water vapour it is said to be saturated. The quantity of oisture depends only upon the temperature, and is estimated by aid of :—

DALTON'S LAW.—The pressure, and consequently the mass of vapour which saturates a given olume, is the same at the same temperature, whether the volume already contains a gas or is acuous.

Consider a volume of V cubic feet of saturated air at a pressure of P lbs. per sq. in., and temerature t°F. By Dalton's Law this consists of (1) V cubic feet of water vapour at the pressure lbs. per sq. in. corresponding to t°F., as in column 1 of above table, together with (2) V ubic feet of dry air at pressure (P—P′) lbs. per sq. in., and temperature t°F.

Thus the weight, S, in lbs. of 1,000 cubic feet of saturated air at temperature t°F. and pressure lbs. per sq. in. is :—

$$S = \frac{1000}{u} + 80{\cdot}73 \times \frac{492}{460 + t} \times \frac{P - P'}{P} \quad . \quad . \quad . \quad . \quad . \quad (17)$$

e values of u being given in column 2 of table. If the pressure be atmospheric, P = 14·7, and this case :—

$$S = \frac{1000}{u} + 80{\cdot}73 \times \frac{492}{460 + t} \times \frac{14{\cdot}7 - P'}{14{\cdot}7} \quad . \quad . \quad . \quad . \quad . \quad (18)$$

By aid of Eq. (18), the table on p. 1912 has been compiled.

This table may be useful in connection with the heat expended in providing the moisture den air supplied to gas producers.

Efficiency.

The most important thermodynamic cycles are the constant volume (C_v) and constant ressure (C_p) cycles, and the general formulae for efficiency are as follows :—

$$\text{Constant volume efficiency} = 1 - \frac{T_1 - t}{T - t_c}.$$

$$\text{Constant pressure efficiency} = 1 - \frac{\frac{1}{\gamma}(T_1 - t_1) + (t_1 - t)}{T - t_c}$$

here,

t = initial temperature of air ;

t = temperature of compression ;

T = temperature after explosion ;

T_1 = " " adiabatic expansion ;

γ = ratio of specific heat $\frac{C_p}{C_v}$;

$t_1 = T_1 \frac{\text{atmospheric pressure}}{\text{pressure of explosion}}$.

SECTION XXXI

PART II

GAS ENGINES.

Types of Gas Engines.

Gas engines may be classified under the following types:

Type I.—Engines igniting their charge at constant volume, without compression. This pe is obsolete; it included the Lenoir and Hugon.

Type II.—Engines igniting at constant volume without compression, with free piston, id utilisation of vacuum during instroke. This type also is obsolete; it included the Barsanti, enham, and Otto and Langen.

Type III.—Engines igniting at constant pressure, with previous compression of the charge. his type includes the early Brayton and Simon engines, and the modern Diesel engine.

Type IV.—Engines igniting at constant volume, with previous compression. This type cludes the very great majority of gas engines in everyday use.

The vast majority of present-day gas engines are operated upon the Otto, Beau de Rochas four-stroke cycle, wherein the sequence of strokes is suction, compression, working, and exaust; and in most cases, particularly of British engines, the cylinders are single-acting; the rge double-acting engines have been perfected mainly by the great Continental firms.

A number, especially of engines of large size, are built upon the two-stroke cycle, both single nd double-acting, and much attention has been devoted to this type.

Crossley Gas Engines.

Messrs. Crossley Bros. Ltd., of Openshaw, produce annually a very large number of gas engines horizontal and vertical design, working on the four-stroke cycle. The range of power is from to 260 b.h.p., and over 80,000 engines have been supplied.

Horizontal engines of 30 b.h.p. and upwards can be made with two cylinders, the flywheel eing mounted on the crankshaft between the cylinders. These double-cylinder engines are pecially suitable for all purposes where very steady driving is required, as they run with great gularity. The vertical engines, which are of the four-cylinder high-speed design, are also ost suitable for driving dynamos.

The rated powers of the producer-gas engines are obtained when running on gas made from nthracite, bituminous coal, and wood fuel, but are reduced by 6 per cent. when running on gas ade from coke. Working on town gas, the increase in power varies from about 20 per cent. on he small sizes to about 1½ per cent. on the largest size, which develops 130 b.h.p. in one cylinder. he weight of the standard horizontal engine varies from about 2¼ to 3 cwts. per b.h.p., and the eight of the double-cylinder engines is about 2 cwts. per b.h.p.

The sizes from 6 b.h.p. and upwards are now all governed on the throttle, giving a smooth rive and low pressures at reduced engine loads. Fig. 2 shows a recent horizontal single-acting our-stroke design; the girder-type bed and balanced crankshaft will be noted. Other feaures included are the absence of any liner bolts in the water-jackets; adjustable timing to he electric ignition; double ring lubrication to the bearings with forced lubrication to the ylinders and other parts; screw-down producer-gas cock; hardened cams, rollers, and pins; nd a combustion chamber so designed that dust and oil cannot collect at the bottom and form roublesome deposits, but are swept out of the exhaust valve with the burnt gases.

CROSSLEY GAS ENGINE.

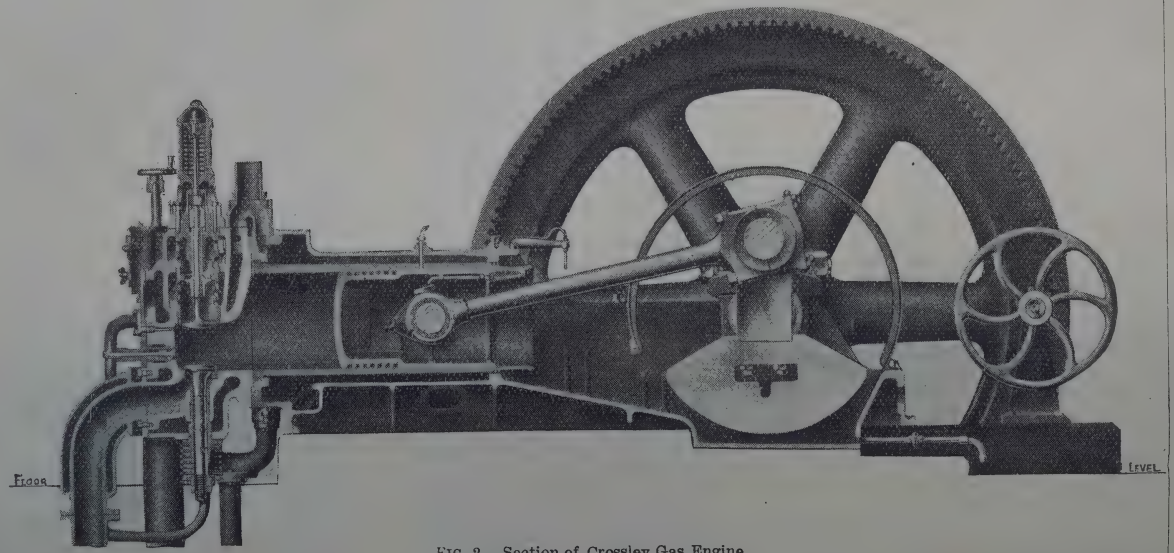

FIG. 2.—Section of Crossley Gas Engine.

Ruston-Hornsby Gas Engines.

The Ruston gas engines and the Hornsby-Stockport engines are now made by Messrs. Ruston Hornsby, Ltd., Lincoln, the engines being of the horizontal four-stroke cycle type, built in ngle and multi-cylinder sizes. The range of powers is from 17 to 340 b.h.p. Fig. 3 shows ne of these engines in conjunction with a Ruston gas-producer. The engines supplied to the l-fields are capable of working either on gas or on oil, so that the natural gas found when well-nking can be used, and, when the supply of this diminishes, the engine can be changed over to l fuel.

The bed-plate is in one piece, carrying the main bearings and cylinder liner, and the thrust of ne connecting rod is taken by the bed-plate, as the cylinder is not overhung. The crankshaft carried by three bearings, the outer bearing being provided to support the weight of the flywheel. egular running is ensured by having a balanced crank, and by using high compression which allows a weak charge being fired.

A special automatic device is used for starting the engine on compressed air, and this is also ade use of for charging the air-receiver, by means of the engine piston acting as an air-pump

Fig. 3.—Ruston Gas Engine with Suction Producer.

or the time being. Efficient lubrication is provided for all of the bearings, the piston, and the xhaust valves. Governing is effected by the Ruston patent throttle gear which varies the open-ig of the gas and air inlet-valves to suit the load. This gear consists of a roller forming a movable ulcrum between a lever having a constant angular movement and the upper surface of the inter-alve plunger, the lift of the valve varying directly as the distance of the roller from the lever ulcrum. The roller and the pressing surfaces are of hardened steel, and the movements are rranged so as to avoid slip.

Campbell Gas Engines.

The Campbell Gas Engine Co. Ltd., Halifax, are builders of horizontal and vertical gas ngines in the single-cylinder type from 15 to 160 b.h.p. and with two and four cylinders up to 40 b.h.p. The engines are of the four-stroke cycle type, and can be arranged for working on as or adapted for oil.

The single-cylinder horizontal design has the cylinder well supported by the bed-plate, which xtends beneath the cylinder as far back as the combustion chamber, and the cylinder liner is emovable. Horizontal engines are also made with two cylinders and four cylinders: these ngines have the bed-plate and crankshaft housing in one casting, to which the cylinders are bolted. The cylinders are also supported on a sole plate resting on the foundation, and the combustion hambers are detachable.

A throttle governor is fitted giving variable-quality governing, in which the piston receives a impulse at every cycle and the compression pressure is the same at all loads. The weights the horizontal as well as of the vertical engines are about 2½ to 3 cwts. per horse-power.

Cylinders and pistons are fitted with forced lubrication, crankshaft and camshaft bearing with ring lubrication, and the big-end and small-end connecting-rod bearings with sight-fee automatic lubricators.

The Campbell vertical gas engines are of the enclosed crank-chamber type, and are bui with two, three, or four cylinders from 75 to 585 b.h.p. Forced lubrication is fitted to t cylinders and all enclosed bearings. Ignition is by low-tension magneto with separate machi and operating gear to each cylinder. Governing is on the throttle, the governor being drive direct from the crankshaft by its own independent gearing. The vertical engines run at a high speed than the horizontals, and are well adapted for direct coupling to dynamos owing to the good balance and low coefficient of speed fluctuation. The rotation is so uniform that it claimed even alternators may be operated in parallel.

National Gas Engines.

Horizontal and vertical four-stroke cycle gas engines are made by the National Gas Engi Co., Ltd., of Ashton-under-Lyne, the power ranging from 2 to 2,500 b.h.p. Up to 10 b.h.p. t engines are of the horizontal overhung cylinder design; for greater powers a special design girder bed and supported cylinder is adopted.

The horizontal engines are built in various sizes up to 100 b.h.p. per cylinder. Ignition is l low-tension magneto, a sparking-plug being fitted in the combustion chamber. Governing the smaller sizes is on the hit-and-miss principle, but throttle governing can be supplied if desire and the larger sizes of engines are fitted with a patent variable admission governing gear.

The National Gas Engine Co.'s vertical engines are of the (*a*) single cylinder per crank desig and (*b*) of the tandem single-acting design. The single cylinder per crank engines are made three sizes, viz. 14 ins., 18 ins., and 24 ins. stroke, and the powers vary from 90 to 900 b.h.p. Th tandem engines are built with 18-in. stroke and 24-in. stroke, and the powers range from 300 2,500 b.h.p. The engines are suitable for working on town, producer, blast-furnace, and coke-ov gases, and the cyclic variation is such that there is no difficulty in running electric alternators parallel.

A recent test of an engine of this type furnished the following results:

Engine.—A 750 b.h.p. National Vertical Tandem Single-Acting engine having three cran and six cylinders, the three upper cylinders being each of 23 ins. bore, and the three lower ea of 22 ins. bore. Piston sleeve 6 ins. diameter, stroke 24 ins.

Details.	At Over-load.	At Full Load.	At ¾ Load.	At ½ Load.	At ¼ Load.	At No loa
Duration of trial; minutes	60	60	45	30	15	18

Brake thermal efficiency, per cent.	24·64	25·72	25·32	20·0	13·7	—

The engine was driven by Mond gas. At full load 6·55 gallons of cooling water were rais 42° F. in temperature per b.h.p. hour, being 27·8 per cent. of the heat evolved by the gas us

The pistons are unwatered. Forced lubrication is supplied to all parts, the oil pressure bei about 20 lbs.

Vickers Gas Engines.

Large gas engines of the horizontal four-stroke cycle type are constructed by Vickers Lt Barrow-in-Furness. The engines are double acting, and range from 800 b.h.p. in single 1 tandem cylinders to 5,000 b.h.p. in twin tandem engines.

A number of these engines have been supplied for driving dynamos, alternators, etc. Eight of ese engines for the Appleby Iron Co., of Appleby and Frodingham, have cylinders 800 mm. dia. 1,200 mm. stroke, and develop 1,200 kw. when running at 100 r.p.m.

Separate cylinder liners are fitted. The inlet valves are located on top, and the exhaust valve the bottom of the cylinder; they are operated by shaped rolling levers driven by eccentric the half-speed shaft. The crankshaft is forged in one piece and balance weights are fitted. ie main bearings are in four parts, lined with white metal, and have self-aligning wedge ljustment. The main bearings of the 1,500 b.h.p. engine are 21 ins. diam. and the piston rod ·75 ins. diam.; the latter is hollow to convey the cooling water to the pistons.

Governing is on the 'quantity and quality' system, and it is possible to run direct-driven ternators in parallel. Hand adjustment is provided for regulating the speed while running. parate hand control for gas and air for each end of both cylinders is provided.

Ignition is effected by means of two low-tension 'make-and-break' ignition plugs in each end each cylinder. A motor generator delivers current at 70 volts, which is distributed by a rotary per, fitted at the rear end of the side shaft.

The 1,500 b.h.p. blowing engine runs at 80 r.p.m. and delivers 27,000 cub. ft. of free air per inute against 12·5 lbs. per sq. in. The total weight of this engine is approximately 305 tons.

Hindley Gas Engines.

Messrs. E. S. Hindley & Sons manufacture vertical single-acting four-stroke cycle gas engines sizes from 40 to 700 b.h.p. of the fast revolution type designed for direct coupling to high-eed machinery as dynamos, centrifugal pumps, fans, etc.

The engines are light and compact; special care has been given to the balancing, and the eight of pistons and connecting-rods has been reduced as much as possible to enable the engines run freely and quietly at high speeds; being multi-cylindered, and having adequate flywheel ertia, the cyclic variation is small.

Governing is effected by varying the quality of the mixture of gas and air; ignition is by gh-tension magneto, with variable timing; frequently high-tension coil ignition is also fitted a stand-by.

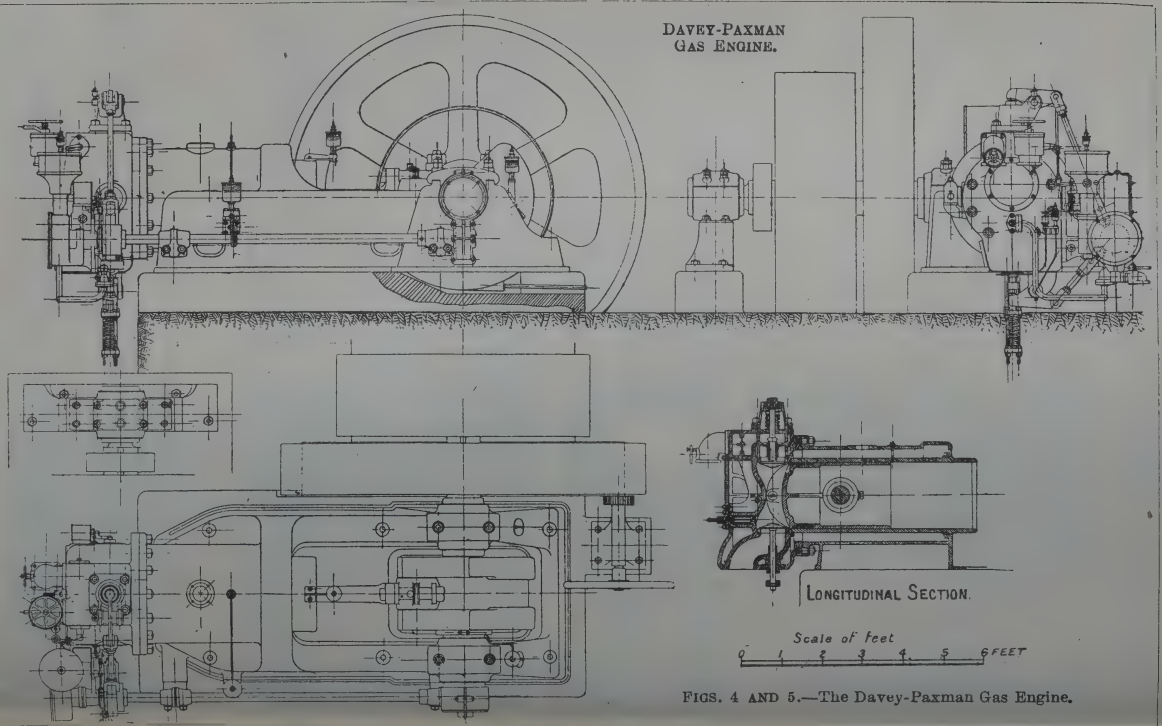
The cylinders are cast in one with the valve-boxes, the construction of the water-jacket being ie subject of a patent. The outer water-jacket, the cylinder, and the valve-box form one casting, that there is no joint to cause trouble. At the same time the special corrugated form of ater-jacket permits of unequal expansion between the cylinder walls and the jacket. All joints the cylinder which are subject to the pressure of the power-stroke are ground-in metal-to-etal joints, no packing being used either in the case of the top cylinder cover, valve cover, or nition plugs. The connecting-rods are of forged steel, and are so arranged that, together ith the pistons, they can be withdrawn through the top cover, which can be easily removed ithout disconnecting any gear. The crankshaft is of special quality steel, machined from a lid forging, and is not bent or subjected to strain in manufacture. The governor controls the lmission of gas, so that compression is practically constant at all loads.

The camshaft runs in three or more bearings, and is driven from the crankshaft by means gearing, the whole being enclosed in the crankcase. The crankcase is of box section, rongly webbed, and carrying the crankshaft bearings; it is provided with large inspection ors, which give easy access to all the working parts. The lubrication is forced under pressure all bearings by a valveless oil pump; this system of lubrication ensures economy in oil consump-on, which is in some cases as low as ·0002 of a gallon per b.h.p. per hour.

Davey Paxman & Co.'s Gas Engines.

The Paxman gas engine of the horizontal type, in sizes from 23 to 270 b.h.p., operates on the ur-stroke cycle. For large powers two engines are coupled with a single crankshaft, having ie flywheel between the cylinders. The engine is illustrated in figs. 4 and 5. Producers, suitable r anthracite and coke, are also made by Davey, Paxman & Co., Colchester.

Special features of the engines are the shape of the combustion chamber, which gives an excel-nt combustion of the fuel together with freedom from fracture, and the patented timing arrange-ient for the spark to facilitate starting, the general design following accepted practice and aving supported cylinder with removable liner.



FIGS. 4 AND 5.—The Davey-Paxman Gas Engine.

Gas engines of the vertical design are also made in various sizes from 25 b.h.p. to 900 b.h.p. in single and multi-cylinder types, and are most suitable for driving factories, electric generators, etc. They occupy little floor space and have a small cyclic variation.

A large number of Davey, Paxman & Co.'s gas engines are in operation, working on a variety of fuels. The utmost attention has been given to securing reliability, and their design of combustion chamber makes the engines very economical.

Fielding & Platt's Gas Engines.

Gas engines of the horizontal four-stroke cycle type are manufactured by Fielding & Platt Ltd., Gloucester, in various sizes from 6 to 150 b.h.p. For larger powers, two engines are coupled together, having a flywheel between the cylinders mounted on the two-throw crankshaft, these engines being made in sizes up to 300 b.h.p. Four-cylinder engines are also made.

The cylinder has a separate liner supported throughout its whole length in the water-jacketed extension of the bed. The variable-admission governor controls the opening of the gas-and-air-mixing valve, thereby varying the volume of charge admitted to the cylinder. The stroke of the mixing-valve is directly under the control of the governor, and, although the volume of charge is varied, the ratio of gas and air in the mixture remains practically constant. By this means an explosion takes place every cycle, and it is claimed that, when working with a suction plant, this steady method of drawing the gas ensures a better quality of gas, and avoids the possibility of trouble through insufficient gas under variable loads.

The cylinder jacket and combustion chamber have separate water circulation, and specia care has been taken to reduce the number of parts. Ignition is by means of a low-tension magneto, and the ignition plug can be readily removed from the cylinder for examination. The engines are suitable for running on gas produced from a large variety of fuels, and the 'Fielding' suction gas plants have several important features, enabling the plant to be quickly started up and to respond instantly to all varying loads.

The Fielding gas engine installations are extremely simple to operate, and the makers state that any man of ordinary intelligence can be entrusted to work it, as they have made a special study of simplicity.

Premier Gas Engines.

The Premier Gas Engine Co., Ltd. (*Crossley Brothers, Ltd.*), of Sandiacre, specialise in multi-cylinder gas engines of the horizontal type, ranging in powers from 100 to 1,000 b.h.p. Large numbers of these engines have been installed for all classes of work, including the driving of alternating current generators in parallel. The speeds of the engines are suitable for coupling to electric generators, and the engines have but a small cyclic irregularity.

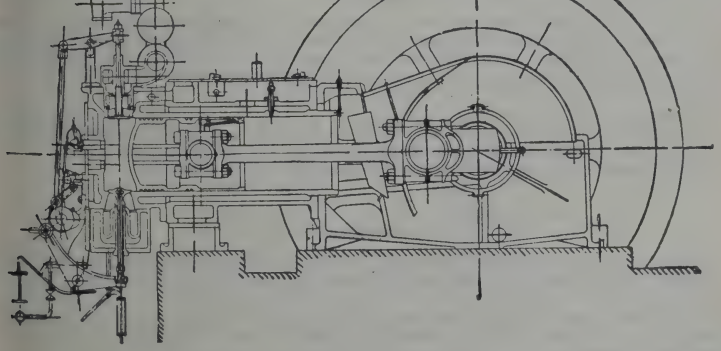


Fig. 6.—Premier Gas Engine.

From the sectional view, fig. 6, the arrangement of the cylinder, combustion chamber, valves, and cam operating gear can be seen. It will be noticed that the breech end and cylinder form one casting, and the usual joint in the combustion space is avoided. This removes any risk of water leaking into the cylinder.

These engines work on the four-stroke cycle and are made in two, three, and four cylinders, bolted to massive beds which support the crankshafts. The cranks are completely covered by oil splash guards, and the main bearings are supplied with oil by a pump, which is of the valveless oscillating type, operated by the side shaft. The cylinders, piston pin, crank pin, and exhaust valve spindles are also lubricated under pressure automatically.

The valves open directly into the cylinders, the inlet valve being directly over the exhaust valve, a design introduced by the Premier Co. as far back as 1893. A large throttle valve is fitted to control the air supplied to all the cylinders, and can be readily adjusted by hand; in addition, separate throttle valves are fitted on each cylinder. All the valves are operated by a shaft running in self-oiling bearings behind the cylinder, so arranged that the jacket inspection cover can be removed without disturbing it.

Governing is effected by controlling a throttle valve in the gas supply, and the governor is of the high-speed type, powerful and sensitive, driven direct from the crankshaft.

Starting is automatic by means of compressed air, which makes the engines easy to start.

Except in cases where engines are driving alternators in parallel, an isolating valve is fitted in the gas manifold by which the gas supply to one or more cylinders may be shut off when working on light loads with a consequent saving in fuel consumption.

These engines have the advantages of even turning moment, good balancing, forced lubrication, and they occupy little floor space for their power. Very high economy, both in fuel and lubricating oil, is claimed.

As will be seen from the illustration, the Premier gas engine is very accessible, both for cleaning and overhauling, as all of the working parts can be inspected and reached from floor level. This allows of good supervision, and as the piston and connecting-rod can be removed from the crankshaft end of cylinder, this operation can be carried out without disturbing any part of the valve gear or cylinder covers.

The Premier Gas Engine Co., Ltd., also manufacture a special type of cross-head vertical gas-engine, which differs from the usual type in many ways and possesses special features. It is made with 2, 3, or 4 cylinders for moderate powers at moderate speeds. The lower ends of the cylinders are shut off from the crank case by light covers, through which piston rods pass. Cross-heads and guides are therefore used, and the design corresponds in many respects to that of a steam-engine.

The Premier Company were the first to introduce this cross-head type of gas engine, and it is now generally adopted by Diesel engine makers in this country and on the Continent of Europe.

For powers of 1,000 b.h.p. to 5,000 b.h.p., the Premier Company manufacture a special type of double-acting vertical engine. This engine is of the four-stroke type, and therefore with four cylinders there are four impulses per revolution. As there is a compression on every stroke smooth running is obtained as a result of this and also because of the forced lubrication system which supplies oil at a pressure to all motion joints.

The design is suitable for powers of 1,000–2,250 b.h.p. continuous load with four cylinders and one crank, and for twice these loads, 2,000–4,500, with two-crank and eight-cylinder design, the speeds being from 125 r.p.m. for the smallest to 94 r.p.m. for the largest. A single crank for every four cylinders is one of the greatest innovations of the engine, and the small space required for this type of engine is a valuable characteristic.

It is specially adapted for the generation of electricity at steelworks and blast furnaces, especially where gases are available as a bye-product, and not produced artificially, and the rough usage of a steelworks is more readily resisted by this moderate speed engine. Fig. 7, p. 1923, shows, in plan and sectional elevation, the D.A.V. type of engine.

Tangye Gas Engines.

Horizontal gas engines of the four-stroke cycle type are made by Tangyes, Ltd., Birmingham, in sizes from 3½ to 490 b.h.p. Two designs, AA and T, are supplied, and a large number of engines have been sold.

The smaller sizes of engines have horizontal cylinders bolted to the beds, and the liners are removable. Governing is on the hit-and-miss principle; the AA design have highly sensitive inertia governors.

Engines of the HT type have the cylinders well supported by the bed, which extends up to the combustion chamber and forms the water-jacket. The cylinder liners are separate and are made of a special hard mixture of cast iron. Governing is on the variable-admission system with Tangye's patent operating gear, which controls the quantity of the charge admitted to the cylinder and an impulse is obtained every cycle.

THE PREMIER GAS ENGINE.
(D.A.V. type.)

Plan and Sectional Elevation.

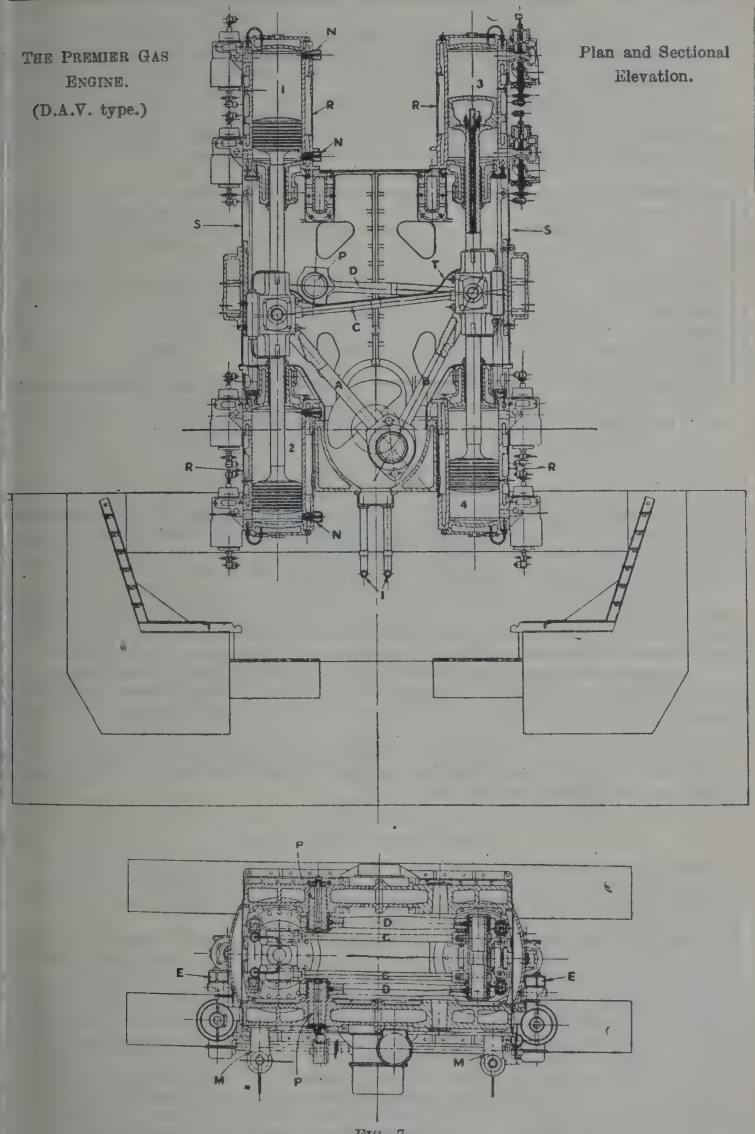

FIG. 7.

Ignition is by means of low-tension magneto, the spark being produced in the combustion chamber by means of a mechanically operated make-and-break arrangement, with variable timing device. On the larger sizes the sparking-plug is arranged so that the internal sparking points can be cleaned while the engine is at work. The engines are designed so that they can make long continuous runs; they are very simple to operate and are easily started, compressed-air apparatus being supplied with the larger sizes.

Tangyes were among the first firms to call attention to the fuel economy to be obtained from the use of gas engines with suitable suction gas producers, especially as engines would work on such inferior fuels as wood refuse, etc. The economy may be gathered from the following table which gives the approximate cost of fuel in a plant developing continuously 50 b.h.p. for sixty hours:

Nature of Fuel.	Rate of Fuel Cost.	Consumption per b.h.p. per hour.	Cost of 50 b.h.p. for 60 hours per week.
'Town' gas	2/- per 1,000 cubic ft.	15 cubic ft.	£4 10 0
Anthracite	40/- per ton	·75 lb.	2 0 0
Gas coke	30/- "	1 lb.	2 0 0
Charcoal	40/- "	1¼ lbs.	3 7 0
Bituminous non-caking coal	24/- "	1¼ lbs.	2 0 0
Wood refuse	Nil	2½ lbs.	Nil

The figures given above are an average, but the cost of running will depend, of course, upon the size of the engine and the relative prices and qualities of the different fuels.

Gardner Gas Engines.

The Gardner engines are made of both vertical and horizontal design and operate on the four-stroke cycle. The range of sizes is from 1½ to 180 b.h.p. Horizontal engines up to 14 b.h.p. can be supplied to work on either town gas, paraffin, or spirit.

The engines are of very neat design and substantially constructed. They give particularly smooth running, and a large number have been supplied.

The small sizes have been specially designed for gaseous and liquid fuels and are substantially constructed in order to make them suitable for heavy commercial duties and long continuous runs, such as for electric-lighting, etc. The workmanship and design of even the smallest size are exceptionally high class, as the engines are intended for production in large quantities.

The larger horizontal engines are fitted with single fly-wheel and outer pedestal bearings. The special features are the sensitive centrifugal throttle governor, giving low-speed variation, and the silent-running that is obtained. They are easy to start, economical to work, and have a high efficiency.

In addition, a range of Gardner engines made in twelve sizes, from 10 to 180 b.h.p., have been designed for marine and stationary work. They are supplied for running on town and producer gas, paraffin, spirit, and heavy oils, and are most suitable for marine work, driving electric generators, and for industrial purposes.

Peter Brotherhood Gas Engines.

Horizontal engines of the single-cylinder, four-stroke cycle type, developing 10 to 150 b.h.p., are manufactured by Messrs. Peter Brotherhood, Ltd., Peterborough. The engines are made with two cylinders in sizes from 172 to 300 b.h.p. Producer gas plants capable of working on a wide range of fuels are also made by this firm.

The engines are very simple and neat in appearance, being well proportioned. They are easily operated, and there are no parts liable to get out of order. Several patented features are embodied in the design, which make for efficiency and reliability.

The governor is on the variable-admission principle; the charge of gas and air admitted to the cylinder is varied in quantity to suit the load, but there are no cut-outs and the engine receives an impulse every cycle. Special attention has been given to all the working parts of the valve gear, etc., the cams are of hardened steel and the valves are made from nickel steel, alloy steel being used for the exhaust valve lever.

The bed of the engine is formed with the cylinder jacket and supports the cylinder liner throughout its length. The combustion chamber has specially large water-jacket spaces, which are quite accessible for cleaning, it only being necessary to remove a cover.

Ignition is by means of a low-tension magneto, having powerful double magnets; special timing gear is fitted so that the engine can be easily started. The ignition plug is arranged to

prevent any possibility of the striking spindle bearings becoming coated with rust or deposit, and patented terminals are used on the plug and magneto.

Positive lubrication has been provided, so that when running the engine requires very little attention. A low-pressure self-starter can be fitted for engines of moderate powers, but, for engines of 100 h.p. and over, air starting is recommended, as with this it is claimed that even the largest engines start up as easily as a steam engine.

A number of improved features have been embodied in the producer, making it very simple to operate and capable of working with all grades of anthracite, coke, charcoal, and other inferior fuels.

Lilleshall Gas Engines.

Gas engines ranging in power from 500 to 4,000 b.h.p. are manufactured by the Lilleshall Co. Ltd., of Oakengates, Shropshire. The engines are of the tandem, horizontal, double-acting, four-stroke cycle type, and a working impulse on every stroke is obtained. A section is shown in fig. 8 of the 2,500 b.h.p. engine, from which the general disposition of parts can be clearly seen.

The Lilleshall Co. have recently introduced a number of important improvements, making for additional strength and reliability. The pistons and rods are, of course, water-cooled, the water supply being of a pressure of from 45 to 65 lbs. per square inch on account of the reciprocating motion of these parts; this is supplied by a pump worked from the crankshaft. For the jackets of the cylinders and covers the water is supplied at a pressure of about 15 lbs. per square inch. Each cylinder is provided with an open tank into which all exit water-pipes deliver, the discharge from each being thus always in view; each exit-pipe is fitted with a thermometer and regulating valve by which the temperature of the cooling water can be maintained at the desired degree.

These engines are installed to a very large extent in iron and steel works and collieries, as well as in electrical power stations.

An output up to 1,500 b.h.p. can be developed in one cylinder, the consumption of heat per b.h.p. hour amounting—at normal output—to about 9,900 B.Th.U.

The engines are very strongly constructed, and simple in general arrangement as well as in each individual part. The surface pressures on the moving parts are small, and their lubrication is effected automatically. The frame, cylinder, connecting piece, and rear slide are centrically connected with one another, so that the engine axis is accurately fixed.

The cast-iron cylinders are symmetrically formed, in order to avoid undue strains caused by the heat, and are amply cooled. The cooling-water jackets are easily accessible for purposes of cleaning. In addition to the cylinders, the exhaust-valve seats, the hollow piston rod, and the pistons, are cooled.

The cooling-water consumption amounts per b.h.p. hour to 7·7 gallons at an inlet temperature of 60° F.

The weight of the pistons and piston rod is not carried in the stuffing boxes, but by special crossheads, in the frame, the connecting piece, and the rear slide.

The inlet valve gear consists of a positive action which opens the air valve and gas inlet valve. By means of the governor the valve lift, and consequently the quantity of mixture, is changed according to the engine output. The ignition is effected electrically by a small accumulator battery. The time of ignition can be easily regulated during operation.

By means of compressed air the engines are very easily started.

Alternate-current dynamos driven by these gas engines can be connected in parallel without any trouble.

From tests of a tandem double-acting horizontal four-stroke engine of this type, developing 1,200 b.h.p. on blast-furnace gas, and having cylinders of 33·46 ins. bore with 43·3 ins. stroke, the following results were obtained :—

Test Results from a 1,200 h.p. Engine using Blast-Furnace Gas.

Item.	Quarter Load.	Half Load.	Three-Quarter Load.	Seven-Eighths Load.	Full Load.

Lilleshall Gas Engine.

Fig. 8.—Longitudinal Section of Lilleshall Gas Engine.

Galloway Gas Engines.

Messrs. Galloways, Ltd., Manchester, took up in 1909 the manufacture of the large gas engines of the Ehrhardt and Sehmer type and have since introduced many improvements. The range of powers is given in the following table :—

Electric Generating Engine.

Cylinder Diameter.		Stroke.		R.P.M.	Normal continuous B.H.P.	Max. continuous B.H.P.	Max. Momentary B.H.P.	Blowing Engines.	
Mm.	Ins.	Mm.	Ins.					Max. R.P.M.	Normal B.H.P. at Max. R.P.M.
950	37·4	1,100	43·3	107	1,200	1,300	1,440	95	1,060
1,050	41·4	1,200	47·3	94	1,400	1,540	1,680	85	1,270
1,150	45·3	1,300	51·2	94	1,850	2,000	2,200	85	1,650
1,250	49·2	1,400	55·1	94	2,320	2,550	2,780	80	1,970

The standard Galloway engine is tandem double-acting four-stroke cycle with horizontal cylinders. For sizes over 3,000 h.p. a twin tandem engine is adopted, i.e. two lines of cylinders working on two cranks on a common crankshaft. The engines are designed to run on blast-furnace gas, coke-oven gas, and producer gas.

The special features of the engine are : (*a*) Patented built-up cylinder. The barrel is in two main parts, and the water-jacket is formed by a steel plate casing. Both casting and expansion stresses are eliminated. (*b*) Patent piston with internal diagonal ribs to prevent bending stresses. (*c*) Patented method of fixing piston on rod, allowing of longitudinal adjustment. (*d*) Improved piston rod packing. (*e*) Patented water-cooled exhaust valve box and seat, the exhaust valve itself not being water-cooled. (*f*) Simplified valve gear. (*g*) Powerful servo-motor governor.

The piston and rod are water-cooled and all water discharges are open for inspection purposes. The engine is of simple and strong construction, arranged for ease of accurate alignment, and free to expand when working without distortion or stress. All water-jackets and internal parts are easily accessible for inspection and cleaning.

Experience with a recent installation of these engines showed that the period between overhauls could be safely extended to two years, and even after that lengthy period of running the cylinders and piston rings were found to be in excellent condition, and all the main working parts free from appreciable wear.

Browett-Lindley Gas Engines.

Messrs. Browett-Lindley & Co. Ltd., Patricroft, have developed a vertical gas engine of the ordinary four-stroke cycle type for direct coupling to electric generators and other purposes.

The engines are made with two, three, four, and six cylinders ranging in power from 60 to 1,200 b.h.p. A number of these engines have been supplied for such industrial work as driving mills, etc., and are very satisfactory in operation.

The sectional view of a four-cylinder engine given in fig. 9 shows the accessibility of these vertical engines. The design allows the piston to be easily removed and the cylinder covers are quite free from valves or other gear. The valve gear is quite simple, hardened steel cams are used to operate the valves and the cam roller guides are of the piston type. Both the inlet and exhaust valves can be readily removed for inspection when desired, and the latter are provided with renewable seats.

The governor fitted to these engines is very powerful and the working parts are lubricated by oil under pressure, so that reliable operation can always be expected. Forced lubrication is provided for all of the principal bearings on the engine, the oil being supplied under pressure from a valveless pump.

Features of the Browett-Lindley engines are the simple design, the absolute freedom from back firing, and the equal distribution of power to each cylinder at all loads. A large number of installations are at work on town and producer gas, and very economical running is obtained.

The lowest heat consumption recorded with these engines is 9,540 B.Th.U. per b.h.p., and the highest 10,260. The mechanical efficiency of the engines is about 85 per cent. A cyclical regularity suitable for driving alternators in parallel can be obtained without the need of excessively heavy flywheels. The weights of the standard engines vary from about 2 to 2½ cwt. per horse-power.

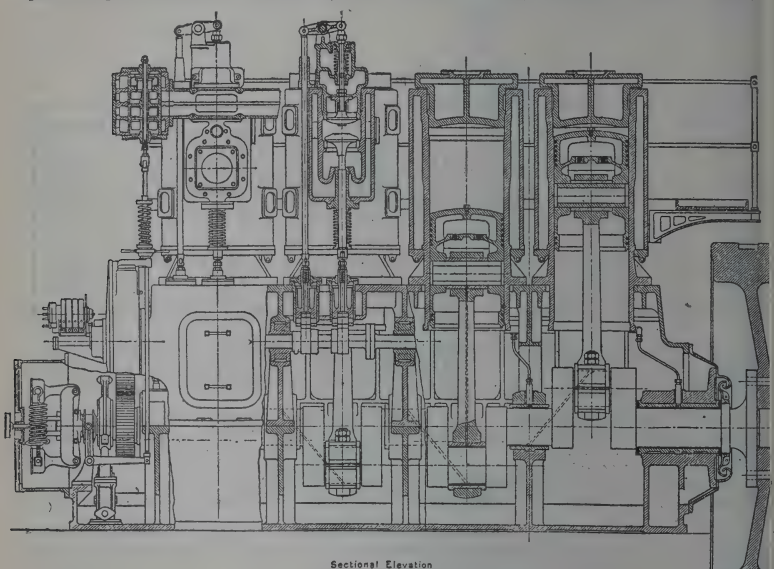

FIG. 9.—Browett-Lindley Gas Engine—Elevation.

FULLAGAR GAS ENGINES.

An important development of the opposed piston type of engine appears in the recent two stroke design of the late Mr. H. F. Fullagar (fig. 10), and a few of these gas engines are now at work.

Each 'unit' comprises *two* open-ended cylinders placed side by side; each cylinder contains two pistons as in the Oechelhauser design, but in the Fullagar design opposite pistons of each cylinder are connected by diagonal rods as indicated, thus dispensing altogether with return connecting rods, while a *two*-throw crankshaft suffices for the four pistons of the unit.

The obliquity of the tie-rods is small, and the side thrusts due to this obliquity are taken by the crossheads and guides shown above A and C; it will be seen that pistons A and D are connected, as also are B and C, by long diagonal rods. An explosion between A and B drives B downwards, thus actuating the left-hand crank, and simultaneously drives A upwards, thus actuating the right-hand crank through the tie-rod connecting A and D; the crankshaft accordingly receives as the result of each explosion a practically pure turning couple, or 'torque.' It will also be observed that as the cylinders are open-ended there are no vertical stresses set up in the framing of the engine when running; hence the Fullagar engine may be expected to be light in relation to its power output.

The engine works on the two-stroke cycle, and thus each cylinder furnishes one working impulse per revolution. As a unit includes two cylinders, each *unit* furnishes *two* working impulses per revolution. Stationary engines for land installation usually comprise two or three units, furnishing four or six working impulses per revolution. In the case of great power, or where height is limited and the speed must be high, as e.g. in submarines, engines would consist of even four units. The usual inlet and exhaust ports are indicated in fig. 10; the charge is supplied at a pressure of between 2 and 3 lbs. per sq. in. by gas and air pumps, which may be driven by the engine.

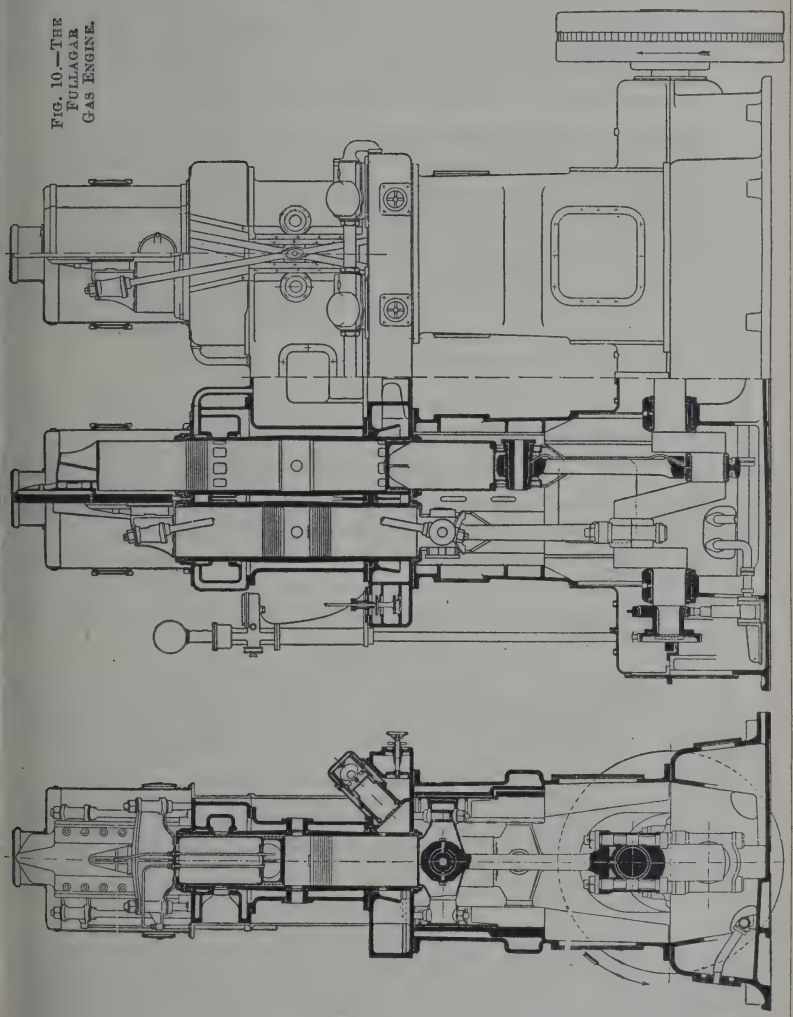

FIG. 10.—THE FULLAGAR GAS ENGINE.

The upper guides are modified to act as scavenge air pumps, the upper crosshead being fitted to operate as pistons, unless separately driven blowers or pumps are required.

The Fullagar engine may be arranged to run in either direction; it is only necessary to alter the timing of the fuel admission valve and the ignition.

An experimental gas engine of 550 b.h.p., constructed by Messrs. W. H. Allen, of Bedford, to the designs of the Fullagar Engine Ltd., has been installed at the Newcastle Electricity Supply Company's station at Gateshead-on-Tyne; this engine consists of *two* units, the cylinders being of 12 ins. bore, while each piston has a stroke of 18 ins. The normal speed is 250 revolutions per minute, corresponding to a piston speed of $\frac{250 \times 18}{6} = 750$ ft. per minute.

Sectional views of this engine are given in fig. 10.

If p denote the mean effective pressure in lbs. per sq. in. within a cylinder during the working stroke, then the work done upon *each* piston in foot-lbs. is $p \times \frac{\pi}{4} d^2 \times \frac{s}{12}$. Where d and s are respectively the bore and piston stroke, in inches.

As each cylinder contains two pistons, the work done by each cylinder per working stroke is $2 \times p \times \frac{\pi}{4} d^2 \times \frac{s}{12}$ foot-lbs., and this is the work done per cylinder per revolution of the crankshaft. Now a unit comprises two cylinders, and hence the work done by a unit per crankshaft revolution is $2 \times 2 \times p \times \frac{\pi}{4} d^2 \times \frac{s}{12}$ foot-lbs., that is $\frac{\pi}{12} . pd^2s$ foot-lbs. Accordingly if the crankshaft makes n revs. per minute, the indicated horse power is given by :—

$$\text{I.H.P.} = \frac{1}{33{,}000} . \frac{\pi}{12} . pd^2sn \text{ per unit} \quad . \quad . \quad . \quad (19).$$

As the Gateshead engine includes two units, its i.h.p. will be twice this, or:—

$$\text{I.H.P.} = \frac{\pi}{33{,}000 \times 6} . p.d^2sn \quad . \quad . \quad . \quad . \quad . \quad . \quad (20).$$

Though the mechanical and thermal efficiency of this type of engine is high, the ratio $\frac{\text{B.H.P.}}{\text{I.H.P.}}$ on the experimental engine was only about 0·8, as for experimental purposes the air blower and gas pumps were of a somewhat temporary character; hence 550 b.h.p. corresponds to $\frac{550}{0{\cdot}8} = 690$ i.h.p. roundly.

Putting 690 for i.h.p., 250 for n, 12 for d, and 18 for s, in Eq. 20 we get as the value of the mean effective pressure :—

$$p = 67 \text{ lbs. per sq. in.}$$

A 30-hour test by Prof. Hopkinson showed that this engine has an overall thermal efficiency from heat supplied to b.h.p., of 30 per cent., while the indicated thermal efficiency attains the value 37·6 per cent., the difference being due to the somewhat inefficient pumps.

The weight of the engine, including flywheel, is roundly 21½ tons; this corresponds to only about 87½ lbs. per b.h.p., which is much lighter than other stationary gas engines of the same power.

A 2,000 h.p. engine, constructed by Mssrs. Belliss & Morcom, Ltd., of Birmingham, to the designs of the Fullagar Engine Ltd., of Gateshead, was started during 1918 in a Waste Heat Station on the North-East Coast, using coke-oven gas of a calorific value of about 440 B.Th.U. per cubic foot (net value). This engine has six cylinders, i.e. three Fullagar engine units with 12 pistons. The cylinders are 18-inch bore and 27-inch stroke, the speed being 171·4 r.p.m. The engine is of the totally enclosed forced lubrication type, the overall dimensions over engine and alternator being :—

Length, 38 ft. 7½ ins. Breadth, 15 ft. 3½ ins. Height, 21 ft.

The approximate weight of the engine, including all auxiliaries but without alternator, is 110 tons. The piston heads are oil-cooled and scavenge air is supplied by a separate electrically driven blower, the gas-charging pumps being coupled directly to the crankshaft of the engine. The preliminary full load trials have shown a gas consumption of under 30 cubic feet per kilowatt hour, with an electrical output of 1,250 k.w. net at the generator terminals (i.e. after deducting the amount of power required by all auxiliaries). The direct-coupled alternator supplies electricity to the Newcastle Electricity Supply Company's system.

The Fullagar system is being developed for use with liquid fuel by Messrs. Cammell, Laird & Co. Ltd., of Birkenhead, John Brown & Co. Ltd., David Rowan & Co. Ltd., Palmer's Shipbuilding and Iron Co. Ltd., and The English Electric Company. (*Merz & McLellan.*)

(See also p. 2427.)

Prices and Weights of Gas Engines.

The prices and weights of gas engines vary considerably, depending on the type and design, but may be taken as from about 7*l.* to over 10*l.* per horse-power at the makers' works. The weight is largely affected by the type and design, engines being single or multi-cylindered, slow speed or high speed, horizontal or vertical, the different designs being necessary to suit the various requirements.

Thermal Efficiency of Gas Engines.

The brake thermal efficiency of four-stroke gas engines has risen from 14 per cent. in 1882 to 32 per cent. in 1908; the following table from Sir Dugald Clerk ('The Gas, Petrol, and Oil Engine,' p. 243) illustrates the rise in efficiency :—

INDICATED AND BRAKE THERMAL EFFICIENCIES OF FOUR-STROKE GAS ENGINES FROM 1882 TO 1908.

(*Sir Dugald Clerk, F.R.S.*)

Year.	Experimenter.	Engine.	Bore & Stroke, inches.	Efficiencies per Cent.		
				Mech.	Indic. Thermal.	Brake Thermal.
1882	Slaby	Deutz	6·75 × 13·7	87·6	16	14
1884	Thurston	Crossley	8·5 × 14	84·2	17	14·3
1888	Soc. Arts	Crossley	9·5 × 18	86·1	22	18·9
1888	Soc. Arts	Griffin (6 cycle)	9·02 × 14	80·9	21	17
1888	Kennedy	Beck (6 cycle)	7·5 × 15	87·3	21	18·3
1892	Capper	Crossley	8·5 × 18	82·0	22·8	17·4
1898	Robinson	National	10 × 18	87·0	28·7	25
1900	Humphrey	Crossley	26 × 36	83·0	31	25·7
1900	Witz	Cockerill	51·2 × 55·1	81·7	28	22·9
1905	Inst. C. E.	National	14 × 22	85·5	35	29·9
1907	Burstall	Premier	16 × 24	77·1	41·5	32
1908	Hopkinson	Crossley	11·5 × 21	87·5	36·8	32·2

In tests made on a Crossley-Otto engine in 1882, 1 i.h.p. hour was obtained with an expenditure of 23·7 cubic feet of London gas, while at the Society of Arts trials, held in 1888, a Crossley engine consumed 20·55 cubic feet per i.h.p. hour. Sir Dugald Clerk found, in 1894, when testing a Crossley engine, that the consumption of gas (Openshaw) per i.h.p. hour was as low as 14·5 cubic feet.

At the present time it may be taken that the consumption of town gas per b.h.p. hour at full load varies from 15 cubic feet to 25 cubic feet per hour, according to the size of the engine, and also according to the heating value of the gas.

The increased efficiency that has been obtained in the best known forms of engines is probably due to greater compression of the gas, and to some lesser extent to improved means of displacing the burned gases from the cylinders.

Large stationary gas engines are commonly of the horizontal tandem double-acting four-stroke type, as with this arrangement a working impulse is obtained at every stroke. Pistons and piston-rods are of course always water-cooled in such engines.

Piston speed in large gas engines has reached 800 to 900 feet per minute. Mean pressures of 85 to 95 lbs. per sq. in. can be obtained in the cylinder with gas of 110 B.Th.U., though engines are usually rated on an assumed 70 lbs. only.

Generation of Electricity by Gas and Oil Engines.

The Electricity Commissioners have published reports * on the output and fuel consumption of electric power stations in Great Britain. The stations are classified in thirteen groups, of which six groups have producer gas engines and six groups oil engines, according to output.

* *Generation of Electricity in Great Britain, year ending March* 31, 1926. Electricity Commission. H.M. Stationery Office, Adastral House, Kingsway, London, W.C. 2. Price 1*s.* 6*d.* net.

For four of these groups, representing the largest, the smallest, and two intermediate sizes o station, the following figures are abstracted from the report for the year ending on March 31 1926 :

GAS-PRODUCER STATIONS.

Output of Station Units in Year.	Between 1,000,000 and 2,500,000.	Between 250,000 and 500,000.	Between 100,000 and 250,000.	Under 50,000.
Number of stations in group	3	11	19	4
Total units generated by gas-producer plant	5,563,222	3,828,839	3,130,916	114,744
Total fuel consumed (actual) tons	6,101	3,850	3,679	226
Average fuel consumption per unit generated (converted to basis of coal) lbs.	3·01	2·25	2·64	4·41
	Total units generated.		Total fuel consumed.	
Total output of all gas-producer stations (57) for year ending March 31, 1926	20,485,985		Tons. 22,498	
Figures for year ending March 31, 1925	14,976,846		17,394	

GENERATION OF ELECTRICITY BY GAS-ENGINE STATIONS USING TOWN'S GAS.

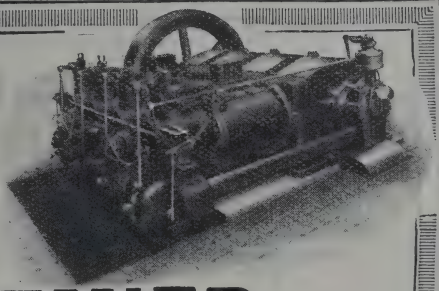
The total units generated by gas-engine stations using town's gas, during the year ending March 31, 1926, was 3,069,174 (from 17 stations).

For the year ending March 31, 1925, the total units were 3,478,315 (from 16 stations).

OIL ENGINE STATIONS.

Output of Station Units in Year.	Between 1,000,000 and 2,500,000.	Between 250,000 and 500,000.	Between 100,000 and 250,000.	Under 50,000.
Number of stations in group	13	18	18	16
Total units generated by oil engines	18,013,960	5,704,943	2,658,435	351,930
Total fuel consumed (actual) tons	1,816	6,679	1,657	228
Average fuel consumption per unit generated (converted to basis of oil) lbs.	1·08	1·24	1·23	1·40
	Total units generated.		Total fuel consumed.	
Total output of all oil engine stations (101) for year ending March 31, 1926	45,686,479		Tons. 26,196	
Figures for year ending March 31, 1925	42,539,281		23,161	

HEAVY-OIL ENGINES
from 300 to 1000 B.H.P.
HORIZONTAL GAS ENGS.
from 275 to 1000 B.H.P.
VERTICAL GAS ENGS.
from 1000 B.H.P. UP.



PREMIER

LARGE OIL & GAS ENGINES

SPECIALLY ADAPTED FOR DRIVING DIRECT-COUPLED ALTERNATORS IN PARALLEL.

We were the pioneers of large gas engines in this country, and our long and unique experience enables us to design and manufacture engines unequalled for economy and continuous reliability.

We have installed thousands of H.P. in large gas and oil engines, both industrial and electric lighting, and shall be pleased to submit specifications and quotations for any type of gas or oil engine.

THE PREMIER GAS ENGINE CO. LTD.

SANDIACRE, Near NOTTINGHAM.

Specialities

ENCLOSED CIRCUIT AIR COOLERS & AIR FILTERS.	For the ventilation of Turbo-Alternators, Generators, Air Compressors and Diesel Engines, etc.
AIR COOLERS.	For the ventilation of Cinemas, Hotels, Workshops, Offices and Mines; also for filtering and extracting micro-organisms in Breweries.
AIR HUMIDIFIERS.	For the humidification of air in Textile and Tobacco Factories, etc.
AIR DEHUMIDIFIERS.	In connection with various Industrial Processes.
DYNAMOMETERS.	For rapidly ascertaining the exact b.h.p. of any description of Prime Mover.
OIL COOLERS.	For cooling the oil of quenching tanks in the Heat Treatment of Steel.
REFUSE DESTRUCTORS, & UTILISATION PLANTS.	For the hygienic disposal of Towns' Refuse with the maximum production of steam, etc.
STRUCTURAL STEELWORK.	For Bridges, Steel Framed Buildings, Piers, etc.
WATER COOLERS.	For cooling the circulating water of Internal Combustion Engines, Air Compressors, Refrigerating Plants, etc.; also for general Industrial purposes.

CONVEYING, ELEVATING & SCREENING PLANTS.

F. 1933

Gas Engine Starters.

Large gas engines are very usually started by means of compressed air pumped by the engine, when running, into a reservoir. They may be started by means of a small gas engine, after the fashion of the barring engine for steam-engines. This small engine must be able to compress the charge of the large cylinder or one of them sufficiently to ignite; or gas and air may be pumped into the cylinder by a small engine and ignited just as the engine is turned off its dead point.

The Wells Starter.—The Wells Bros. starter consists of a small hand-pump fitted at the rear end of the combustion chamber. The action of this pump is to force gas into the cylinder, the crank of the engine being already fixed in the forward position; the action of a valve then permits the pumping of air into the cylinder, and upon the proper mixture being obtained the charge is ignited by ordinary means.

The Fielding and Platt Starter.—Arranged in close proximity to the engine is an air receiver, into which air is pumped under pressure. After gas has been admitted into the engine cylinder, indicated by a flame at a junction pipe, compressed air is admitted into the cylinder from the receiver, and the mixture is ignited at the moment of combination.

The air pressure self-starter was introduced by Fielding & Platt, Ltd., in 1895, and standardised by practically all other makers, and is in common use to-day. On four-stroke cycle engines it has been brought up to date by an automatic control worked by cam on the countershaft, so arranged that the air impulse is only permitted during the power stroke, and is cut off automatically on the other three strokes of the engine, thus avoiding the risk of attendant leaving the air pressure to oppose the piston on the return stroke. No explosive mixture is used. The air tank is automatically charged by the engine itself.

Cooling Water for Internal Combustion Engines.

With stationary engines a cooling water tank or reservoir is usually provided, and in such cases the loss by evaporation varies from 0·2 to 0·4 gallon per b.h.p. hour; with large gas engines it is usual to employ cooling towers. The water is pumped from a well through the engine jackets, etc., and passes thence to the top of the tower; falling to the bottom, it returns to the well at but little above the atmospheric temperature. With a cooling tower the loss by evaporation is greater than with a cooling tank, and commonly amounts to from 0·4 to 0·5 gallon per b.h.p. hour. From 30 to 35 gallons of cooling tank capacity is required per b.h.p.

The 'Heenan' Water Cooler (p. 1296) is particularly suitable for these installations, and in addition to occupying small space has the advantage that it consumes only approximately 0·1 to 0·2 gallon of water per b.h.p. hour.

The ordinary standard sizes of these machines vary in capacity from 625 gallons of water per hour up to 55,000 gallons per hour, which the machines are capable of cooling from 120° down to 90° F. under temperate climatic conditions.

As an example, a *medium* size cooler of the type in question is capable of dealing with the following problems and providing the corresponding water temperatures:

Application.	Quantity g.p.h.	Water Temperatures.	Heat extracted per Hour.
1. Petrol engines and dynamometers	10,000	170°/100° F.	7 million B.Th.U.
2. Gas, oil, and Diesel engines	,,	120°/90° F.	3 ,, ,,
3. Steam-engine condensers	,,	105°/85° F.	2 ,, ,,
4. Air compressors	,,	85°/75° F.	1 ,, ,,
5. Refrigerating plant	,,	72°/67° F.	500,000 B.Th.U.

DATA RELATING TO COOLING WATER USED IN INTERNAL COMBUSTION ENGINES.

Type of Engine.	Bore and Stroke. Ins.	B.H.P.	Cooling Water Temperatures.			Gallons circulated through Jackets, etc., per B.H.P. hour.	B.Th.U. removed by cooling Water per B.H.P. hour.
			Inlet. °F.	Outlet. °F.	Rise of Temp. °F.		
Normal petrol car engines	—	15 to 75	160	200	40	7·5	3,000
Diesel, 3-cyl.	17·75 × 27	360	54	103	49	5·62	2,750
Diesel, 1-cyl.	11·8×18·1	40	60	100	40	6·25	2,500
Oechelhauser	26·5×37·5	500	72	108	36	5·9	2,125
Nuremberg double-acting tandem	33·5×43·3	1,200	60	100	40	7·5	3,000
National single-cyl. horizontal	22·5×30	140	60	140	80	3·5	2,800
National 6-cyl. tandem vertical	22×24	750	58	100	42	6·5	2,730

The water necessary for cooling the pistons and valves is also included in this table in the cases of engines so provided.

Rosseline.

This medium (*Boilerine, Ltd.*) is for the purpose of obviating the incrustation which takes place in water-jackets when salts are present in the cooling water. There are no acids in the preparation, so that joints or attachments cannot sustain any injury. Where scale is already in existence, the action of Rosseline is to cause it to flake and crumble. An average of a quarter pound of Rosseline per brake h.p. per week should be used, the proportion being one pound per 1,000 gallons of water, the approximate quantity of water used to keep a cylinder cool being four gallons per b.h.p. per hour.

Parts of Gas Engines.

In the following formulæ (mainly from Gyldner), a maximum explosion pressure of 350 lbs. per square inch is implied.

1. *Cylinders* are of hard, close-grained cast iron; for the inner wall (*i.e.* working barrel) the working stress may be taken in design at 1,500 lbs. per sq. in. to reduce wall thickness and distortion under heat. If d be the cylinder bore, in inches, and t the wall thickness, then :—

$$t = \cdot 047\, d + \cdot 375 \qquad (21)$$

the ·375 being added as an allowance for reboring, etc. Cylinders up to about 8 ins. bore may have cylinder walls not less than $\frac{1}{4}$ in. thick if cast in one, or $\frac{5}{8}$ in. if with separate working barrels. For bores of 24 ins. and above, the wall thickness may be diminished gradually, or by steps, until at the open end it becomes :—

$$t = \cdot 02\, d = 0 \cdot 5 \qquad (22)$$

2. *Pistons* are of close-grained cast iron; in large engines cast steel is sometimes used. Piston rings are of medium hard, but not very brittle, cast iron. The rings are usually parallel and are of the Ramsbottom type.

3. *Gudgeon, or wrist pins* are usually of steel with a hardened outer surface; the diameter δ may be estimated from the formula :—

$$\delta = 0 \cdot 35 \sqrt[3]{d^2 l_0} \text{ ins.} \qquad (23)$$

where l^0 is the distance from centre to centre of the gudgeon pin lugs, in inches. The intensity of bearing pressure at the moment of explosion should not exceed about 1,800 lbs. per sq. in. of projected area of bearing; this leads to the formula for the length, l, of gudgeon bearing :—

$$l = 0 \cdot 15 \frac{d^2}{\delta} \text{ ins.} \qquad (24)$$

The gudgeon bush is of phosphor bronze; sometimes white-metal lined in larger sizes.

4. *Connecting Rods* in small engines are usually drop-forgings of mild steel; in large engines steel forgings machined all over are used. Connecting rods are treated in calculations as long

columns supported at the ends; a factor of safety of 12 is usual; Euler's formula then leads to the result that the full diameter, $\triangle$, of a rod of circular section may be :—

$$\triangle = 0{\cdot}128\ \sqrt{d\ L}\ \text{ins.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (25)$$

where L is the length of the rod in inches. Towards the gudgeon end, the diameter may be diminished to ·9 or ·8 $\triangle$. The big end of the connecting rod is very commonly of marine type; when of more than about 5 ins. diameter this bearing is usually of cast iron or cast steel, white-metal lined; for smaller sizes bronze is general.

5. *Crankshafts.*—For large engines high-grade steel forgings with an u.t.s. of at least 70,000 lbs. per sq. in. and 20 per cent. ductility in 8 ins.; or open-hearth steel of u.t.s. at least 65,000 lbs. per sq. in. and 18–20 per cent. elongation in 8 ins. may be used. Recently, in special cases, nickel steel has been adopted with an u.t.s. of about 98,000 lbs. per sq. in. and 21 per cent. elongation in 8 ins.

For ordinary steels the allowable working stress is about 12,000 lbs. per sq. in. If s be the stroke, in inches, then H. Allen gives for the crankshaft diameter, D :—

$$D = 0{\cdot}42\ \sqrt[3]{d^2\ s} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (26)$$

With the higher pressures occurring in engines of the Diesel type (see p. 1939) the constant 0·42 must be increased to 0·52 in this equation.

Crank-pin diameter may be about 1·1 times the crankshaft diameter; the length should be about $0{\cdot}18\ \frac{d^2}{D}$ ins. The bearing pressure in crankshaft bearings should be about 400 lbs. per sq. in. of projected area of bearing.

The crank web may have a depth of 1·33 to 1·66 D and a thickness of 0·85 to 0·55 D.

Valves of Internal Combustion Engines.

The valves of present-day internal combustion engines of all kinds are practically all of the 'Poppet' or 'Mushroom' type. In small sizes the valves and stems are in one piece, and usually either of medium carbon steel or nickel steel. Large valves, especially when water-cooled, have cast-iron discs and medium carbon steel stems; such valves in some cases attain large dimensions, the Siegener Co., for example, having built Koërting type engines with valves 19·68 ins. in diameter and a lift of 3·14 ins. Valve cages and seats are of hard close-grained cast iron. Inlet valves are sometimes automatic; exhausts must be mechanically operated. It is preferable to place valves with their axes vertical whenever possible. The mean velocity of gas through the valves is 5,000 to 6,000 ft. per minute in good practice.

Packings for Heavy Gas Engines.

See 'Britimp' Brand Metallic Packings, p. 1949.

Flywheels.

6. *Flywheels* when of cast iron in one piece should not have a rim velocity exceeding 100 ft. per second. If b be the breadth, and R and r the outer and inner radii of the rim, all in feet, and if n denote the number of revolutions per minute, then the kinetic energy, or stored work in the rim, is :—

$$\text{Kinetic energy} = 0{\cdot}1205\ (R^4 - r^4)\ b\ n^2. \quad \text{Foot-lbs.} \quad . \quad . \quad . \quad . \quad . \quad (27)$$

The 'Cyclic Irregularity' or 'Coefficient of Fluctuation of Speed' is the ratio borne by the difference between the maximum and minimum angular velocity of the crankshaft in any one complete cycle, to its mean angular velocity.

The Cyclic Irregularity is often denoted by $\frac{1}{m}$; its permissible value varies with the nature of the work to be done by the engine; the following are a few typical cases :—

Nature of Work.	m
Ordinary workshops; wood-working, pumping, etc.	30–40
Belt-driven continuous-current dynamos in series	80
,, ,, in parallel	120
Belt-driven alternators in parallel	180
Cotton-spinning machinery	200
Direct-coupled alternators in parallel	250

Mathot has proposed the following formula for rapidly calculating flywheel sizes :—

$$W = C \cdot \frac{m\ P}{R^2 n^3} \cdot 10^6 \text{ tons} \quad . \quad . \quad . \quad . \quad . \quad . \quad (28)$$

where,

W = weight of flywheel rim in tons.
R = mean radius of rim, in feet.
P = b.h.p. of engine.
n = normal speed, in revs. per min.
C = a numerical coefficient.

The following are suitable values for C :—		C
1.	For single-cylinder, single-acting engines	265
2.	For two single-acting cylinders side by side; cranks at 180°	167
3.	" " opposed; cranks at 180°	125
4.	" " side by side; cranks at 0°	125
5.	" " opposed; cranks at 0°	167
6.	" " tandem; cranks at 0°	125
7.	For four single-acting cylinders opposed two and two; cranks at 0°	42
8.	For single-cylinder, double-acting engines	167
9.	For two double-acting cylinders side by side; cranks at 0°	42
10.	" " tandem, on same crank-pin	42

The total weight of the flywheel is about 1·4 W tons.

Flywheels are frequently more massive than the above calculation indicates, especially in cases where the speed fluctuation must be kept small even although one or more explosions be missed due to governor action.

Breakages in Internal Combustion Engines.

The following table is compiled from a wide induction of cases from the records of Insurance Companies, and indicates the relative frequency of failure of the several organs of internal combustion engines :—

Analysis of Failures of Parts of Internal Combustion Engines.

Description of parts which are believed to have given way first.	Average before 1904.	1904-1908.	1909.	1910.
	Per cent.	Per cent.	Per cent.	Per cent.
Valves and valve-gear	30·1	33·3	29·6	42·8
Cylinders and cylinder ends	19·3	16·1	15·4	8·5
Pistons	9·7	5·0	2·7	5·1
Connecting-rods and their bolts	11·9	10·3	9·4	9·1
Main shafts	5·1	11·2	13·4	7·9
Governors and governor-gear	5·1	7·0	5·4	3·4
Silencing-boxes and exhaust-pipes	2·8	3·6	1·3	2·8
Flywheels and driving-drums	5·1	5·4	0·7	2·8
Clutches and couplings	1·7	0·0	0·0	0·6
Frames and pedestals	3·4	1·8	1·3	1·7
Bolts *	4·6	1·5	2·0	1·7
Total wrecks, cause not ascertained	0·6	0·4	0·0	0·6
Main driving-ropes and belts	0·6	0·6	0·0	0·0
Miscellaneous	—	2·2	7·4	4·5
Gas-producer plants	—	1·6	11·4	8·5
	100·0	100·0	100·0	100·0

* These do not include bolts in connecting-rods, valve-gear, or other moving parts, the bolts in these parts being tabulated with the parts themselves.

Notes on Fixing a Gas Engine.*

(*F. R. Parsons.*)

Foundations.

The outline of the foundation of an engine will be determined by the over-all dimensions of its bed or framing. Races for the flywheels must be allowed for if their diameter is such that clearance cannot be obtained otherwise. In a general way a margin of from 3 ins. to 6 ins. all round on engines of from 5 to 25 b.h.p. will meet the case. Above this and up to 100 b.h.p. a margin of from 9 ins. to 12 ins., according to needs and the formation of the bed, will be required. The depth of the concrete foundation depends a great deal upon the character of the subsoil. An engine standing on a good gravel bed would require much less concrete depth than one standing on a clay soil, or made-up ground. Engines up to 10 b.h.p. should in a general way have a bed at least 2 ft. to 2 ft. 6 ins. thick; up to 100 b.h.p. this should be increased to from 3 ft. 6 ins. to

* *Mechanical World*, July 18, 1919.

4 ft. Modern-type horizontal gas engines which have a box-section framing and little cylinder overhang are much less susceptible to vibratory troubles, hence the depth of the bed need not be so excessive.

Opinions vary considerably as to the composition of concrete for engine beds. Always, however, it is much more profitable in the long run to have a fairly strong mixture, thereby diminishing considerably the setting period, and ensuring a good firm job. The following mixture has been found to be a highly satisfactory one for any class of high-speed machinery or engines of any power: broken rubble (stones or bricks), 4; clean river sand, limestone, or granite chippings, 4; cement, 1. Dirt or loose soil adhering to the material detracts from its homogeneity and delays setting. It is a good plan to wash well the stones and larger material from a hosepipe before mixing. Each layer of concrete should be well rammed as it is laid, so as to force the material to the outer extremities of the bed. If the latter cannot be completed right out of hand, the old surface should be well wetted before proceeding with the new material.

Holding-down Bolts.

Always leave ample bolt freedom in the concrete bed so that there shall be no difficulty of getting the engine into position, and also permitting it within certain limits to be moved in either direction if so desired. Use square-necked bolts and washer-plates with square holes, the plates being of ample area in order to resist the pull enforced by the nuts. Grout the bolts in with a mixture of clean fine sand and cement in equal parts when the exact position of the engine has been found, and it has been levelled and set. Holding-down bolts are better not arranged below the concrete foundation, but embedded therein; say, allowing from 6 ins. to 18 ins. of concrete, according to the size and thickness of the bed, below them. Set the bolts and plates on this, then proceed with the filling in. Bolts need not be tied together with a single long plate unless one happens to come so close to the outside of any part of the bed as to have insufficient hold. Always set the bolts in a wood-frame templet having holes in it similarly placed to those in the engine bed.

Size of Gas Meter.

Given the brake horse-power of the engine, the size of a meter required to pass a sufficient quantity of gas per hour can be ascertained by the following rule: Multiply the b.h.p. of the engine by the constant 3·4, then add the constant 5, the result being the size of the meter in 'lights.' For example, suppose the engine we are erecting is 60 b.h.p., then $3{\cdot}4 \times 60 + 5 = 209$. As this rule allows ample margin, we should therefore decide upon a 200-light meter.

Size of Gas Service.

To find the correct size of gas pipe to connect between the meter and the engine, the following rule may be applied: Multiply the meter size, in lights, by the constant 0·008, then add the constant 0·75, the result being the bore of the service pipe in inches. Thus, using the previous example, we have $200 \times 0{\cdot}008 + 0{\cdot}75 = 2{\cdot}35$ ins. In this case, if the connection between the meter and the engine was fairly straight, and not over-long or containing many curves, a pipe 2½ ins. bore would be ample. But if a considerable distance divided the two points indicated, or many bends were introduced, it would be better to use a 2½ in. bore pipe.

Exhaust Pipes.

Generally, engines from 1 to 5 b.h.p. may have an exhaust pipe from 1 in. to 1¼ ins. diameter; 5 to 30 b.h.p., from 1¼ ins. to 2½ ins.; above this and up to 100 b.h.p., from 2½ ins. to 5 ins. in the bore.

Circulating Water.

Almost all gas engines require on an average about 4½ gals. of water per indicated horse-power hour, in order effectively to reduce cylinder temperature, this assuming the temperature of the return water not to exceed 150° F. To effect this by means of circulating tanks would be equivalent to an amount of from 25 to 30 gals. of water per b.h.p. as the contents of the tanks. The effective height of a tank should not be less than 2½ to 3 times its diameter. The higher the tank is situated above the cylinder jacket the more brisk becomes circulation. To keep the bottom of a tank at or about cylinder level causes circulation to be sluggish, and promotes the accumulation of sediment and deposit. For this reason it is generally best to keep the tank bottom at least a foot above the centre of the engine cylinder. A ball tap should be provided to supply cold water to the coldest tank, and if the engine is heavily worked it may also be necessary to arrange for an overflow from the hottest tank. Engines up to 25 b.h.p. can be served from 2 ins. diameter pipes; above this to 50 b.h.p., 2½ ins.; up to 100 b.h.p., 3 ins. to 3½ ins. diameter pipes should be used. The return pipe should be sloped all the way to the tank.

General.

In setting a gas engine on its concrete bed it is advisable to keep the cylinder end slightly the highest, an amount of about ¼ in. in every 3 ft. being ample. This assists in draining the waste oil from the cylinder and other parts of the engine to a point where it may be drawn off and collected.

The exhaust box should not be built solid into the ground or in a pit. It is advisable to mount it on iron rollers placed upon a flat stone or on an iron plate. This provides the necessary means for expansion, without which the joints and connections might suffer.

The gas-inlet pipe to the meter, or from the meter to the engine, should on no account be placed close alongside the hot exhaust pipe. This tends to raise the temperature of the gas, thus making it more rarefied and of less heating value per cubic foot. The cooler the gas admitted the more dense is the charge and the more powerful the explosion.

SECTION XXXI

PART III

OIL ENGINES.

DIESEL ENGINES.

A Diesel engine is a prime mover actuated by the gases resulting from the combustion of a liquid or pulverised fuel injected in a fine state of subdivision into the engine cylinder at or about the conclusion of the compression stroke. The heat generated by the compression of air within the cylinder is the sole means of igniting the charge. The combustion of the charge proceeds at, or approximately at, constant pressure.

The Diesel engine, fig. 11, was patented by Dr. Diesel in 1892, and was brought to a commercial success during the next four or five years by certain engineering firms, with whom he was associated. It differs from the gas engine, or petrol-paraffin engine, where the combustible charge is drawn into the cylinder during suction stroke, and therefore the degree of compression is limited to avoid pre-ignition, the charge being usually ignited electrically. In the case of the Diesel engine, only air is drawn into the cylinder and compressed to about 480 lbs. per sq. inch, and the oil is injected in a fine spray into this compressed air and burns gradually as long as the injection is maintained. During this whole period the pressure in the cylinder does not rise above the compression pressure which therefore is the maximum pressure that the working parts of the engine have normally to withstand.

Diesel engines are made either of the four or two-stroke cycle type, and according to requirements run at various speeds. In the four-stroke cycle type, air at atmospheric pressure is drawn into the cylinder during the first stroke, and compressed during the second stroke to a pressure of about 480 lbs. per sq. in.; this compression of the air causes its temperature to rise to about 950° F., which is more than amply sufficient to ignite the spray of oil injected during part of the third or working stroke. When the injection stops the gases expand and the exhaust valve opens shortly before the piston reaches the end of the third stroke. The products of combustion are expelled during the fourth stroke of the piston.

In engines of the two-stroke cycle type the air, instead of being drawn into the cylinder by the engine piston, is delivered thereto under low pressure and is also used partly to expel the exhaust gases. After the air-inlet ports or valves have closed, this charge of air is compressed to the same pressure (480 lbs. per sq. in.) as in the case of the four-stroke engine. The fuel is injected in the same manner as in the four-stroke engine. The gases expand as soon as combustion is completed, and the exhaust ports are uncovered by the piston shortly before reaching the bottom dead centre, the gases being expelled by the entering charge of air.

The thermal efficiency at full load reckoned on the b.h.p. is about 36 per cent. and the fuel consumption at this load about 0·4 lb. per b.h.p. hour. The products of combustion are invisible and odourless.

Nearly all four-stroke engines are built of the vertical type, with a strong cast-iron 'A' frame, the upper part of which forms the outer cylinder of the water jacket; into this upper part is fitted a liner of special close-grained cast-iron, which is water-jacketed for almost its entire length.

F. 1941

The cylinder cover contains four valves, the two large ones being the exhaust and air-inlet valves. The central valve is a needle valve which gradually admits fuel to the cylinder about 1° or 2° before the completion of the compression stroke, to 15° to 20° of the working stroke. The fourth valve controls the admission of the compressed air which is used in starting the engine. The cover is thoroughly water-jacketed to prevent the valves from overheating.

The exhaust and air-inlet valves are of the mushroom type and are self-contained in cast-iron casings which bed on cone seatings in the cover, so that should it be necessary to replace a valve with the minimum loss of time a complete valve and casing can be substituted.

The starting valve, like the suction and exhaust valves, opens into the cylinder. The fuel admission valve opens outwards, except in the Burmeister & Wain engine, in which it opens inwards. The fuel valve of most Diesel engines works through a packing gland to prevent leakage of injection air, remote cases of valves sticking in this packing are occasionally recorded. To prevent even this possibility, Mirrlees, Bickerton & Day, Ltd., and also Tosi, use fuel valves which require no packing.

All valves are closed by springs and opened by rocking levers actuated from the horizontal camshaft, which is supported by ring-lubricated bearings, bolted to the cylinder frame. The camshaft derives a half-speed motion through spiral gearing from a vertical shaft, which in turn is driven by spiral gearing from the crankshaft. In some engines there is a direct gear drive from the crankshaft to the camshaft. This vertical shaft drives a centrifugal governor acting directly on the suction valve of the fuel pump.

A cast-iron trunk piston is adopted, made sufficiently long to be a guide in the cylinder and to take the side thrust due to the angularity of the connecting rod, and is provided with three to six 'Ramsbottom' rings to maintain a gas-tight cylinder; in recent large engines the crosshead type is, however, becoming usual.

The fuel pump of the engine operates as follows:—

The plunger draws a full stroke of oil from a reservoir into the pump chamber past the suction valve. This quantity of oil is in excess of that required for combustion. The excess is returned past the suction valve on the delivery stroke by the action of the governor, which holds open the suction valve for a sufficient length of time to allow the excess fuel drawn in to escape back into the reservoir. In this way the amount of fuel delivered to the engine is precisely the amount required to do the work taken from the engine at that instant, and steady running is ensured, as there is never any actual cut-out.

A feature of the Diesel engine is the facility and certainty with which it starts, it being quite possible to start the engine within 45 seconds. It was the first type of internal combustion engine to be started from cold on crude oil.

The engine is able to burn any class of oil, from refined to the cheap petroleum residue, as well as tar oil, and provided the calorific value is not less than 18,000 B.Th.U.'s per lb., the makers guarantee the consumption at full load not to exceed 0·4 lb. per b.h.p. hour in the larger sizes and 0·45 lb. per b.h.p. hour in the smaller sizes.

The following information taken from the published figures of The Diesel Engine Users' Association relates to the running costs of a 335 b.h.p. 'Mirrlees-Diesel' engine at the Buxton Electricity Works, Derbyshire, for a period of one year, 1925–26:—

Load factor	33 per cent.
Fuel cost	0·344*d.* per unit
Lubricating oil	0·019*d.* ,,
Wages	0·104*d.* ,,
Water	0·004*d.* ,,
Stores	0·004*d.* ,,
Repairs and maintenance	0·047*d.* ,,
	0·522*d.* per unit generated.

The fuel consumption of Diesel engines increases per b.h.p. hour as the load decreases, but the increase is not so marked as in the case of steam engines. The following figures (p. 1942) relating to a test carried out by the writer on a 300 h.p. high-speed Sulzer-Diesel engine are representative and indicate approximately the average extent of the increase in specific consumption with a decrease of load. It will be noticed also that at the maximum overload of 30 per cent.

the fuel consumption per b.h.p. hour is also increased. High-speed engines are always slight less economical than those of the low-speed type. The amount of cooling water usually requir in ordinary Diesel engines is in the neighbourhood of four to six gallons per b.h.p. hour, the ou let temperature being generally 150 to 120 degrees.

TEST ON 300-H.P. FOUR-CYLINDER HIGH-SPEED DIESEL ENGINE.

B.H.P.	Load.	Lbs. per b.h.p. Hour.
75	Quarter	·635
150	Half	·465
225	Three-quarters	·435
300	Full load	·42
330	10 per cent. Overload	·425

'MIRRLEES-DIESEL' ENGINES.

'Mirrlees-Diesel' engines (figs. 12 & 13) are constructed by Messrs. Mirrlees, Bickerton & Da Ltd., of Hazel Grove, Stockport, whose works are specially equipped for the sole manufactu of heavy oil engines.

The first Diesel engine made in Great Britain was a 'Mirrlees-Diesel' of 20 b.h.p., whi was made so far back as 1897, and it is interesting evidence of the life of a Diesel engine th this engine is still working daily. 'Mirrlees-Diesel' engines are thus the outcome of thirty-o years' experience, and the total power supplied aggregates over 200,000 b.h.p.

All 'Mirrlees' engines are of the vertical type, and various sizes of cylinders have be standardised as briefly shown below.

Cylinder Output (b.h.p.)	R.P.M.	No. of Cylinders per Engine.	Range of Engine Power (b.h.p.)
Four-stroke Cycle 'Mirrlees' Engines.			
25	450	3 to 6	75 to 150
55	300	1 to 6	55 to 330
100	250	3 to 6	300 to 600
125	200	3 to 6	375 to 750
150	200	3 to 6	450 to 900
Two-stroke Cycle 'Mirrlees' Engines.			
375	187	3 to 6	1125 to 2250

Engines of 1,125 b.h.p. and upwards are of the two-stroke cycle type, and of 'Mirrlees-Nobe design. The engines are single acting, and have one piston per cylinder, and a low speed rotation.

The fuel valves of 'Mirrlees' engines are of a patent 'packingless' type, thus removing t necessity for any packing, and thereby eliminating any possibility of sticking. The pistons us in 'Mirrlees' engines are of a greatly improved design; they incorporate a 'floating' piston pi and special design of top-end bearing, giving larger bearing surfaces than is possible with ordina practice. Formerly all piston pins have been a driving fit in the piston. The 'Mirrlees' pist

pin is free to rotate both in the piston and connecting rod, thus obviating any piston distortion due to expansion or 'driving in' of the pin, also giving easier dismantling, greater life and reliability.

The fuel consumptions of 'Mirrlees-Diesel' engines are remarkably low, as shown by the following results, and are obtained in regular working over long periods, even with engines of small powers.

At full load	. . . .	0·4 lbs. per b.h.p. per hour	
,, three-quarters	. . .	0·42	,, ,, ,,
,, half	. . . . .	0·47	,, ,, ,,

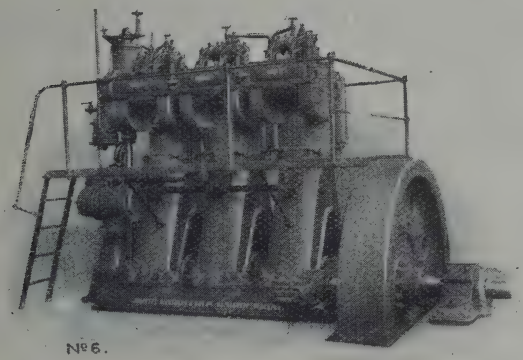

FIG. 12.—165 b.h.p. 'Mirrlees-Diesel' Engine.

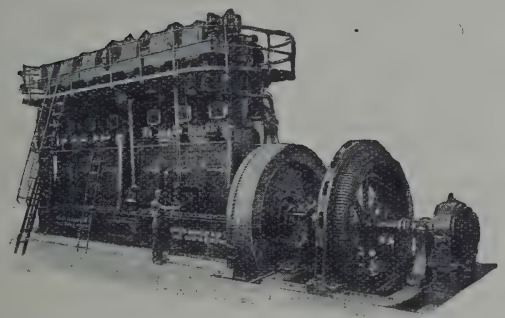

FIG. 13.—1,000 b.h.p. 'Mirrlees-Diesel' Two-Stroke Engine.

Messrs. Mirrlees, Bickerton & Day also specialise in enclosed type Diesel engines which have been largely adopted on board ship for lighting and power purposes. Over eighty engines of this type, aggregating over 18,000 h.p., have been supplied to the British Admiralty alone, mainly for use on capital ships of the 'Dreadnought' and later classes. This type of engine has also been adopted by several foreign navies and many of the principal steamship companies.

Another development which has proved a great success is the use of tar oil or creosote a fuel for Diesel engines, and a special device has been introduced by the above firm for this pur pose. The modified arrangement of fuel pump, etc., required is shown in fig. 29, p. 2144.

Belliss & Morcom Diesel Engines.

Diesel engines of 60 and 100 b.h.p. per cylinder are standardised by Belliss & Morcom, Ltd Birmingham, in three, four, five, and six-cylinder units. They are of the vertical design and ru at 330 and 350 r.p.m.

The rated powers vary from 185 b.h.p. three-cylinder to 600 b.h.p. six-cylinder, in eight size and the design has been developed from their extensive experience in the building of submarin engines and conversion of ex-German submarine engines for central station work.

Forced lubrication is applied throughout; the overhead camshaft is also lubricated und pressure, and oil escaping from the bearings is led back to a tank under the bedplate for re-u after filtering.

The cylinders are separate castings with liners and detachable heads, water cooled, and eac head has one inlet, one exhaust and one fuel valve. The pistons are oil cooled on the high ratings.

A vertical three-stage air compressor is driven from the crankshaft, and the second stage below the first to avoid oil-laden air being drawn in from the crankcase. Starting air is admitte to three cylinders, the valves being grouped at the end of the camshaft.

The adoption of the higher speeds and the complete system of forced lubrication and coolin result in a very efficient engine, which runs smoothly, and the freedom from vibration is ver noticeable. The loss of power due to altitude is given as 4 per cent. for each 1,000 ft. above se level, and the loss of power due to air temperature is 2 per cent. for each 10° F. above 80° F.

English Electric Co.'s Diesel Engines.

The Willans-Diesel oil engines are manufactured at the Rugby Works of the English Electr Company Limited, and have been made since 1906. These engines are in use in all parts of th world, driving all kinds of machines, centrifugal pumps, electric generators, etc., both dire coupled and by means of belts or ropes. They are made in standard sizes from 250 to 500 b.h.

The engines are of the vertical type, the crank chamber is enclosed and forced lubrication use The air-compressor for supplying air for fuel injection and starting purposes is fitted on th end of the engine bedplate and driven from the crankshaft. The speed is controlled by a centr fugal governor acting upon the inlet valve of the fuel pump, thus regulating the quantity fuel exactly to the load. The consumption of residue oil is guaranteed not to exceed 0·41 0·45 lb. per b.h.p. hour at full load, depending on the size of the engine, while at half load th consumption per b.h.p. hour is but 15 per cent. higher.

The engines are made to jigs and limit gauges, thus ensuring interchangeability of spare part which is of the utmost importance in cases where engines are installed in remote countries. Larg engines in powers from 750 to 3,000 b.h.p. are made to the Fullager designs.

Beardmore-Tosi Diesel Engines.

These engines are made in various sizes up to 2,400 b.h.p. and are of the four-stroke cyc enclosed type. The range of horse-power developed per cylinder is 15 to 400 b.h.p., the dimensio ranging from 180 mm. to 630 mm. Crossheads have been adopted in both the land and mari types. The Tosi design gives the greatest freedom from trouble for the piston and gudge pin.

Great attention has been paid to the design of the details of these engines, especially to t lubrication and water circulating systems. The consumption of fuel oil is between ·42 and ·45 per b.h.p. hour. The engines are also very economical in lubricating oil, as only about ·0045 per h.p. is required for the slow-speed engines.

A feature of the Tosi engines is that they will fire regularly at speeds as slow as 40 r.p.m., at which speed compression pressure is 450 lbs., as against 485 lbs. per square inch at normal speed. One reason for the capacity to run at such a reduced speed is the fact that the phase and duration of the fuel injection period can be regulated according to the speed of the engine. At low speeds the quantity of fuel injection air is reduced and the cooling effect of the excessive quantity that would enter the cylinder, were no means of regulation provided, is entirely absent.

Messrs. William Beardmore & Co., Ltd., also make a range of quick-running oil engines with cylinders 8½ ins. by 12 ins., in four, six, and eight-cylinder units, developing 200 to 400 b.h.p. at 750 r.p.m. Also they make engines with cylinders 12 ins. diameter by 12 ins. stroke in four, six, eight and twelve-cylinder units, developing 420 to 1,260 b.h.p. at 750 r.p.m.

These engines are of the four-cycle high compression airless injection type, with steel monobloc crankcase fitted with steel cylinder liners. The lower part of the crankcase consists of a light tray with an oil sump. The main bearings are phosphor-bronze lined with white metal, forced lubricated, and the crankshaft is of high-grade steel with ground pins and journals.

The pistons are made from forgings of a special aluminium alloy fitted with six cast iron piston rings and a floating piston pin of case-hardened nickel steel.

These engines are used for the Diesel electric cars of the Canadian Railways, and are being taken up by the L.M. & S. Railway because of their extremely light weight, high economy, and reliability.

Allen Diesel Engines.

The Allen Diesel engines are made in various sizes from 50 b.h.p. upwards, and are of the Burmeister & Wain design, which has proved very successful. The engines are of the vertical four-stroke cycle type, totally enclosed, and fitted with forced lubrication.

The construction of these engines has received very careful consideration to enable them to make long, continuous runs, such as are required for work on ships. A low fuel consumption is obtained, and the engines are also economical in lubricating oil.

The Allen Diesel engine is constructed mainly for auxiliary work, such as lighting, etc., on board ship. Further particulars of the engines designed by Burmeister & Wain are given on pp. 2411–15.

Schneider Diesel Engines.

Schneider & Co., Le Creusot, have had an extensive experience in the manufacture of large Diesel engines for land and marine purposes. One of the firm's experimental engines, a single cylinder two-stroke cycle type, has developed 1,200 h.p. at 150 r.p.m.

Two-stroke cycle Diesel engines of various powers up to 2,400 h.p. have been made and a number of these have been in regular work for over seven years. Four-stroke cycle engines have also been made and give very satisfactory service.

The Schneider engines are of the vertical type, of both the open and enclosed design, and all of them are fitted with crossheads. The makers have also completed some double-acting stationary Diesel engines of the four-cycle type developing up to 2,600 h.p.

Sulzer Diesel Engines.

Sulzer Bros. of Winterthur, Switzerland, make stationary engines of the four-cycle type from 50 to 1,000 b.h.p. For higher powers they have adopted the two-stroke cycle principle, and all of their marine engines are of this type. A large number of these engines are in operation, and the design of their stationary engines follows that of the marine type shown on p. 2418.

In the larger engines the reciprocating scavenge pumps are replaced by rotary turbo blowers, supplying scavenging air to the cylinder at a pressure of 1½ to 2 lbs. per sq. in. This simplifies the engine, and enables a greater shaft horse-power to be obtained from a given size of engine using the same mean indicated pressure in the cylinder.

Sulzer Bros. now make a new type of airless injection Diesel engine, shown by fig. 14, to meet the demand for oil engines of small powers. The engine operates on the two-stroke cycle, and ignition is obtained by the heat of compression only; the fuel being injected by the fuel pump into a water-cooled space called the pre-ignition chamber, situated in the cylinder head and in communication with the working cylinder. Exhaust ports are arranged in the lower

part of the cylinder liner on the opposite side of which are the scavenge ports, which admi compressed air from the crankcase when the piston is at the bottom of its stroke.

The fuel consumption on a 50 h.p. engine of this type is 0·47 lb. per b.h.p. hour when runnin on ordinary Diesel fuel oil. The engines start immediately from cold, and are able to run a

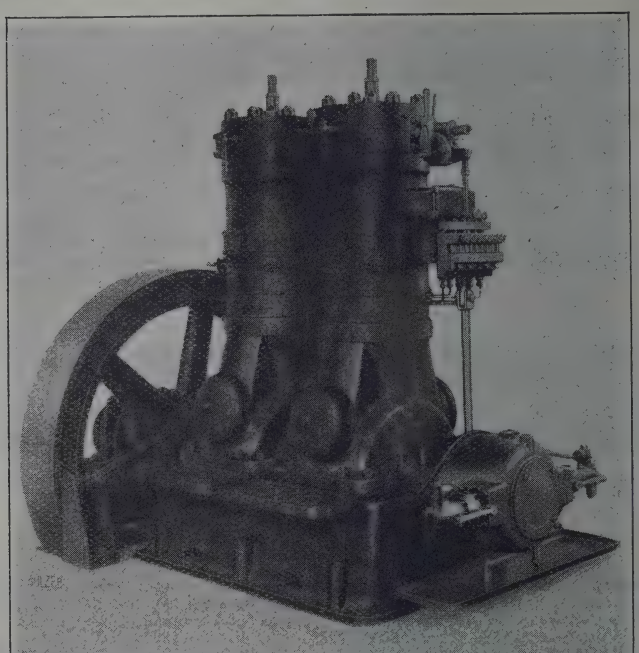

FIG. 14.—Sulzer Airless Injection Diesel Engine.

all loads, even quite light, with regularity. The only valve in regular operation on the cylinde is the fuel injection valve, which is automatic, also the air admission valve on the crankcase i automatic, which greatly simplify the engine, and the robustness of its construction will b apparent from the illustration.

CARELS DIESEL ENGINE.

The Carels Diesel engines are constructed by Messrs. Carels Frrèes, Ghent, Belgium, in size from 50 to 3,000 b.h.p. The first engine was made in 1894, and their standard four-cylinde 600 b.h.p. engine is illustrated by fig. 15.

In 1905 Carels exhibited at Liége a three-cylinder 500 b.h.p. engine; in 1908 they constructe their first 1,000 b.h.p. two-stroke cycle reversible marine engine, and in 1910 they built an engin developing 1,000 b.h.p. in a single cylinder.

Messrs. Carels Diesel & Steam Engines (London), Ltd., which is the British organisation o this firm, have given the following particulars regarding two 320 b.h.p. generating sets installe in 1906 for the Wakefield & District Tramways. The engines are direct coupled to 200 kw generators at 174 r.p.m., and the average run per day during the sixteen years they have bee installed is approximately seventeen hours. Only a small staff is required to run the engines and the guaranteed fuel oil consumptions which were obtained are: full load, 0·42 lb. per b.h.p hour; three-quarter load, 0·45 lb.; and half load, 0·476 lb. One class of lubricating oil

CAREL'S DIESEL ENGINE.

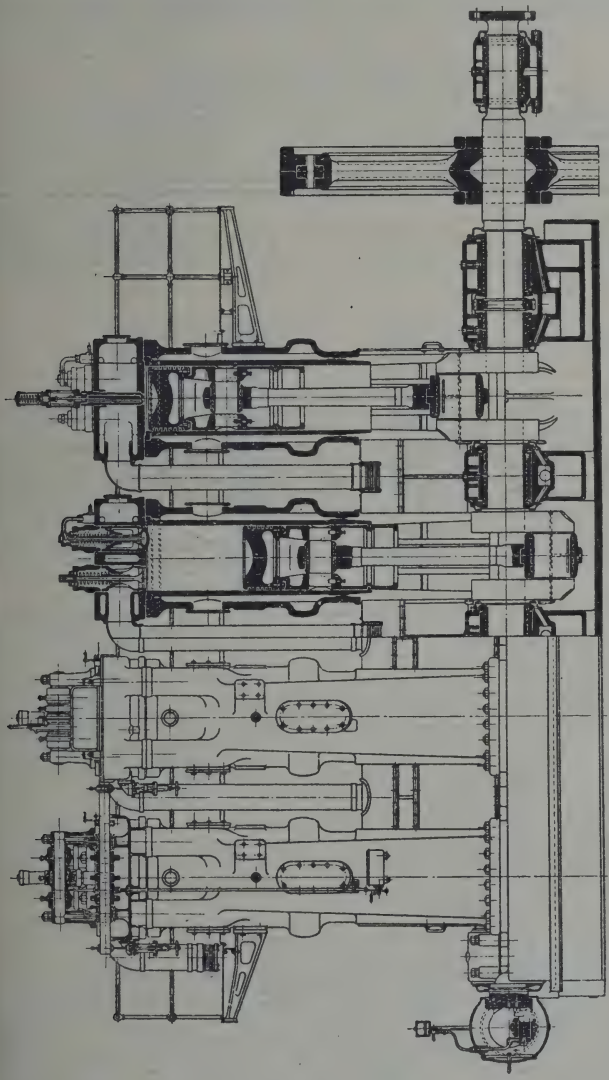

FIG. 15.—Carels 600 h.p. Four-stroke Cycle Diesel Engine.

suitable for all parts of the engine, and the consumption is 4·16 grammes per kw. hour. Th average cost for repairs and maintenance over the sixteen hours is approximately 5*s.* per b.h. per annum.

These two engines are interesting, as they were among the first Diesel engines to be installe to deal solely with a fluctuating traction load, and their performance has been satisfactory also the engines are running well at the present time.

Other Makers of Diesel Engines.

Geo. Ansaldo & Co., Rome, manufacture Diesel engines of large powers, and a number a in regular use. One of their 1,100 b.h.p. two-stroke cycle engines running at 100 r.p.m. w recently subjected to severe tests to determine the flexibility and overload capacity. It w found possible to run the engine at as low a speed as 35 r.p.m., and the following are particula of the overload trials :—

Overload Trial on 1,100 B.H.P. Ansaldo Diesel Motor.

Overload.	Duration of Trial in hours.	R.P.M.	B.H.P.	Fuel Oil consumption, lbs. per b.h.p. hour.	Lubricating Oil consumption, lbs. per b.h.p. hour.
47 per cent.	1	127·7	1,622·5	0·445	—
30 ,,	30	116	1,433	0·440	0·006
12 ,,	5	104·7	1,232·5	0·425	—

These figures dispose of any doubt as to whether the Diesel engine as now constructed c be overloaded for a long period without damage.

Diesel engines are also manufactured by Svenska Aktiebolaget Nobel Diesel, Nynasham Sweden, in various sizes up to 3,000 h.p., and are made in both the four-stroke and two-stro cycles. These engines are of the open vertical type and a large number have been supplie The Nobel engine is one of the best-known Continental designs, for he first commenced its man facture in Petrograd in 1897, and it is noteworthy that the Swedish company now intend specialise on the two-stroke cycle engines.

The Atlas Diesel Co., Ltd., also make these engines in various sizes up to 1,000 b.h.p.

(For further information on Marine types of the Diesel engine, see p. 2409 *et seq.*)

English Electric Co. Fullagar Oil Engines.

The Fullagar oil engine is similar in design to the gas engine described on p. 1928, and made by the *English Electric Co.*, Rugby, in five sizes, from 750 b.h.p. four-cylinder at 250 r.p. to 3,000 b.h.p. The engine is of the vertical enclosed opposed piston type, built up in units two cylinders placed close together, each cylinder having two opposed pistons, there being o crank and one connecting rod per cylinder. The upper piston of one cylinder is connected the lower piston of the second cylinder by diagonal rods.

The pistons move in opposite directions in one cylinder : one piston first uncovers the exha ports which extend all round the cylinder bore, then the other piston uncovers the scaven ports, which also extend round the bore, at the other end of the cylinder, and fresh air at a l pressure is supplied by a pump formed in the upper crosshead, flowing from one end of the cylind to the other, sweeping out the burnt gases and leaving the cylinder filled with fresh air.

The engine works on the Diesel principle, and on the two-stroke cycle, the air in the worki cylinders being compressed until the temperature is raised to about 1,000° F., in order to ign the fuel which is atomised and blown in by compressed air. A three-stage direct-driven compress supplies the air for starting purposes and fuel injection. Fuel is directed horizontally betwe the pistons, so that the fuel does not impinge directly against the pistons. Scavenging air, also that for the compressor, is supplied from chambers in which the upper crossheads wo The crossheads thus act as displacers, the automatic air inlet and delivery valves being arrang behind the chambers in question.

A number of engines are in satisfactory operation driving electric generators in this count and various parts of the world, while several engines of various powers up to 1,500 are now course of construction at Rugby.

The only mechanically operated valves in regular operation are the fuel admission valv there being one per cylinder ; there are no cylinder covers, which is a very desirable simplificati Starting valves, opened by compressed air, are fitted on two cylinders, the valves being operation during the first few revolutions only.

All main bearings, connecting rod bearings, and lower crossheads are forced lubricat whilst the main pistons, upper crossheads, air compressor, and other parts are lubricated mechanically operated lubricators operated from the cam shaft.

The balance of the engine is excellent, owing to the fact that the centre of gravity of t reciprocating masses working side by side nearly coincide ; whilst, owing to its construction a

balance, the engine is suitable for working at higher rotative speeds than the ordinary reciprocating engine. The length of a 6-crank 1,125 b.h.p. engine is no greater than that of an ordinary 500-b.h.p. four-cycle engine; whilst the weight per b.h.p. is about 30 per cent. less than that of the four-cycle engine of equal power, the explanation of this being that the engine is in effect a double acting two-stroke cycle engine without cylinder covers. Also the height to crane hook for removing pistons is less than that necessary to withdraw a piston and connectiong-rod of a four-cycle engine of equal power.

Packings for Diesel Engines.

'BRITIMP' BRAND METALLIC PACKINGS.*

(*British Metallic Packings Co., Ltd., 7 Princes Street, Westminster, S.W.1.*)

Each complete packing (which is equally suitable for heavy gas engines) is made up of two types of rings—viz. the fire rings shown by 'E' (fig. 15A), and the packing rings indicated by 'C.' The fire rings are to protect the packing rings from the heat of the burning gases and are placed next to the cylinder. Each fire ring unit consists of two inner rings, 'E,' in segments, surrounded by an outer ring 'F.'

Each packing unit is made up of two complete rings of cast iron. Each ring is in three sections, with staggered joints. The outer surfaces of the rings are coned in opposite directions, and the coned surfaces are shrouded by a cast-iron ring in three sections (see 'D,'), and the whole is kept together by a spiral spring. Fig. 15A shows a complete packing unit.

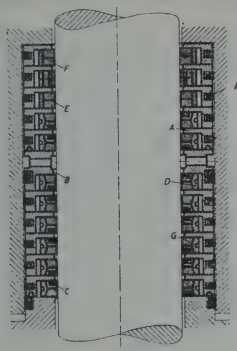

FIG. 15A.

The coned surfaces produce radial and axial surface pressure components which form the gas-pressure seals between the radial and axial surfaces of the packing.

Each fire ring unit and packing unit is enclosed in a chamber ring 'A,' and the pressure seal between these rings and the stuffing box is obtained by the rings 'H.' Lubrication is provided by way of the lantern ring 'B.'

This is a typical example of a Diesel engine packing, and similar arrangements are used for heavy gas engines. The designs, however, are varied to suit any special conditions which may exist.

Weight of Diesel Engines.

For land installations, considerations of economical production have resulted in cast iron being extensively used in the Diesel engine; due to this, and to the high pressures employed, the weight per b.h.p. is somewhat high; thus, including fly-wheels, Guldner gives as the weight per b.h.p.:

A.	In single-cylinder engines:			600 lbs.
B.	,, two-	,,	,,	520 lbs.
C.	,, three-	,,	,,	350 lbs.

In recent practice, and particularly in cases where weight reduction is of importance, as *e.g.* in Diesel engines for submarines, these figures have been largely reduced; this is effected by using materials of considerably greater tensile strength in place of cast iron, and weights as low as 300, 250, and 200 lbs. per b.h.p. for cases A, B, and C respectively, may be found. In high-speed engines the weight has even been reduced to as little as 60 lbs. per b.h.p. with four-stroke engines, and 45 lbs. with two-stroke designs.

The Diesel engine is more economical in fuel consumption than any other type of internal combustion engine, but in construction it is necessarily a somewhat costly type.

* See also pp. 1263, 1805, and 1844.

Care of Diesel Engines.

The causes of perhaps 90 per cent. of all the troubles that occur with Diesel engines ar either insufficient cooling, improper lubrication, or poor combustion. Good results cannot b expected from the engine unless adequate cooling and lubricating systems are provided and fue oil of a certain quality used. The owner should not expect his operator to show good results i he has failed to furnish the needed apparatus and materials. The owner should further under stand that a Diesel engine requires periodical minor adjustments and repairs, and the enginee should be given an opportunity to do this work.

Following out a schedule of inspection, such as one gives any high-grade machine, will resul in a reliability and economy of operation that will justify the slight additional labour involved There can be no justification for the neglect that the engine so often experiences. (*Power.*

Cost of Diesel Engines.

The price of Diesel engines varies considerably, depending upon the design and speed, an may be taken as being from about 9*l.* to over 12*l.* per h.p. at the maker's works.

Diesel Engine Crankshafts.*

All shaft failures investigated owe their origin to lack of alignment of the main bearings This is usually the result of unequal rates of wear of the several bearings supporting the shaft though in some cases it can be traced to negligence during erection, or, in older engines, t defective foundations.

The following system of assuring perfect alignment of the shaft is recommended, especially t those engineers who have no reserve plant and who have to get repairs done during the week-en

If the engine is a 4-cylinder, take out bearing C first and micrometer it. Look up the log book and ascertain how much it has worn since the shaft was last realigned. Then take ou bearing A, micrometer it, and ascertain the extent of wear in the same period. If it has worn dow $\frac{8}{1000}$ in., and bearing C has worn down $\frac{12}{1000}$ in., then scrape down bearing A $\frac{4}{1000}$ in. more, re-bed i to the shaft, or, preferably, to a special dummy journal, and then replace it. Treat all the bearing in like manner. If the engine is a 2-cylinder, or a single-cylinder unit, then probably the bearin adjacent to the flywheel is most worn. It therefore should be taken out first, measured up, an replaced, scraping only if found 'high' at one end. Then take out the other bearings and scrap them in accordance with the data obtained. In the case of a 3-cylinder engine, the probability i largely in favour of bearing B being the lowest, and this, therefore, should be taken out first.

Thus, where plant is not in excess, the engineer can readjust a bearing each week-end until th whole set is completely put in order, and he runs very little risk of heated bearings if he is carefu The system has its limits. It would not do to apply it in this manner if rate of wear were ver variable.

It is necessary to dismantle the whole engine to make a good start with the system. If th engine has been very carefully erected, and is not more than a year or two old, then one ma exercise his discretion and assume that any large differences in the thickness of the main bearin shells is due to difference in rate of wear.

As regards the subsequent adjustment, running clearance of main bearings, it is not usuall feasible to measure this with feelers. Where possible it is preferable to feel the lift in eac bearing, and let the cap closer and closer until the bearing either heats (in which case scrape ou the cap) or until the lift just disappears.

Recourse may be had to leads so long as they are considered only as a means of obtaining th *relative* and not the absolute clearance in a bearing. In the ordinary way, if one uses 20 or 2 gauge lead wire, running clearance will be right if the lead squeezes out to $\frac{8}{1000}$ in. or $\frac{9}{1000}$ i thick. If one uses 16 gauge, then this may squeeze to about $\frac{10}{1000}$ in. or $\frac{12}{1000}$ in. thick. Th actual clearance is probably only $\frac{4}{1000}$ in. to $\frac{6}{1000}$ in. The difference between real and apparen clearance depends upon a number of factors. It should be borne in mind that leads do not sho the true clearance in a white-metal bearing.

Best Proportion of Shafts.

Tensile strength, not less than 34 tons.
Ductility not less than 25 per cent. in 2 ins.
Diameter of pins and journals, 0·525 to 0·54D.
Length of main bearings, 0·75 to 0·8D.
Length of big end pin, 0·525 to 0·54D.
Thickness of webs not less than 0·32D, but centre to centre of cylinder made minimum possibl and any excess over the proposed length of pin and journal to be put into the webs.
Fillets to be not less than one-tenth the diameter of the shaft.

For details of Diesel engine parts see 'Marine Diesel Engines,' Section XXXVI., p. 2409.

* Paper by F. H. Smith read before the Diesel Engine Users' Association, July 12, 1916.

Alignment of Crankshafts and Engine Parts.*

(Geo. E. Windeler, M.I.Mech.E.)

Where small units are built up with separate bedplates and columns or crank cases, it is imperative to check the parallelism of the crankshaft journal from the planed surfaces of the bedplate. The other details which require alignment checking are the connecting rod and the piston, it being essential that the top and bottom bearings of the connecting rod are perfectly parallel and free from twist.

The following is a simple and efficient method for measuring the inaccuracies :

Place into the bottom end of the connecting rod (fig. 16) an accurately ground mandril, say $\frac{5}{1000}$ in. or $\frac{6}{1000}$ in. less in diameter than the bore of the bearing. A similar mandril is placed in the top end bearing. Generally speaking, this mandril is five to six times the length of the bearing. The whole is then placed vertically in two V-blocks, and a scribing block fitted with a micrometer screw is then used to measure the height of the mandril at each end which projects through the rod. The difference between the two dimensions is the exaggerated amount of inaccuracy, and, assuming that the bar is five times the length of the bearing, then the actual amount of error on the connecting-rod bearing itself would be one-fifth of the total error

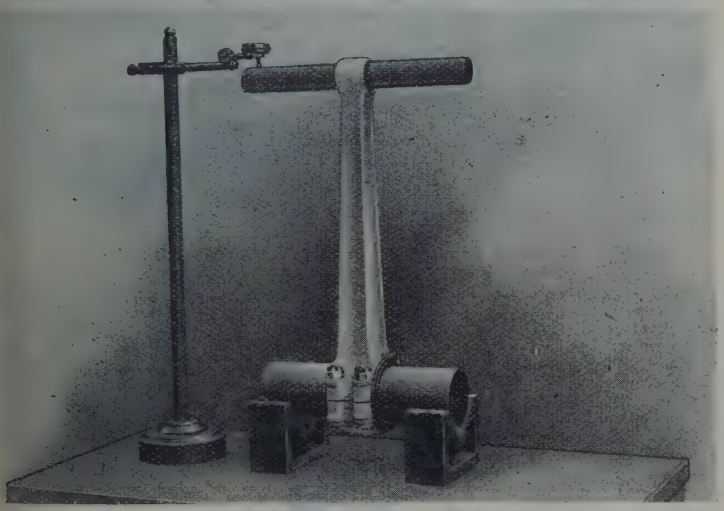

FIG. 16.—Testing the top and bottom bearings of the connecting rod.

shown ; so that if the test-bar showed an out of parallel from one end to the other of $\frac{5}{1000}$ in., then the top end bearing of the connecting rod would be out of parallel with its bottom end bearing to the extent of $\frac{1}{1000}$ in. This is an instance of measuring, by exaggeration, very fine inaccuracies.

It is also desirable to test the rod to ensure that the holes lie perfectly parallel with each other in the vertical plane, that is to say, to ensure that the holes are not twisted with each other. To carry this into effect the rod is lowered down into a horizontal position (fig. 17) and a packing piece is placed under the rod immediately below the centre of the bearing. A scribing block with a micrometer screw is then used to test the height from one side to the other, in the same way as the vertical test was carried out. If any twist occurs with small rods, this can be corrected by twisting the rod, but in large rods other means have to be adopted to remove the error.

The same method is adopted for testing whether the piston pinhole is at right angles to the piston (fig. 18).

---

* Abstract of paper on 'Alignment of Machinery' read before the Manchester Association of Engineers, December 8, 1917.

In moderate-sized units the alignment of the cylinders and parts is often carried out by mean of dummy parts which are accurately made, and may be regarded as a form of jig for testin the parts during the course of erection. With larger sized units this is not always practicabl and other means have had to be resorted to to obtain the same degree of accuracy.

In large units such as are in general use to-day, and in which the rate of revolution i high and the running clearances very close—as, for instance, in a large vertical engine, sa 20 ft. above the crankshaft, with the piston clearance $\frac{14}{1000}$ in. diameter when cold—it i imperative that the cylinder and guide should be at right angles to the shaft, and that th

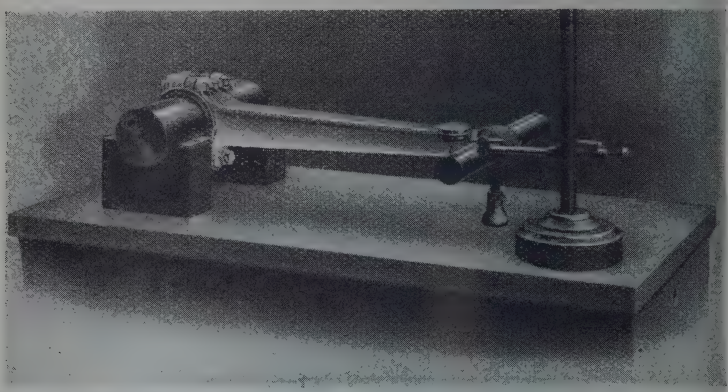

FIG. 17.—Testing the alignment of the holes with the vertical plane.

readings of the alignment should be accurately taken for tabulation. A fine wire is generall used for the alignment of the vertical components, but as it is a flexible member and give to slightest pressure of contact, really reliable data are not obtained from its use in th ordinary way.

The following describes a simple audible electrical device used in conjunction with the fin wire system for accurately checking the alignment of engine parts.

It is assumed that the engine bedplate is machined on the under side and parallel with th top side of the bedplate. The bedplate is then accurately levelled on parallel strips, bot

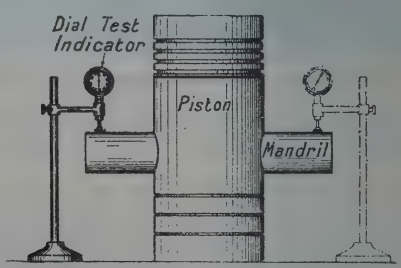

FIG. 18.—Diagram showing method of testing alignment of hole in piston for gudgeon pin.

longitudinally and transversely, and supported by such strips at defined points. The cranksha is then placed in its bearings and tested for parallelism with the planed surface of the bed, an at the same time the shaft journals are tested for concentricity with each other by similar mea to that described under small engines. Assuming this to be satisfactory, the columns a placed accurately in position and the cylinders placed on top of the columns. A fine wire

then stretched over the whole length of engine, the ends passing over uprights secured to the engine bed and adjacent to the ends of the crankshaft. Suspended at each end is a non-magnetic 'plumb-bob' of sufficient weight to keep the wire taut. The wire is then set so as to intersect the centre lines marked on the end of the crankshaft.

The cylinders are then lined true longitudinally to this wire and correctly pitched one with another. Long wires are then passed through each cylinder, of sufficient length to pass between the crank webs, and a heavy 'plumb-bob' is secured to each wire and immersed in viscous oil contained in a small vessel, to prevent oscillations of the 'plumb-bob' and the wires. These wires are set accurately to the centre of the top end of the cylinders by means of the audible device, and readings are then taken at the top and bottom of cylinders and between the crank webs. The wire is suspended over a rounded knife-edge metal bar at the top end of the cylinder, in such a way as to prevent kinking and cutting of the wire, and this metal bar is supported on hard wood blocks from the top face of the cylinder. The use of wood blocks is necessary to

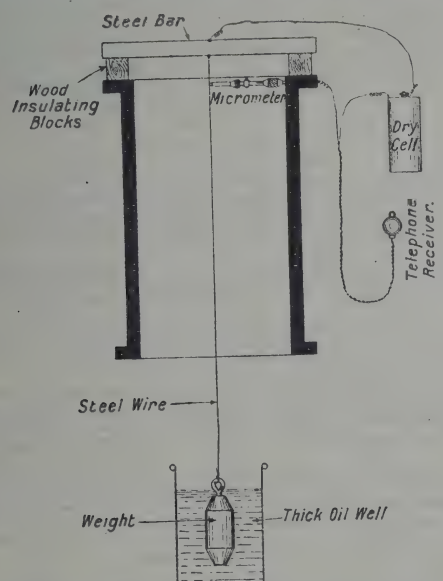

FIG. 19.—Diagram showing method of aligning cylinder using audible warning device.

insulate the metal bar from the engine parts. Connected to the metal bar by one of its terminals is a dry battery (fig. 19), the other terminal of which is earthed to the engine frame with a telephone receiver in circuit; then contact between the suspended wire and the cylinder will cause the electrical circuit to be closed.

The micrometer gauge is then set to half the diameter of the cylinder, less half the diameter of the wire, plus, say, $\frac{1}{2}$/1,000 of an inch. This setting allows $\frac{1}{2}$/1,000 in. pressure against the wire when the wire is set dead central at the top of the cylinder. The micrometer gauge is then inserted between the wire at the points named above, and if the gauge touches the wire the electrical circuit becomes closed by this contact and a distinct noise is transmitted through the telephone receiver. To enable the operator to have the use of both hands, the receiver may be held to his ear by means of an elastic band passed round his head. The micrometer gauge being adjustable, any 'plus' or 'minus' readings can be taken at will with a definite known amount of contact pressure on the wire. The readings obtained are entered on a chart. By reference to this chart the foreman decides what action should be taken to rectify the error shown, and the preliminary and final records are filed for reference.

With this device it is possible to obtain the same readings consistently, and it has the advantage that it is portable and adjustable to any engine, either horizontal or vertical. It

can be sent out to inspectors to check the alignment of engines which have been some tim at work. Also the wear of the bore of the liners can be accurately recorded with the exac position at which the wear has taken place.

In multi-cylinder engines it is important that the crankshaft should be properly supported e each journal, otherwise springing of the shaft takes place at each compression and power stroke which may ultimately result in fracture of the shaft. It is therefore important that the shaf and bearings should be periodically examined. One of the insurance companies has adopted simple means of measuring the amount, and proceeds in the following manner:

The engine is barred round with each crank on its respective top centre, and the distanc between the crank webs is measured with a micrometer gauge at a definite point and recorded Each crank is then barred down to its bottom centre, the distance between the crank webs agai taken, and the difference between the two readings noted. A simple calculation gives a clos approximation of the amount that the shaft is clear from its bearings, and a new bearing can b fitted by gauging the thickness of the existing shell from outside diameter to inside diamete and then making the new bearing thickness plus the amount calculated from the figures take between the crank webs. This method can also be used to detect any want of alignment o outboard bearings of gas and oil engines, and is invaluable for this particular difficulty. I is a very accurate and reliable method, and has saved many cranks from ultimate fracture.

Cyclic Variation Recorders.

A number of arrangements have been made for the purpose of accurately recording the cyclic variations of the rotational speed of an engine; the first attempts were mainly with tuning forks, and this form of apparatus was well developed by Manlove, Alliott & Co. A variation o this was first used by the writer to test the cyclic regularity of steam engines built by Davey Paxman & Co. in 1907.

In this apparatus the tuning-fork was replaced by an electric motor running at a constant speed and the records were taken on the peripheries of the flywheels, the flywheels having been suitably prepared.

Mirrlees, Bickerton & Day have taken tests of the cyclic variation of their Diesel engines in a similar manner, and the arrangement of the apparatus is as follows:—

On a base is formed a V, so that an ordinary lathe compound tool rest can be fitted to same, which tool rest is operated across the face of the wheel by a quick-pitch, square-thread screw, actuated by a heavy handwheel, so as to obtain as near as possible uniform movement across the space to be traversed, though this is not essential to the accuracy of the results.

Mounted on the compound rest is a small electric motor arranged in such a manner that it can be worked towards or away from the surface of the wheel by the compound rest. Secured on the end of the motor spindle is mounted a carefully balanced disc into which is inserted a hardened steel, accurately-ground pointer. Immediately below this is fixed a small bracket which holds another adjustable pointer vertically below the point of the rotating pointer on the disc when touching the face of the flywheel of the prime mover.

The object of the fixed pointer is to scribe a line in the form of a helix circumferentially on wax on the rim of the flywheel, whilst the duty of the rotating pointer is to cut short intersecting marks across these lines at constant intervals of time. These objects are obtained by moving the slide rest parallel to the surface of the wheel whilst the prime mover is running at normal revolutions and the electric motor at uniform speed.

The fixed pointer marks a helical line in the wax deposited on the periphery of the flywheel and the pointer marks off distances on this line at equal intervals of time. These distances are a record of the average speed of the flywheel during small intervals of time and from them a speed curve can be plotted.

It is essential that the points are in line vertically, so that the mark cut by the revolving pointer is bisected fairly accurately by the helical line. The electric motor, which is run at a high speed of revolutions, is supplied with current from an ordinary 12-volt motor-car lighting battery, which forms part of the equipment.

Generally speaking, the length of the record should be not less than 4 or 5 revolutions, though the number is only limited by the width of the flywheel surface and the pitch of helical line, which is usually about $\frac{1}{2}$ in. The motor is arranged at such a speed as to give a suitable number of readings on the periphery of the wheel, so that slight variations in the velocity of the rim can be detected. The distances between the marks are then carefully measured off with a steel tape and

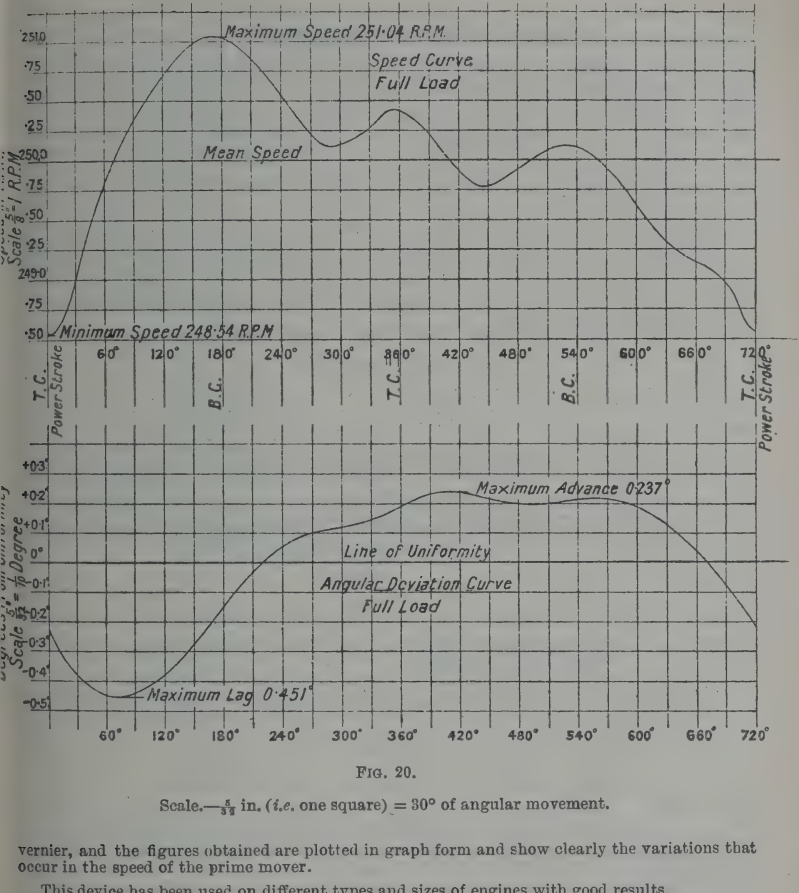

FIG. 20.

Scale.—$\frac{5}{8}$ in. (*i.e.* one square) = 30° of angular movement.

vernier, and the figures obtained are plotted in graph form and show clearly the variations that occur in the speed of the prime mover.

This device has been used on different types and sizes of engines with good results.

The theoretical figures and graphs were based on information obtained from diagrams from actual engines several years before the results were taken by the instrument. The graphs shown on fig. 20 indicate these theoretical figures, and the graphs shown on fig. 21 are those produced by the information obtained with the Mirrlees, Bickerton & Day Cyclic Variation Recorder.

The novelty of the device lies in the use of the periphery of the flywheel of the prime mover as the recording drum, and the application to the flywheel of a delicate recording substance such as wax.

Having plotted a correct speed curve from data given by the trial, the angular deviation from true uniformity of rotation is obtained either (1) fairly accurately by direct calculation from the speed curve, or (2) very accurately by plotting another graph from the speed curve showing the changes in angular position of the flywheel relative to an imaginary wheel rotating uniformly.

The apparatus is inexpensive and of such a character that it can be readily manufactured and easily operated by any careful person with engineering experience. The data obtained can readily be transposed into scaled graphs by a skilled draughtsman

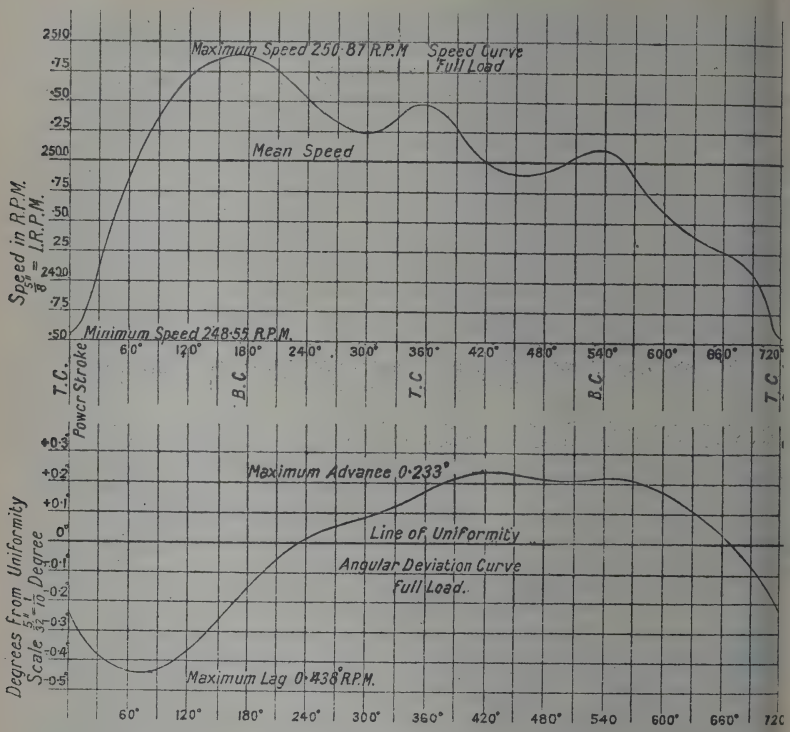

FIG. 21.

Scale.— $\frac{5}{32}$ in. (*i.e.* one square) = 30° of angular movement.

The amount of current used for operating the electric motor is very small, as its duty is to merely maintain at a constant speed the disc carrying the pointer, and to overcome the slight resistance offered by the pointer scratching the marks (one per revolution of the motor) on the surface of the wax.

The method adopted for securing the wax to the wheel is as follows :—The wheel is thoroughly polished and carefully rubbed down, whilst running, with turpentine ; the wax, which is pure beeswax, is carefully heated to a liquid state in a glue kettle and then plastered on to the surface of the wheel. The use of the glue kettle was found necessary, as if the wax were overheated during the process of warming it would not adhere to the surface, the overheating apparently reducing its resilience and causing it to become ' short.'

The thickness of wax deposited on the wheel should be about $\frac{3}{16}$ in. and turned down till it is about $\frac{1}{16}$ in. thick. It can be readily removed afterwards with a scraper, but it was found undesirable to use the same wax over and over again, as a certain amount of greasy matter (probably oil vapour condensed on the wax) mingled with it and destroyed its nature ; so that in carrying out experiments it is desirable to use fresh wax each time.

SEMI-DIESEL ENGINES.

A semi-Diesel engine is a prime mover actuated by the gases resulting from the combustion of a hydrocarbon oil. A charge of oil is injected in the form of a spray into a combustion space open to the cylinder of the engine at or about the time of maximum compression in the cylinder. The heat derived from an uncooled portion of the combustion chamber, together with the heat generated by the compression of air to a moderate temperature, ignites the charge. The combustion of the charge takes place at, or approximately at, constant volume.

The semi-Diesel engine is the simplest form of oil engine, especially if of the two-stroke cycle type, and can be arranged to work satisfactorily with practically the same range of fuel oil as the Diesel engine.

Moderate compression pressures of 150 to 200 lbs. per sq. in. are adopted, consequently the working pressures are low and a comparatively light and inexpensive engine is obtained. The majority of engines operate on the two-stroke cycle and have solid injection of the fuel.

The weight of the engines varies from about 1½ to 2¼ cwts. per h.p., and the price at the makers' works is from about 7½*l.* to 9*l.* per b.h.p., depending on the size.

Crossley Crude Oil Engines.

The Crossley semi-Diesel engine of the two-stroke vertical type, built in four sizes from 6 to 20 b.h.p., and has a separate scavenging pump. Crankcase compression is eliminated, and this enables forced lubrication to be used for the bearings.

The engines will work on paraffin, gas oil, and the heavier crude and residual fuel oils with good economy, and because of the forced lubrication system the lubricating oil consumption is only about 1 per cent. of the fuel consumption.

The scavenge pump is attached to the side of the engine and delivers the air to the cylinder through water-cooled ports uncovered by the piston. The fuel pump is operated from the crankshaft by a cam, and governing is by allowing the excess oil to pass back to the suction side of the pump, through the control valve in the pump.

Petter Medium Compression Heavy-Oil Engines.

The Petter heavy oil engine has recently been modified to dispense with the usual hot bulb, and is built in sizes from 25 b.h.p. in one cylinder to 600 b.h.p. in six cylinders.

The vaporiser is entirely water-cooled and ignition is effected spontaneously by the internal heat of the compressed air, after the initial heat at starting. The piston and under-side of the cylinder head are entirely symmetrical, so that they are free for expansion. The atomiser is a simple automatic spraying device arranged to be adjustable to suit different grades of fuel oil. The improved design enables a very low fuel consumption to be obtained, this being only 0·43 lb. per b.h.p. per hour in the larger sizes.

The engine is illustrated by figs. 22, 23. Crankcase compression is adopted and is maintained dry from lubricating oil, with the result that the consumption is extremely low. This, together with the improved efficiency, renders the exhaust practically invisible at all loads.

Smaller engines of the semi-Diesel type from 5 to 42 b.h.p. are manufactured at the Yeovil works of Messrs. Petter.

Petter marine engines are made in units of one, two, three, four, and six cylinders, ranging in power from 5 to 600 b.h.p.

The single and two-cylinder engines are fitted with a clutch and reverse gear; the three, four, and six-cylinder engines are directly reversible by compressed air, and these engines do not require a clutch, but are supplied with an independent air compressor and electric generator oil engine driven set. Also these engines have a thrust block of the Michell type.

All of the engines are fitted with bilge and circulating pumps, and the main bearings are water-cooled, and the marine engines comply with Lloyd's, Bureau Véritas, and Board of Trade requirements.

Clayton-Babcock Crude Oil Engines.

These engines are made in sizes 6 to 150 b.h.p. They work on the two-stroke cycle principle, with an impulse at every revolution, securing a very even turning movement, rendering the engine especially suitable for electric lighting and other purposes where very steady running is essential.

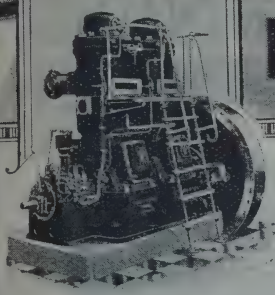
PETTER

OIL ENGINES



The World's Best Oil Engine

Thirty Years Reputation

LOW PRESSURES.
LOW TEMPERATURES.
LOW MAINTENANCE.

OVER 500,000 BRAKE HORSE-POWER of Petter Oil Engines are running in all parts of the world for industrial, electrical and marine purposes. They are famous for their reliability, simplicity and clean combustion.

THE PETTER LATEST MODEL "C" TYPE HEAVY-OIL ENGINE with Completely Cooled Combustion Chamber is a medium compression engine which works perfectly on any grade of residual or heavy fuel oil. Its fuel and lubricating oil consumption over long periods is lower than that of the four-cycle high compression or Diesel engine.

THE PETTER ENGINE is a **British** production throughout and represents the outcome of over thirty years' accumulated experience in oil engine design and manufacture.

They are of the simplest possible construction, there being no exhaust or inlet valves, side shafts, cams, skew gears, and rocking levers, and the absence of these complications ensures long life and low cost of upkeep.

The engines work on all kinds of fuel oil, the consumption being very low, and the working cost ½*d.* per b.h.p. per hour, based on the present price of fuel oil in this country.

A special feature of these engines is that while the crankcase is totally enclosed, protecting all working parts from dust and dirt, complete accessibility is secured by the patent removable crank-case cover, which can be easily and quickly lifted off, thus rendering the engine as accessible as the open type four-cycle engine.

Marshall Crude Oil Engines.

Messrs. Marshall, Sons & Co., Ltd., Gainsborough, were one of the earliest makers of the semi-Diesel engine, having commenced their manufacture in 1911, and they make horizontal engines from 8 to 25 b.h.p., and vertical engines from 30 to 450 b.h.p. The horizontal typeis largely supplied on portable carriages for agricultural and other work.

The engines operate on the two-stroke cycle, and have an impulse every revolution. The governor is mounted on the crankshaft and controls the stroke of the fuel pump plunger automatically at all loads, so that the amount of fuel injected into the cylinder is proportional to the load and no hand regulation whatever is required. A noteworthy feature of the governor and fuel pump gear is that they are totally enclosed and work in an oil bath.

Marshall engines have a wide range of speed variation and do not cool down when running quite light. Also they will take overloads without trouble and no water injection is required in the cylinder. Separate cylinder liners are fitted on all sizes, and the engines are extremely economical in fuel and lubricating oil. Numbers of these engines have been supplied for Town and other Councils, for lighting, pumping, and sewage disposal. Among the many installations of Marshall engines may be mentioned one of three 200 b.h.p. engines which supply power continuously day and night in a chemical works.

Campbell Crude Oil Engines.

Vertical engines of the two-stroke cycle are made by the Campbell Gas Engine Co., Halifax, in sizes from 23 to 270 b.h.p. for land and marine purposes. They are supplied with single, two, and four cylinders.

The engines are of the usual valveless type, and have ports in the cylinder so that the air inlet and exhaust periods are controlled by the piston. All of the parts are substantially constructed and the engines are easily started; all sizes being arranged to start by means of compressed air at 120 to 150 lbs. pressure.

Lubrication, as well as other important details, has received careful attention on the engines, and the large number in use indicate the success of the engines. They work on gas oil, solar oil, kerosene, and the lighter crude and residual oils.

Beardmore Oil Engines.

Engines in powers from 10 to 600 b.h.p. are made by William Beardmore & Co. Ltd., Coatbridge. The engines are of the vertical design working on the two-stroke cycle and are supplied in from one to six cylinders for both land and marine purposes.

The crank-case of the engine is used as a pump, the air drawn in through the covers is compressed during the downward stroke of the piston and admitted to the cylinder when the piston is nearly at the bottom of its stroke. The exhaust ports are already uncovered and the shape of the piston top deflects the air to assist in scavenging the cylinder. The air in the cylinder is compressed during the upward stroke of the piston and fuel is injected by means of a pump through an atomiser into the combustion chamber when the piston is nearly at the top of its stroke.

A number of these engines are in use for electric lighting and power purposes and for driving various kinds of industrial machinery, but the majority have been installed in yachts, barges and coasting vessels of all descriptions.

The weight of the engines varies from about 1¾ to 2¼ cwts. per horse-power for land work and from about 1½ to 2 cwts. per horse-power for marine propulsion.

Allen Oil Engines.

Crude oil engines are made by W. H. Allen, Sons & Co. Ltd., Bedford, in single, two and four cylinder sizes ranging in power from 10 to 320 b.h.p. Particulars of the engines, giving cylinder dimensions, are given on p. 1960. The rating and speeds are moderate and the engines are capable of running continuously at full power.

The engines work on the two-stroke cycle and have an impulse every revolution, the governor being arranged to control the amount of fuel oil injected in proportion to the load. They can be started in a few minutes by preliminary heating of the vaporiser with a blow lamp, which is used at starting only. They will run at any load for an indefinite period without the starting lamp or any other additional device; also no adjustment is required for light running, and the engine will run under no-load without misfiring.

A noteworthy feature is that the engines will work satisfactorily when running at reduced speeds, down to as low as half the normal speed. Regular running is obtained and the exceptional economy of these engines is still maintained.

The engines will work on almost any good quality crude or residual oil of specific gravity up to ·95, and the fuel consumption is only ·5 pint per b.h.p. per hour at full load. At ¾-load the consumption per b.h.p. is slightly increased and at ½-load the increase is not more than 20 per cent. Thus each engine has a large economical range of power.

Brotherhood Oil Engines.

Single and twin cylinder horizontal crude oil engines from 16 to 130 h.p. per cylinder are manufactured by Peter Brotherhood, Ltd., of Peterborough.

An illustration of an engine of 130 h.p. is shown in fig. 24.

These engines use compressed air for starting only, the injection of the fuel being performed by a pump the stroke of which is varied according to the load by a centrifugal type governor.

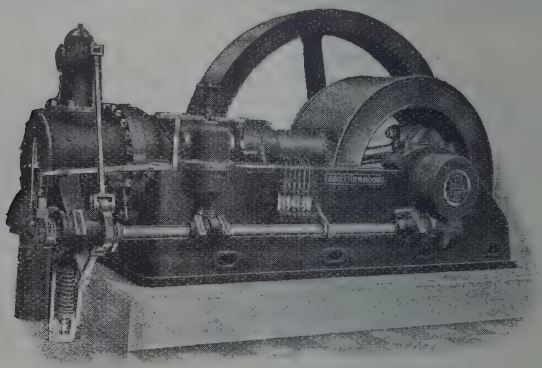

Fig. 24.—Peter Brotherhood Oil Engine.

They start without any preliminary heating when using all kinds of petroleum and its derivatives, such as crude oil, mazout, and tar oil.

The compressor for providing the air for starting is an independent unit, arranged to be driven by belt or separate motor, and, in case of need, by hand.

The consumption of crude oil with a calorific value of about 18,000 B.T.U. per lb. varies from 0·42 to 0·55 lb. per b.h.p. hour at full load, according to size.

Robey Oil Engines.

Semi-Diesel engines for land and marine work are made by Robey & Co., Ltd., Lincoln, in various sizes from 12 to 280 b.h.p. They are of the vertical two-stroke cycle type and are extremely simple.

The fuel is injected into the combustion chamber through a special form of sprayer, which gives good atomisation. The governor is of the centrifugal type mounted direct on the crankshaft and controls the amount of fuel injected in proportion to the load.

Robey engines will run on the usual kinds of refined, crude, or residual oil, and they have worked satisfactorily on tar oil.

Bolinder Engines.

The Bolinder engine (fig. 25), although essentially of the hot-bulb type, contains several features which distinguish it from other motors of this class. It is a high standardised production, and is now made in sizes up to 500 b.h.p. in four cylinders. As in most other motors of this design, the air is drawn in the crank chamber on the compression stroke of the piston, this air being compressed to a relatively low pressure in the crank chamber by the piston on its outward stroke. Just before the piston reaches the end of its stroke the exhaust ports are uncovered in the cylinder, allowing the exit of the exhaust gases, which are finally completely driven out through the exhaust pipe by the admission of the compressed air from the crank chamber through further ports in the cylinder wall uncovered by the piston as it continues on its downward stroke. On the upward stroke the piston compresses the air thus taken into the cylinder, and on reaching the top of its stroke the fuel is sprayed into the hot-bulb, thus causing combustion, vaporisation, and expansion within the cylinder. The bulb is kept hot by the heat due to the combustion, and the compression is usually about 125 to 150 lbs. per square inch. It is, of course, necessary to heat up the bulb by a blow-lamp before starting, but once the engine is running it is not necessary to keep the lamp burning, even when operating on light load.

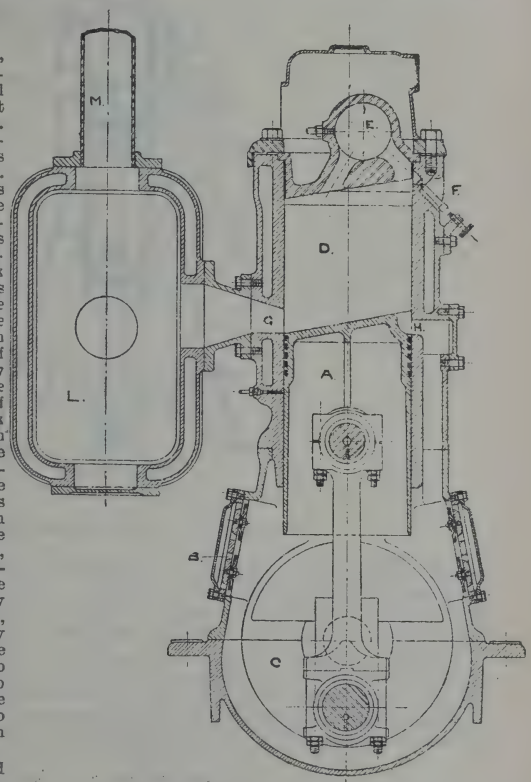

Fig. 25.—The Bolinder Engine.

Engines of 90 b.h.p. and above dispense with water injection into the cylinder, and are fitted with small two-stage air compressors driven from the main crankshaft. Compressed air is forced into the bulb at the same time as the fuel. If required the engine can be run at about three-quarters power with the air compressor disconnected and without overheating. On the smaller sizes, water injection is retained, as it is possible to obtain a higher power for given cylinder dimensions.

For marine work, the Bolinder engine is made directly reversible, the principle being, broadly, the injection of fuel to cause an explosion after the engine has slowed down nearly to the point of stopping, and whilst the piston is on the upward stroke, so that reversal of motion follows. This is carried out by a special device regulating the action of the fuel pump.

The Bolinder motor is manufactured in Stockholm, but is handled in Great Britain by Messrs. James Pollock, Sons & Co. Ltd.

'MIRRLEES-SIMPLEX' OIL ENGINES.

Messrs. Mirrlees, Bickerton & Day Ltd., of Stockport, are now manufacturing a semi-Dies type of oil engine known as the 'Mirrlees-Simplex' engine. This series of engines is an additio to the firm's extensive range of 'Mirrlees-Diesel' engines, for which they have a world-wic reputation, and the powers are from 35 b.h.p. to 240 b.h.p.

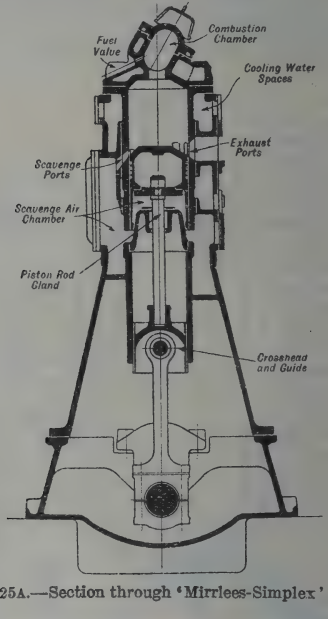

FIG. 25A.—Section through 'Mirrlees-Simplex' Engine.

The 'Mirrlees-Simplex' engine is a low-compression two-cycle engine employing mechanica fuel injection and forced lubrication for the bearings. The outstanding feature of this engine i the elimination of the use of crankcase compression. This important departure from the commo practice has been attained by employing the crosshead type of construction and compressing th scavenging air in the chamber formed between the piston and a gland plate through which th piston rod passes (see fig. 25A).

This design completely isolates the crankcase from the cylinder, so a copious supply of lubri cating oil can be used for all working parts within the crank-chamber without oil being carrie over with the scavenging air into the cylinder, and the consumption is reduced. Also the crank chamber oil is unaffected by piston and cylinder temperature, no grit is drawn into the crank chamber with the scavenging air, the crosshead pin is not affected by the piston temperatures and the side thrust on cylinder walls and piston is eliminated.

FIELDING AND PLATT OIL ENGINES.

The well-known 'Fielding' Horizontal Four-stroke Semi-Diesel Oil Engines, of which ther are many hundreds in operation, have special features, and are of the low compression hot bull type. They are made in sizes from 12½ b.h.p. to 400 b.h.p., and the compression is 250 lbs. pe sq. in. In practice this compression enables engines to be started with 150 lbs. air pressure and it is important to note that for factory work, if ever the air receiver becomes exhauste these engines can easily be started by hand with the half compression cam in action.

The engines will run without attention from the time they are started, and, being fitted with the 'Fielding' patent pump and governor control, work with exceptional smoothness. Al patterns are of the single flywheel and third bearing type with separate water chamber at bac end, and the cylinder is fully supported with oil tray round bed. Up to 100 b.h.p. single-cylinde engines are standardised, and above this power twin cylinder. The consumption of fuel varie from 0·45 lb. per b.h.p. per hour on the larger sizes down to 0·55 lb. per b.h.p. per hour on th smaller engines.

THE STILL (I.C. + STEAM) ENGINE.

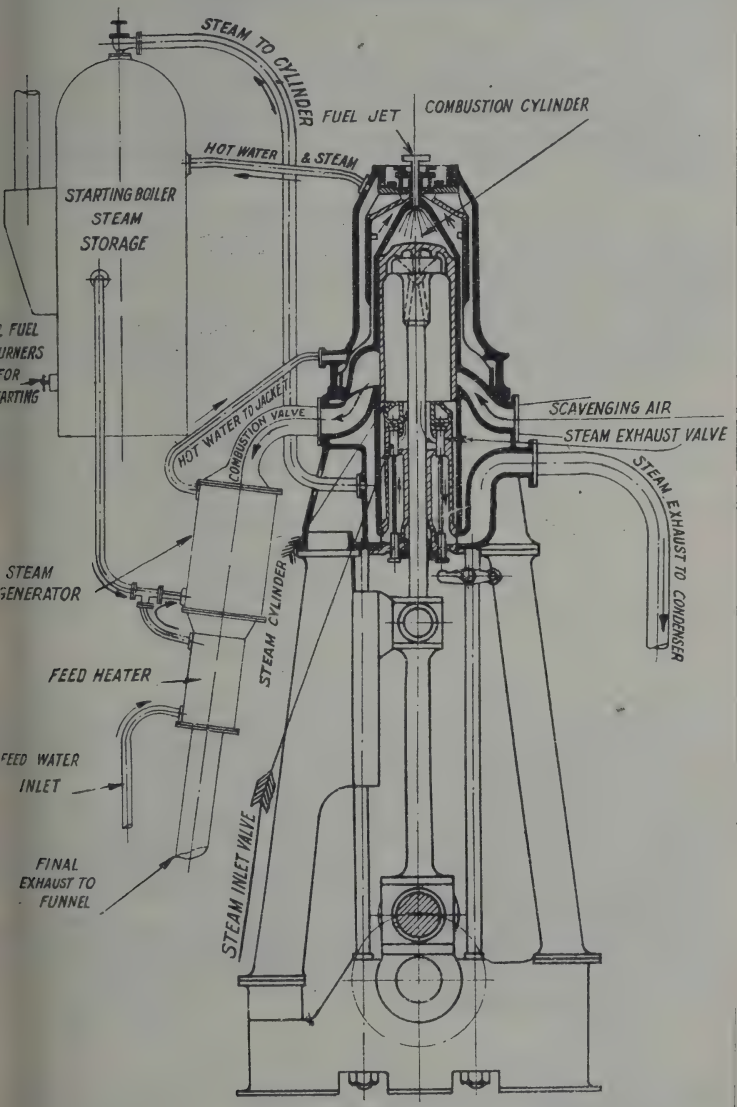

FIG. 26.

The fuel-injection system consists of a plunger pump fitted with a sleeve valve which is un control of the governor, and acts as a cut-off valve. The injection pump works very smooth and without noise.

Other Makes of Semi-Diesel Engines.

Semi-Diesel engines of the horizontal four-stroke cycle type are manufactured by Tangy Ltd., Birmingham, and Bates & Scholes, Ltd., Denton, Manchester.

Engines of the vertical design operating on the two-stroke cycle are also made by Plenty Son, Newbury; the Aster Engineering Co., Wembley; John Kirkaldy, Ltd., Burnt Mill; Nor Henty & Gardners Ltd.; the Keighley Gas & Oil Engine Co., Keighley; Widdop & Co., Keighl Clayton & Shuttleworth, Lincoln; Babcock & Wilcox; and the Hamworthy Engineering Ltd., Poole.

Still (I.C. + Steam) Engines.

An engine of high thermal efficiency has been developed by the Still Engine Co. and is ma factured by several licensees. The main working cylinder uses liquid or gaseous fuel, and in same cylinder, on the opposite side of the piston, steam is employed. The steam is produced the recoverable heat from the internal combustion side, which passes through the walls of cylinder as well as into the exhaust gases.

Heat, wasted in other internal combustion engines, is usefully employed in the Still eng to increase the power of the engine and reduce the consumption of fuel per horse-power develo

As will be seen from fig. 26, the jacket and cooling water form part of the circulating sys of a steam generator, which may be an integral part of the engine. The cylinder liner is speci

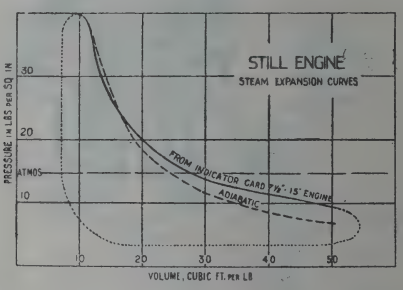

Fig. 27.

constructed and is about one-third of the usual thickness; it is ribbed externally to add t conducting surface. The quantity of steam capable of being generated from the rejected h of an internal combustion engine depends upon the efficiency of the combustion cycle and on load. At full load the quantity may be about 7 lbs. per b.h.p. of the engine.

In the indicator diagram (fig. 27) taken from the under, or steam, side of the piston, adiabatic expansion line as plotted shows there is no loss from condensation. Heat is ta from the piston and cylinder walls and the steam exhausts at a slight superheat.

An experimental engine tested by Professor Vernon Boys generated 3·28 lbs. of steam f the jacket alone, and from the jacket and exhaust together 6 lbs. of steam per b.h.p. hour. average m.e.p. from the combustion stroke was 90 lbs. per sq. in. The steam evaporated by heat rejected gave 14 lbs. m.e.p. per sq. in. on every return stroke of the piston. Thus, the f stroke cycle engine had a total m.e.p. of 118 lbs. per cycle.

The possibilities of this design are very great; by admitting additional steam generated fuel under the boiler, the total m.e.p. can be increased considerably. This enables the en to take big overloads, and by the use of steam easy starting and manœuvring are obtained.

The thermal efficiency of the Still engine compared with other prime movers is shown in ollowing table:

Marine steam engine, superheated	16% to 17%
Parsons steam turbines	15 ,, 20
Gas engines	22 ,, 30
Petrol engines	23 ,, 27
Semi-Diesel engines	27 ,, 30
Still gas engine	31
Still petrol engine	33
Diesel engines	30 ,, 36
Still oil engines	38 ,, 44

HIGH-COMPRESSION OIL ENGINES.

The high-compression oil engine is the outcome of experiments to simplify and reduce the cost of Diesel engines. Many attempts have been made to produce engines capable of burning cheap heavy oils with an economy approaching that of the Diesel, but in which the high-pressure air blast is avoided without sacrificing the capability of the engines to start immediately from cold.

Among the first of the successful engines was the Vickers, which has been largely developed for propelling submarines. Several other makes of high-compression engines are now on the market, and the elimination of the air compressor has produced a marked improvement as regards simplicity compared with Diesel engines.

What is known as 'solid injection' is adopted for spraying the fuel into the cylinder, the oil being raised to a high pressure by the fuel pump momentarily at the period of injection, or permanently in a small receiver and admitted to the cylinder by timing the opening of the fuel admission valve.

The weight and price per horse-power are lower on these engines than Diesel engines, but up to the present the economy is not quite so good.

Vickers Oil Engines.

High-compression oil engines for land or marine purposes are manufactured by Vickers. Ltd., Barrow-in-Furness, in sizes from 500 b.h.p. upwards. The engines are of the vertical, multi-cylinder, four-stroke cycle type.

The mechanical fuel injection system on these engines has been used for the last eleven years and no air blast is required for the fuel. The engines will start from cold without preliminary heating of any part. A sufficiently fine spray into the cylinder is obtained by forcing the oil at a high pressure through minute holes in a special nozzle below the fuel-injection needle valve.

A fuel pump may be fitted for each cylinder, or two pumps can be used for all the cylinders, and delivering the oil at a pressure of from 2,000 to 4,000 lbs. per sq. in. into a pulsator tube from which it passes through a special strainer to the needle valve in the cylinder head. The pressure depends upon the speed and power at which the engine is running. Control of the power is obtained by varying the time and the amount of opening of the fuel valve, and by adjusting the pump to the desired pressure.

Engines of a total horse-power of nearly 500,000 have been built, and the makers claim the following advantages over Diesel engines :

High-pressure air for fuel injection eliminated.

Increased safety in working and lower compression pressure.

Reduction of space, weight, and cost.

Elimination of cooling effect of air blast on p ston and cylinder head.

The six-cylinder 1,250 b.h.p. engine has cylinders 24·5-in. diam. by 39-in. stroke, and the normal speed is 118 r.p.m. The fuel consumption is stated to be as low as 0·38 lb. per b.h.p. per hour.

Crossley Oil Engines.

Crossley Bros., of Openshaw, Manchester, make high-compression oil engines in sizes from 20 to 300 b.h.p. single cylinder, and up to 260 b.h.p. double cylinder. The engines are of the horizontal four-stroke cycle type.

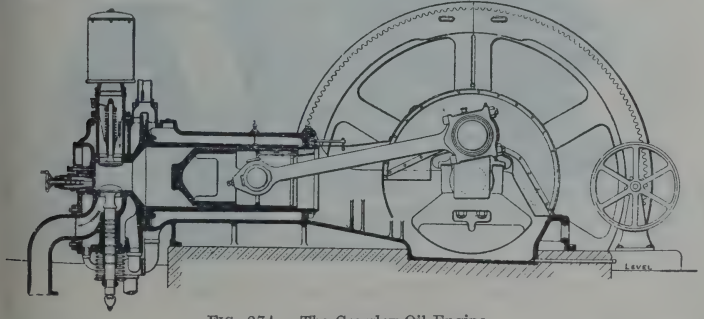

Fig. 27A.—The Crossley Oil Engine.

All of the engines start up from cold without preheating, and will work on crude, refined, or residual and vegetable oils. The patent fuel pump and governor gear are particularly interesting, as the commencement of the fuel injection is constant at all loads. Governing is effected by

reducing the amount of the charge delivered by the fuel oil pump at reduced engine loads; t full consumption is thus, as far as possible, proportioned to the power output. Messrs. Cross state that in a recent test the consumption of (crude) oil for b.h.p. hour at full load was 0·39 l and at about half load rose to only 0·44 lb. with their governing arrangement. They point that this performance compares favourably with that of the more costly Diesel type of engine

These engines can be supplied as convertible engines to work with either fuel oil or produ gas, whichever may be the cheaper fuel at the time.

Crossley Premier Oil Engines.

The Premier Gas Engine Co., Ltd., of Nottingham, in combination with Messrs. Crossley Bro Ltd., now build cold-starting multi-cylinder horizontal heavy-oil engines with solid injection fuel. The engine is made in units up to 1,200 b.h.p. and is specially adapted for direct coupling electric generators.

Up to 500 b.h.p. there are three and four cylinders mounted on one bedplate, above 500 b.h there are two bedplates, each having mounted thereon three or four cylinders, with central dri

The engine has the advantage of low head room and accessibility to all working parts. It very economical in fuel and lubricating oil, and is specially suitable for working on heavy residu fuel oils; also will start from cold without preheating.

Ruston-Hornsby Oil Engines.

This engine of Messrs. Ruston & Hornsby, Ltd., fig. 28, is of the solid injection type. T makers have succeeded in dispensing with the high-pressure air blast for fuel injecti altogether, a quick-acting fuel force-pump being employed to inject the fuel oil through a specia designed mechanical atomiser.

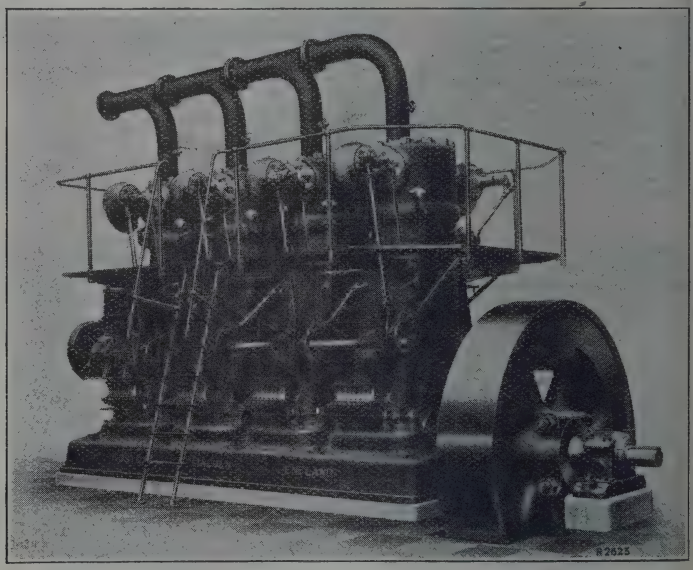

Fig. 28.—Ruston Four-cylinder Vertical Engine.

Starting is effected with certainty from cold under all conditions without any prelimina heating or any special starting device being employed.

The engines are built in single and multi-cylinder units, and range from 16 b.h.p. to 340 b.h. in the horizontal form, and from 55 b.h.p. to 825 b.h.p. in the vertical type.

Fig. 28 shows a 440 b.h.p. engine of the vertical type.

CROSSLEY

Ruston Economy Maintained!

Experience Counts

"Averaged over the whole 8.029 hours' run by the engine, the fuel consumption has been 0.698 lb. per kw.-hour, with a running plant load factor of 46.5 per cent. The question has been raised as to whether the fuel economy would be maintained with this type of engine. In connection with this it will be useful to state that during the last 1,120 hours' run by the engine the consumption has been 0.693 lb. per unit generated with a running plant load factor of 50 per cent. Therefore there was no sign of falling off in economy after 7,000 hours' running.

"The engine has now run 8,000 hours and experience of it has justified the installation of a further engine of the same type."

Extract from paper read July 9th, 1925, before the Diesel Engine Users' Association by the Municipal Engineer in charge of the above 4 Cylinder Ruston Engine.

Ruston & Hornsby, Ltd., Lincoln

A special feature is the valve gear, which is actuated by means of an eccentric gear and one slide shaft, thus reducing the number of working parts to a minimum, and giving a compact and silent running engine.

The action of the engine is as follows:—The piston on its outstroke takes in air, which, on the return stroke, is compressed in the combustion chamber, and nearly at the point of greatest compression, the oil fuel is injected by a pump, which forces the oil through a mechanical atomiser. The compression temperature is sufficient to ignite the charge. The power stroke follows, then the exhaust, after which the cycle is repeated. By adopting this cycle, on the one hand a high compression can be used with its attendant economy, without incurring pre-ignition, whilst, on the other hand, an air compressor and air receiver are avoided.

The oil-fuel pump is driven through a lever by a quick-acting cam on the layshaft, which is completely enclosed and runs in oil. A lever is provided by which each pump can be worked by hand, or thrown out of action altogether to stop the engine. The fuel pumps and side shafts of the horizontal engines are carried by the bedplate, thus relieving the cylinder head.

The mechanical atomiser, which is fixed in the combustion head, consists of a duplex valve loaded by a powerful spring, which is lifted at each stroke of the oil-fuel pump. The valve has two seats of different diameters, the smaller of which closes the opening of the combustion chamber, and the larger a leak pipe to the oil tank. When the smaller valve lifts, the oil is forced through channels converging to a central outlet, which so split up the stream that it emerges on either side of the nozzle in a cone-shaped cloud of oil particles. The movement of the valve is about $\frac{1}{70}$th inch, and is entirely automatic in action. There is no packing or oil-tight diaphragm, or any complication liable to get out of order, and the action, though delicate, is found in practice to be absolutely reliable.

The regulation of the speed is effected by the opening of a by-pass valve by the governor, the toe of the valve resting upon a lever carried upon a cam. The fulcrum of the lever is adjustable by a screw, so that although the lift of the valve is minute, there is always a means at hand for easily keeping it in perfect adjustment. The consumption of oil, even the lowest grade of crude, residue, or fuel oils, is complete, while the economy is remarkable.

Tests which have been made show that a high thermal efficiency is obtained with the cheapest fuel oils on the market, the consumption ranging from 0·40 to 0·47 lb. per b.h.p. hour according to the size of the engine.

National High-Compression Oil Engines.

The National Gas Engine Co., Ltd., Ashton-under-Lyne, make high-compression oil engines in sizes from 18 to 100 h.p. single-cylinder type, and up to 200 h.p. in double-cylinder engines. The engines are of the horizontal four-stroke cycle type. These engines start up from cold without pre-heating, and will work from crude and residual oils.

A special fuel pump and governor gear are fitted, which give efficient and silent running, and the engines fire at all loads. The fuel consumption of these engines is as low as 0·42 lb., and does not rise above 0·5 lb. at half load.

Campbell Cold Starting Heavy Oil Engines.

The 'heavy-oil' engines made by the Campbell Gas Engine Co. Ltd., of Halifax, Yorks, work on the four-stroke cycle with a compression pressure of about 300 lbs. per sq. in.

Air only is taken into the cylinder and compressed by the piston. The fuel is injected at about the end of the compression stroke, so that pre-ignition is rendered practically impossible. The fuel is injected by a cam-operated ram pump through a mechanical atomiser which delivers the fuel into the combustion chamber in the form of an extremely fine spray or mist. The speed of the engine is governed by increasing or diminishing the stroke of the fuel pump and thus the quantity of fuel injected in each cycle; there is no by-pass on the fuel pump. This system provides a working impulse in every cycle at all loads, thus ensuring minimum speed fluctuation and approximate equalisation of the working stresses in consecutive cycles.

By a recent improvement the heating lamp can be dispensed with entirely and the engine started up immediately from cold. The cold-starting system is now the standard for all except small engines, but it can be applied to the latter if required.

In the Campbell heavy-oil engine water drip or injection to the cylinder is not required under any conditions, and no provision is made on the engine for using it.

It is claimed that any kind of crude or residual petroleum may be used, even if it contains asphalt or bitumen. Tar oil (distilled from coal, specific gravity 1·05) can also be used.

The Campbell Co. state that the consumption varies with the size of engine and heat value of the fuel. When using residual petroleum of about 18,000 B.Th.U. per lb., the consumption varies from 0·55 lb. per b.h.p. per hour in an engine of 9 b.h.p. to about 0·43 lb. in one of 100 b.h.p. A test was recently conducted on an engine of 35 maximum b.h.p. extending over a fortnight,

running not less than 12 hours per day, including runs of 24 and of 30 consecutive hours, an finishing with a non-stop run for seven days and nights. This last run consisted of 72 hour consecutively at full load, 24 hours each at $\frac{3}{4}$, $\frac{1}{2}$, and $\frac{1}{4}$ load with a two hours' interval each da at loads varying from zero to maximum, and concluding with 24 hours at full load.

The fuel used during this trial was Mexican fuel oil of 0·96 sp. gr. containing about 3·2 pe cent. of asphalt and having a viscosity of 1,500 sec. as tested in a No. 1 Redwood viscomete The whole of the fuel used was weighed, and the consumption was found to be :—

At full load	. . . . .	0·49 lb. per b.h.p. per hour	
,, $\frac{3}{4}$,,	. . . . .	0·485 ,,	,,
,, $\frac{1}{2}$,,	. . . . .	0·515 ,,	,,
,, $\frac{1}{4}$,,	. . . . .	0·656 ,,	,,

The test was carried out by independent engineers, and during the whole of the time r adjustment of any kind was made to any part of the engine.

The Campbell heavy-oil engine is built in a range of standard sizes from 3½ to 100 max. b.h.p single cylinder, 120 to 340 b.h.p. in two cylinders, and 240 to 680 b.h.p. in four cylinders. It also built in the vertical type with three or four cylinders, from 48 to 630 b.h.p., the larger siz being fitted with crossheads and slipper guides. The makers claim that this engine possess all the advantages of the Diesel engine, while it is simpler in construction, easier to handle, ar lower both in first cost and in running and maintenance.

Blackstone Oil Engines.

Messrs. Blackstone & Co., Ltd., of Stamford, make cold-starting heavy fuel oil engines in siz from 6 to 900 b.h.p., and their patent system of spring injection enables the engines to start fro cold without preheating and work with great economy.

Fig. 29 shows a sectional view of the combustion chamber and the spring injection system. T fuel is injected at the same point at all loads and the combustion period is prolonged so that the is no great rise in initial pressure at the moment of injection. The fuel consumption on the larg engines is only 0·4 lb. per b.h.p. per hour.

The fuel-injection arrangement consists of a low-pressure fuel pump, a moderate-pressure fu injector, consisting of two members with a spiral spring between, and a spring-loaded fuel injecti

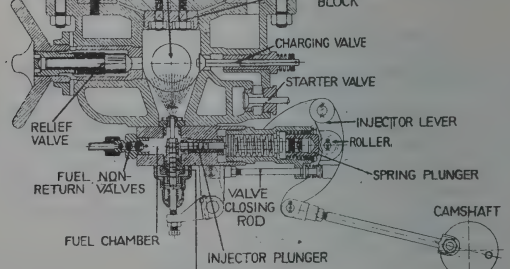

Fig. 29.

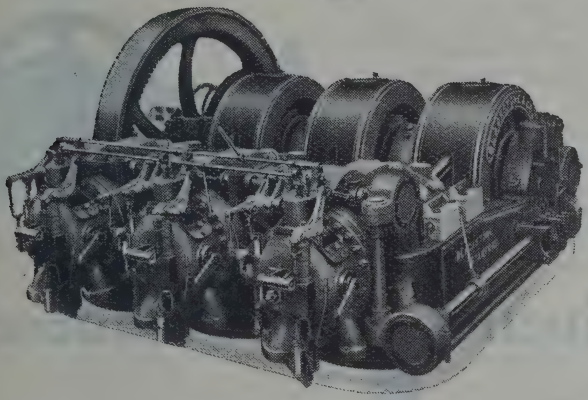
valve. The correct quantity of fuel is delivered by the pump and displaces the injector plung outwards, there being no pressure on this at the moment. The injector lever next compresses t spring, and the injector plunger is held by abutting upon the fuel retained by the injector val which is held on its seating by the compression of an auxiliary spring. This spring is released the timed operation of the injector lever, so allowing the fuel which is under pressure of 1,000 l per sq. in. to open the injector valve. The injector plunger is then forced inwards and injects t fuel through the valve jet orifice into the combustion chamber.

"BLACKSTONE"

SPRING - INJECTION

Oil Engines



These engines are to be found in all parts of the world supplying power for varying requirements — driving pumps for water supplies, drainage, sanitation — operating aerial ropeways—producing electricity for supply companies—providing power direct or electric power and light for large or small workshops, factories, mills, farms, estates, plantations, etc. The fuel consumption per B.H.P. hour is the lowest recorded in this type of engine. This is due to more perfect combustion, and results in a maximum power output, thus providing the power user with

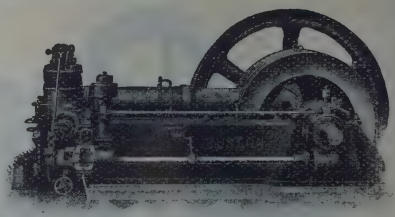
RUSTON

Horizontal Oil Engines

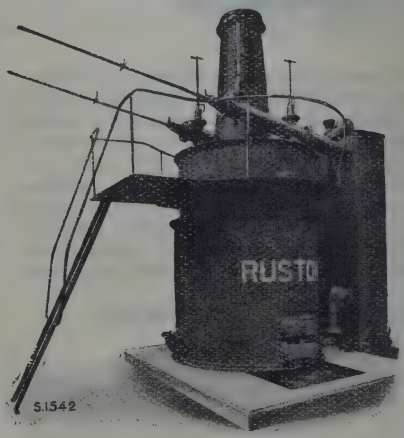
The Best by Test.

Starts from cold under all conditions, has low guaranteed fuel consumption, and works on lowest grade fuel oils.
Made in sizes up to 340 B.H.P.



May we Send you Catalogue?

Suction Gas Producers



Will produce power, light and heat from waste such as wood chippings, sawdust, plumstones, bark, coconut shells, cotton seeds and any combustible refuse.

Paxman Oil Engines.

Cold-starting high-compression heavy fuel oil engines are made by Messrs. Davey-Paxman & Co., Ltd., Colchester, in single, two, three, four, five and six cylinder units, ranging from 25 to 900 b.h.p. at speeds of 360 to 250 r.p.m.

The engines work on the four-stroke cycle with 380 lbs. compression and a maximum pressure in the cylinder of about 550 lbs. Each cylinder stand is a separate casting bolted to the bed, and has a removable liner. The cylinder head is fitted with inlet valve, exhaust valve, and spring injection fuel valve. The crankshaft bearings are ring lubricated, and a mechanically operated lubricator is fitted for the piston and connecting-rod bearings.

The valve gear is their patented eccentric-driven type, which gives a very smooth action to the valves and in a large measure is responsible for the absence of shock and the quiet running of the Paxman engine.

LOW-COMPRESSION OIL ENGINES.

The early oil engines were all low-compression engines, and the desire to use the heavier grades of petroleum, which are cheaper than the more refined grades, caused the development of higher pressures, so that the increased temperature could completely vaporise the heavier fuels.

The low-compression oil engines still have, and will always continue to have, a wide application, owing to the low working pressures and small cost.

In the normal 'oil engine' a heavy kerosene is usually employed as fuel; Russian oil is, in general, rather preferred, though the ordinary American brands are also used with quite satisfactory results. A standardised oil described as R.V.O. (Russian vaporising oil) of specific gravity 0·825 and flash point 86° F. (close test) is regarded as the normal fuel for these engines; other descriptions commonly used, however, include Rocklight, Russolene, Homelight, Gladiator, Phœbus, Silver Spray, Crown Diamond, Royal Daylight, White Rose, Tea Rose, and Bear Greek. Among the heavier fuels used are refined shale-oils as Broxburn and Scotch Lighthouse, and also the refined heavy oils of Burma, Assam, Roumania, etc.

The average composition of the petroleum oils used is 85½ per cent. carbon, 13½ per cent. hydrogen, and 1 per cent. oxygen, and the mean calorific value, by Berthelot calorimeter, is roundly 19,600 B.Th.U. per lb. When arranged to use either petrol, kerosene, or heavier oils, engines usually develop powers in the proportion of about 100 : 90 : 80, respectively.

It should be carefully noted that the nominal power of internal combustion engines in general is for location at sea-level; when required to work at an altitude a deduction from the nominal power should be made of 3 per cent. for each 1,000 ft. of height, due to the diminished density of the air (see table, p. 2024).

In the ordinary oil engine the heavy kerosene fuel is vaporised in a heated chamber maintained at the necessary temperature either by heat derived from the successive explosions (hot-bulb vaporisers), or from the exhaust of the engine; or, lastly, in a few cases, by means of a separate blow-lamp. In most cases a preliminary heating of the vaporiser by a blow-lamp is necessary for 10 to 15 minutes before the engine can be started. These engines are practically all of the single-acting four-stroke type, and compress a mixture of kerosene vapour and air into the combustion chamber.

Ignition of the charge is sometimes automatic; high and low tension magneto ignition is also used, while in cases where lamp-heated vaporisers are adopted tube ignition is general. On account of the care and attention necessary where lamps are used, and also in some cases due to increased fire risks, makers are in general favouring one or other of the methods of lampless ignition.

Ruston-Hornsby Oil Engines.

This widely known engine, invented by Mr. Akroyd Stuart, 1886-1890, first successfully adopted the now largely used 'hot-bulb' in order to vaporise the oil fuel and automatically explode the charge at the proper instant. A sectional view is given in fig. 30 of a present design by Messrs. Ruston & Hornsby, Ltd.; the hot-bulb is seen as an unjacketed, or partly jacketed extension of the combustion chamber, the connection being by a narrow passage as shown; this hot-bulb receives a preliminary heating by a blow-lamp for 10 to 15 minutes and the engine is then turned by hand. On the suction stroke the piston draws a charge of air only into the combustion chamber and cylinder while at the same time a few drops of air are injected by the fuel pump into the hot-bulb and there vaporised; on the compression stroke the air is packed into the combustion chamber and hot-bulb and mingles therein with the heavy petroleum vapour; the mixture is at first too rich to explode, but as the compression proceeds it becomes more and more dilute, and the capacities are so adjusted that just as the piston reaches the end of its stroke the heat of the walls of the hot-bulb automatically explodes the charge. The working stroke next follows and is succeeded by the exhaust; the cycle then recurs.

The temperature of the hot-bulb is maintained by the heat derived from the successi explosions and the ignition is entirely automatic. The engine is thus of the single-acting fou stroke type.

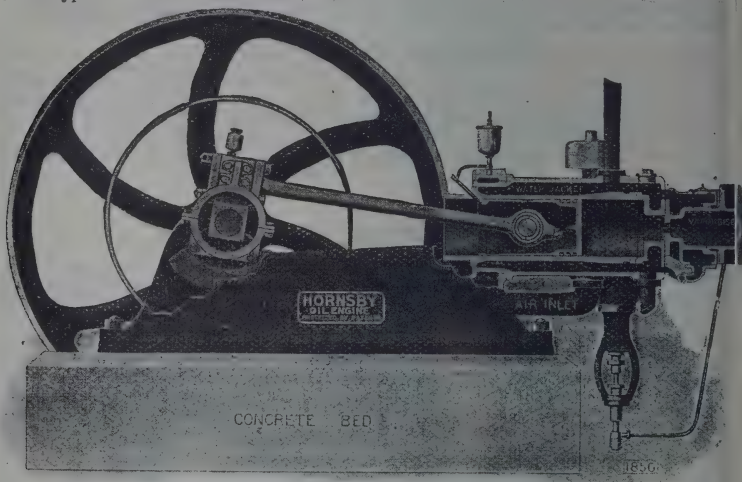

FIG. 30.—The Ruston-Hornsby Oil Engine.

A test by Professor W. Robinson in 1908, of a single-cylinder 32 b.h.p. Hornsby engine, usi 'Russolene' as fuel, furnished the following results:

Duration of trial	1 hour	Brake horse-power	32
Compression pressure, lbs. per sq. in.	85	Total oil burned, lbs.	19·6
Explosion pressure, lbs. per sq. in.	260	Lbs. oil per b.h.p. hour	0·6
Revolutions per minute, mean	230·2	Brake thermal efficiency, per cent.	22·6

BLACKSTONE OIL ENGINES.

When starting these engines the vaporiser and the igniter are heated by a lamp in from four six minutes. The flywheel is then turned forward by hand (unless a self-starter is used) to obta the first explosion, after which the engine works automatically, the necessary heat for the vaporis and for ignition being maintained by the successive explosions; a continuous burning lamp therefore dispensed with. A timing or ignition valve is used to regulate the period of ignitio During compression this valve cuts off all heated parts, and the utmost regularity of the explosio under all loads is secured. A patented water drip valve is fitted to enable a small quantity of wat to be admitted to the vaporiser to regulate its heat on long, continuous, heavy loads. As long there is oil in the tank the engine continues to work.

The engine is governed by means of our patent direct-acting shaft governor, which contr the vapour valve—this system having been found to give the most economical and efficient resul It regulates the oil consumption to the power given off. The speed may easily and instantly regulated whilst the engine is running.

Any ordinary lamp oil may be used, but the efficiency of the engine depends upon the qualit

BLACKSTONE 'COLD-STARTING' KEROSENE ENGINE.

This engine (which has magneto ignition) is specially suitable for small electric-lighting uni It works on the following cycle: On the suction or forward stroke, the cylinder is filled with pu air, which is drawn in through the air valve and compressed during the return stroke into the co bustion chamber; during the last quarter of return stroke a charge of oil is forced by the fuel pun through the oil jets and broken up into fine mist by a blast of compressed air which blows it throu the bunsen port directly into the centre of combustion space. This air blast also induces a flo of air from the combustion chamber through circulating ports, thus forming a rich combustib mixture surrounded by excess air, which is fired by an electric spark from the sparking pl

situated so as to ignite the tail end of the mixture. The working or expansion stroke is thus produced, at the end of which the exhaust valve opens and allows exhaust products to be driven out of the cylinder on return stroke of piston, after which the whole cycle is repeated. As each charge of fuel is measured directly from the sensitive graduating governor great economy and low speed, variation is assured, and speed can be instantly regulated by hand whilst the engine is running. The engine can be started instantly from cold, on paraffin without petrol, lamp, or other external heat for the A size and upwards, but the V to O are hand-started and require an egg-cup full of petrol to give the first few impulses.

National Oil Engines.

Oil engines of the horizontal four-stroke cycle type are made by the National Gas Engine Co., Ltd., Ashton-under-Lyne, in sizes from 2½ to 47½ b.h.p. These engines are made in two types: (*a*) the petrol-paraffin engines, which start on petrol and then run on paraffin, and are fitted with electric ignition, and (*b*) the hot-bulb engines, a special feature of which is the vaporiser and ignition timing device, which secures effective vaporisation of the oil and the proper timing of the ignition at all loads. A lamp must be used for starting on the hot-bulb engines, and the vaporiser needs to be heated for about ten minutes to make it hot enough to start the engine.

The engines are supplied both stationary and portable, and are suitable for agricultural and industrial work.

Hamworthy Oil Engines.

Hamworthy oil engines are made in eight sizes—2½, 3½, 6, 9, 11, 15, 20, and 25 b.h.p.—and are manufactured on strictly repetition lines by the Hamworthy Engineering Co., Poole.

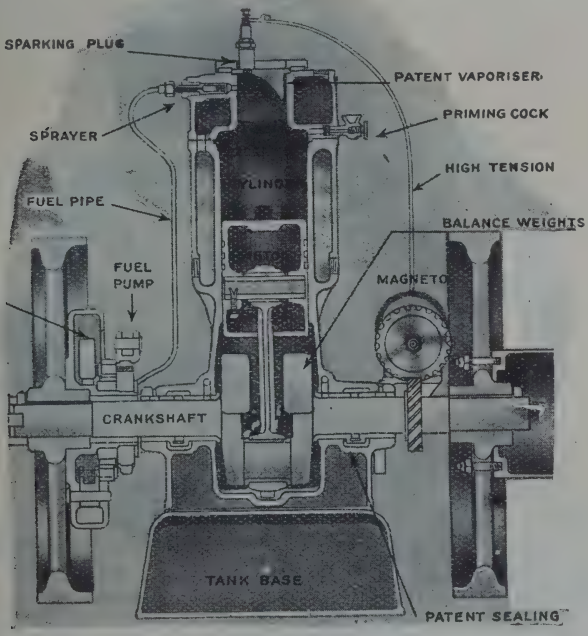

Fig. 31.—The Hamworthy Oil Engine.

These engines are supplied stationary, semi-portable, or portable. They are exceptionally reliable, and are suitable for any purpose requiring power.

Fig. 31 shows the extreme simplicity of these engines; they are stated to be most economical, the full load fuel consumption being only 0·44 pint per b.h.p. hour in the larger sizes.

Magneto ignition is fitted on sizes 2½ to 9 b.h.p., and the engines can be started up immediately by one turn of the crankshaft on petrol, then changed over to paraffin fuel. The larger sizes work on any residual fuel oils up to 0·95 sp. gr. and are now made in multi-cylinder sizes up to 150 b.h.p.

Robson Oil Engines.

Horizontal oil engines of the four-stroke cycle type from 9 to 75 b.h.p. are manufactured by John Robson Ltd., Shipley.

The engines are suitable for using paraffin and light crude oils. A separate cylinder liner is fitted and the bed is well supported on the foundation, the bed and cylinder jacket being in one casting.

The combustion chamber is a separate casting bolted to the bed, and the valves are arranged vertically, so that they are easily accessible. The governor is of the centrifugal type and regulates the amount of fuel injected into the combustion chamber.

Petter Oil Engines.

Engines of the two-stroke vertical type have been manufactured by Messrs. Petters, Ltd., of Yeovil, for many years, and the company have supplied over 25,000 oil engines. The small sizes are the well-known Petter 'M' type engines, suitable for farm, estate, and factory machinery, electric lighting, pumping, and other purposes.

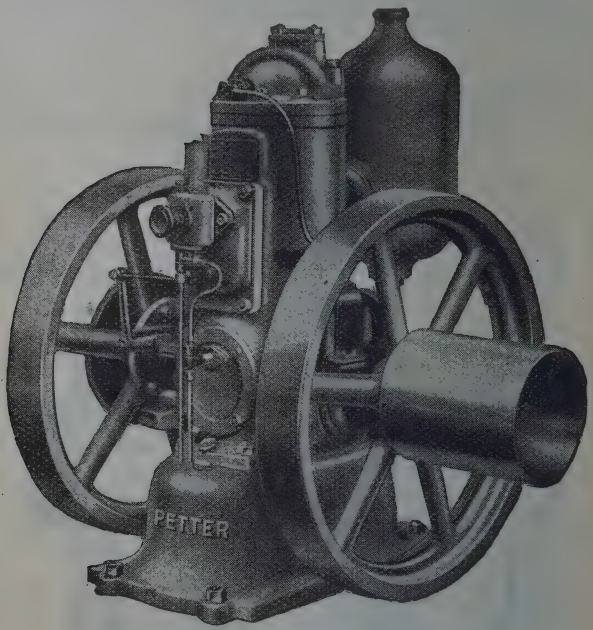

Fig. 32.—The Petter 'M' type Oil Engine.

The Petter 'M' type engines are made in three sizes: 1½, 3, and 5 b.h.p.; and in three patterns: stationary, for fixing on concrete (as illustrated), semi-portable on wood skids, and portable on four-wheeled carriage.

These engines work on paraffin and have magneto ignition. They are started on a small quantity of petrol, and change over automatically to paraffin after working for a few minutes. By means of the patent fuel injector, the paraffin is vaporised and burnt with the same completeness as in a petrol engine, and at half the cost of fuel.

A STATEMENT OF FACT

PROMISES v. REALITY

Electricity for power can rarely be bought for less than **1d.** a unit.

Generated by a

BROTHERHOOD HEAVY OIL ENGINE

of 130 H.P., working at $\frac{3}{4}$ full load 3,000 hours a year and making full allowance for fuel, interest, depreciation, wages and stores, the cost is $\frac{5}{8}$d. a unit—

The Dorman Engine.

Messrs. W. H. Dorman & Co., Ltd., Stafford, manufacture two, four, and six-cylinder engines in various sizes developing 8 to 100 b.h.p. at 1,000 r.p.m., as shown in the following table:

No. of Cylinders.	Bore m/m.	Stroke m/m.	Volume c.c.	B.H.P. 1000 r.p.m.	Treasury Rating.
4	66	100	1368	8	10·5
4	69	100	1496	10	11·8
4	80	130	2613	19	15·9
2	120	140	3166	20	17·8
4	95	140	3970	25	22·4
4	100	140	4398	30	24·8
6	95	140	5954	44	33·6
6	100	140	6597	48	37·2
4	120	140	6333	45	35·7
4	120	185	8369	72	35·7
6	120	185	12553	100	53·6

The cylinders are monobloc except on the 100 h.p. six-cylinder engine, where they are cast in two pairs of three each, and on the 45 h.p. engine, where the cylinders are cast in two pairs. The larger sizes are fitted with detachable heads of the Ricardo patent turbulent type. Side-by-side valves have been adopted, owing to their silence in operation, and the inlet valves are 3 per cent. nickel steel, while the exhaust valves are of stainless steel.

These engines are specially designed to meet the demand for increased passenger and weight carrying capacities of vehicles, and the increasing use of internal combustion engines for locomotives and rail cars.

Other Makers of Oil Engines.

Engines of the horizontal four-stroke type are also made by Crossley Bros., Ltd., Manchester; Fielding & Platt, Gloucester; and Tangyes Ltd., Birmingham.

Vertical engines are made by Gardner & Sons, Patricroft; the Parsons Engine Co., Southampton; J. I. Thornycroft & Co., Basingstoke; the New Pelapone Co., Leeds; and Lister & Co., Dursley.

INTERNAL COMBUSTION TURBINES.*

(Contributed by T. B. Morley, D.Sc., M.I.Mech.E.)

The heat engine which has the highest thermal efficiency is an internal combustion engine; the one which can be made in units of maximum power and which, moreover, has many attractive features, such as almost perfect balance due to its purely rotary motion, and small bulk in relation to output, is the steam turbine. It is not to be wondered at, therefore, that engineers have reflected upon the desirability of a prime mover which should combine the merits of both these types. The internal combustion turbine has been the dream of many speculative and inventive minds, but, though many hundreds of patents have been taken out for internal combustion turbines, few have yet been constructed, and none has so far passed the experimental stage.

It is evident, therefore, that there are serious difficulties to be overcome in order to produce a successful internal combustion turbine.

Speaking generally, in all internal combustion turbines, fuel, gaseous or liquid, is burned, and the products of combustion, issuing from the combustion chamber through nozzles at high velocity, impinge upon the blades of a turbine rotor. In comparison with the cycle of a reciprocating engine, the chief difference is that, whereas in that engine the expanding gases do work upon a piston, in the turbine the energy of the gases takes the form of kinetic energy, which is represented in the acquisition of velocity by the jets of gases which are led to the turbine blading.

The combustion, as in the case of the reciprocating engine, may be at constant pressure or at constant volume, or at a combination of the two conditions. If it is at constant pressure, in order to obtain a cycle of reasonable ideal efficiency, the working substance must be compressed before

* See also 'The Internal Combustion Turbine,' by T. B. Morley, *Proc. Manchester Association of Engineers*, February 1925.

ignition or else the products of combustion must be expanded below atmospheric pressure by a exhauster. In either case, a pump or an exhauster is necessary, and it is the large amount o work necessarily absorbed in this stage of the cycle—relatively much greater than in the corre sponding stage of a steam turbine cycle, *viz.* the compression in the air pump and feed pump— which is one of the serious obstacles to the success of this type of internal combustion turbine.

If, as is desirable for a large unit, the compression or exhauster is of the turbo type, its rela tively low efficiency compared with a piston compressor greatly accentuates this drawback.

This particular difficulty may be almost entirely avoided by the adoption of a cycle in whic the combustion is at constant volume. In this case, however, it is not possible to produce steady continuous jet; the action of each combustion chamber must necessarily be intermittent the jets of gas issue at varying velocity, and the blading angles and blade speeds cannot satisf the conditions for maximum efficiency as they cannot vary in accordance with the varying je velocities. The loss of efficiency due to this is not, however, of very great magnitude.

The most serious difficulty in the production of a reliable internal combustion turbine is practical one. In all cases the temperature of the jet of gas striking the blading must be very hig in order that the cycle may be efficient; the blading and the rotor must, therefore, be made o materials capable of withstanding temperatures say up to 800° C., at least, without scaling or los of form, and without undue reduction of strength, as the blades and rotor must run at high spee and are, therefore, subject to considerable centrifugal stresses as well as to the tangential drivin effort.

The combustion chamber and nozzles are exposed to still higher temperatures, but as they ar stationary and not so severely stressed, nor so delicate in form, the problem of suitable materia for them is not so acute.

In order to reduce the temperature of the jet the gases resulting from the combustion of th fuel may be diluted, with steam for example, before they enter the expansion nozzles leadin them to the blading. Interesting types of mixed-fluid internal combustion turbines, *i.e.* turbine in which the working substance is a mixture of gas and steam, are described in Davey's 'The Ga Turbine' (*Constable & Co.*, 1914), but though certain of the turbines proposed, in which the steam is generated partly from the heat of the turbine exhaust and partly from the heat passing throug the walls of the combustion chamber, and in which the cycle is carried out at pressures belo atmospheric, offer good prospects of success, no actual turbine on these principles has been mad

For a description of experimental machines made before 1914, Davey's book may be referred t

The type of internal combustion turbine which has most nearly approached practical succes is that designed by Herr Holzwarth, and constructed by Messrs. Thyssen, in Germany. Th turbine is of the constant volume type. A series of combustion chambers are arranged sym metrically round the shaft, which in the later constructions is horizontal. Gas (or oil) and air a about 20 lbs. per sq. inch abs. pressure are admitted through separate inlet valves; the passag leading from the combustion chamber to the nozzle is closed during the charging operation by nozzle valve. After the introduction of the charge, all valves are closed, and the charge is ignite When the pressure has in consequence reached a certain amount it overcomes the spring whic holds the nozzle valve shut, the nozzle valve opens and is then held open. The gases pass to th nozzle, expand, and acquire velocity in the nozzle and impinge on the blades. When the pressu in the chamber has fallen sufficiently, scavenging air is passed through it, and then the cycle repeated. Similar cycles take place in the other combustion chambers. Several Holzwart turbines have been built and run on gas or on oil fuel, and test results on units in sizes up t 1,000 h.p. have been published: machines up to 5,000 k.w. capacity have been built. Unfo tunately the earlier published results were incomplete and open to severe criticism. Tests mad in 1923 on a 1,700 k.w. unit showed an overall thermal efficiency (based on output at switchboar of 14·2 per cent. Though Holzwarth turbines have been built from 1908 onwards, and orde were placed in 1919 by the Prussian State Railways, none seems as yet to have been in regul service.

Several other forms of internal combustion turbines are being experimented upon in German U.S.A., and England.

Combinations of reciprocating engine and turbine, the turbine being driven by the exhau gases from the reciprocating engine, offer good prospects of success. The Rateau exhaust turbi for supercharging aero-engines is one example of this combination.

As regards the internal combustion turbine, considered as a prime mover by itself and not a an adjunct to a reciprocating engine, the prospects of success in the near future are very doubtfu unless the metallurgist can provide a material which will withstand the very high temperatur called for in the blading.

Lloyd's Rules for Marine Internal-Combustion Engines.

The following rules for the survey of internal combustion engines for marine purposes have en drawn up by Lloyd's Register of British and Foreign Shipping :—

General.

Section 1.—In vessels propelled by internal combustion engines the rules as regards machinery ll be the same as those relating to steam-engines so far as regards the testing of material used their construction and the fitting of sea connections, discharge pipes, shafting, stern tubes, d propellers.

Construction.

Section 2.—1. The following points should be observed in connection with the design of the gines :—

2. The shaft bearings, connecting-rod brasses, the valve gear, the inlet and exhaust valves ust be easily accessible.

3. The reversing gear and clutch must be strongly constructed, and easily accessible for amination and adjustment.

4. In engines of above 60 b.h.p. which are not reversible, and which are manœuvred by clutch, a governor or other arrangement must be fitted to prevent racing of the engine when clutched.

5. In vessels intended for open sea service and fitted with engines in which the lubricating oil circulated under pressure, a spare oil pump is to be supplied with all connections ready for mediate use, and two independent means are to be arranged for circulating water through the l cooler, where this is fitted.

6. When the engines are of the closed-in type they must be so fitted that the contained lubricat- g oil can be drained when necessary, and in wood vessels an easily drained metal or metal- ed tray must be fitted to prevent leakage of either fuel oil or of lubricating oil from saturating e woodwork.

7. Carburettors, where petrol is used, and vaporisers, where paraffin is used, should be so signed that when the engine is stopped the fuel supply is automatically shut off. If an over- w is provided in the carburettor or vaporiser, a gauze-covered tray with means of draining must be fitted to prevent the fuel from flowing into the bilges.

Strong metallic gauze diaphragms should be fitted either between the carburettor (or vapor- r) and cylinders or at the air inlets.

8. If the ignition is electric, either by magneto or by coil and accumulator, all electric leads ust be well insulated and suitably protected from mechanical injury. The leads should be pt remote from petrol pipes, and should not be placed where they may be brought into ntact with oil.

The commutator must be enclosed, and the sparking coils must not be placed where they n be exposed to explosive vapour.

9. In paraffin and heavy-oil engines, where lamps are used for ignition or for vaporising, ese lamps should be fixed by some suitable bracket, and the flame enclosed when in use.

10. The circulating pump sea suction is to have a cock or valve on the vessel's skin placed on e turn of the bilge in an easily accessible position, and the circulating pipe is to be provided with efficient strainer which can be cleared inside the vessel. The discharge overboard is to be ted with a cock or valve on the vessel's skin if it is situated under or near the load line of the ssel.

11. The pumping arrangements are to be the same as would be required in the case of a steam ssel of the same size and power, with the exception that no bilge suction need be fitted to the culating pump. In the cases of vessels fitted with water ballast, the water ballast pump must ve, in addition, one direct suction from the engine-room bilges.

In open launches, and in small sailing vessels in which the engines are auxiliary only, a suitable ditional hand pump, fitted to draw from the engine-room bilges, may be accepted in lieu of a wer-driven pump.

12. Where the cylinder liners are made of hard, close-grained cast iron of plain cylindrical form, curately turned on the outside as well as bored on the inside, so that their soundness can be certained by inspection, they need not be hydraulically tested by internal pressure. If, however, ey are made of complicated form, the question of testing must be submitted.

13. The water jackets of the cylinders, and the water passages of the cylinder covers and stons must be tested by hydraulic pressure to 30 lbs. per sq. in. and must be perfectly tight at at pressure.

14. The exhaust pipes and silencer are to be efficiently water-cooled or lagged to prevent mage by heat, and if the exhaust is led overboard near the water-line, means must be arranged prevent water from being syphoned back to the engine.

15. The machinery must be tried under full working conditions, the report stating the approxi- ate speed of vessel, the number of revolutions of the engines at full power, both ahead and tern, and the lowest number of revolutions of the engines which can be maintained for anœuvring purposes.

Rules for Determining Sizes of Shafts.

Section 3.—1. The diameter of the crank shaft must not be less than that given by the following formula :—

$$\text{Diameter of crank shaft} = \sqrt[3]{D^2 \times (A\,S + B\,L)}$$

where D = diameter of cylinder in inches or millimetres,
S = length of stroke in inches or millimetres,
L = span of bearing adjacent to a crank measured from centre t centre in inches or millimetres.

The values of A S + B L are as given in the following tables :—

TABLE I.—FOR PETROL OR PARAFFIN OIL ENGINES.

4-Cycle Single-Acting Engines.	2-Cycle Single-Acting Engines.	For Smooth Water Service Values of A S + B L	For Open Sea Service Values of A S + B L
1, 2, 3, or 4 Cylinders	1 or 2 Cylinders	0·0308 S + 0·0143 L	0·0342 S + 0·0159 L
6 ,,	3 ,,	0·0310 S + 0·0143 L	0·0344 S + 0·0159 L
8 ,,	4 ,,	0·0351 S + 0·0136 L	0·0389 S + 0·0151 L
12 ,,	6 ,,	0·0474 S + 0·0120 L	0·0526 S + 0·0133 L

The above table applies to engines in which there are bearings adjacent to each side of eac crank. If there are two cranks between consecutive bearings the same rules will apply, but L wi be the span between the centres of the bearings adjacent to the two cranks.

TABLE II.—FOR HEAVY OIL ENGINES IN WHICH THE MAXIMUM PRESSURE IN THE CYLINDERS IS 200 LBS. PER SQUARE INCH.

4-Cycle Single-Acting Engines.	2-Cycle Single-Acting Engines.	Values of A S + B L
1 up to 8 Cylinders	1 up to 4 Cylinders	0·0298 S + 0·0144 L
12 ,,	6 ,,	0·0376 S + 0·0118 L

TABLE III.—FOR HEAVY OIL ENGINES IN WHICH THE MAXIMUM PRESSURE IN THE CYLINDERS IS 550 LBS. PER SQUARE INCH.

4-Cycle Single-Acting Engines.	2-Cycle Single-Acting Engines.	Values of A S + B L
1, 2, 3, or 4 Cylinders	1 or 2 Cylinders	0·0643 S + 0·0340 L
6 ,,	3 ,,	0·0673 S + 0·0347 L
8 ,,	4 ,,	0·0643 S + 0·0340 L
12 ,,	6 ,,	0·0673 S + 0·0347 L

2. For heavy oil engines in which the maximum pressure in the cylinders is intermedia between 200 and 300 lbs. per sq. in., or between 300 and 450 lbs. per sq. in., or between 450 an 550 lbs. per sq. in., the coefficients A S + B L are to be interpolated between those given in th above tables.

3. For auxiliary engines of the above-mentioned types the diameters of the crank shafts ma be 5 per cent. less than given by the foregoing formulæ applying to main engines for open se service.

4. In solid forged shafts the breadth of the webs should be not less than 1·33, and the thick ness not less than 0·56 times the diameter of the shaft as found above, or if these proportions a departed from, the webs must be of equivalent strength.

5. The diameter of the intermediate shaft must not be less than that given by the followi formula :—

$$\text{Diameter of intermediate shaft} = C \times \sqrt[3]{D^2 \times S}$$

where D = diameter of cylinder ;
S = stroke of piston;

the values of C being those given in the tables, p. 1977.

TABLE VI.—FOR PETROL OR PARAFFIN OIL ENGINES.

FOR SMOOTH WATER SERVICE.

In using the foregoing tables the appropriate value of A is found from

$$A \times W \times d^3 \times R^2 = D^2 \times S$$

where D = diameter of cylinder in inches;
S = stroke of piston in inches;
d = diameter of flywheel in feet;
R = revolutions of engines per minute;
W = total weight of flywheel in tons.

6. If a separate flywheel shaft is fitted its diameter must be at least equal to that of the crank shaft.

7. Where ordinary deep collars are used the diameter of the thrust shaft measured under the collars must be at least $\frac{2}{3}\frac{1}{0}$ths of that of the intermediate shaft. The diameter may be tapered off at each end to the same size as that of the intermediate shaft.

8. The diameter of the screw shaft must not be less than the diameter of the intermediate shaft (found as above) multiplied by $\left(0{\cdot}63 + \frac{0{\cdot}03\ P}{T}\right)$, but in no case must it be less than 1·07 T

where

P = the diameter of the propeller in inches or millimetres,
T = the diameter of the intermediate shaft in inches or millimetres.

This size of screw shaft is intended to apply to shafts fitted with continuous liners the whole length of the stern tube, as provided for in Section 11, Clause 3 (Rules for Engines and Boilers of Steam Vessels). If no liners are used, or if two separate liners are used, the diameter of the shaft should be $\frac{2}{3}\frac{1}{0}$ths that given above.

The diameter of the screw shaft is to be tapered off at the forward end to the size of the thrust shaft.

Fuel Tanks and Connections.

Section 4.—1. All fuel tanks and their fittings are to be in accordance with Section 49 (rules for steel ships).

2. Strong and readily removable metallic gauze diaphragms should be fitted at all openings on petrol tanks.

3. No glass gauges are to be fitted to fuel tanks containing either petrol or paraffin oil.

4. Filling pipes are to be carried through the deck so that the gas displaced from the tanks has free escape to the atmosphere.

5. Separate fuel tanks should be provided with metal-lined trays to prevent any possible leakage from them flowing into the bilges or saturating woodwork. Arrangements are to be provided for emptying the tanks and draining the trays beneath them. For petrol tanks the trays must have drains leading overboard where possible, or they should be gauze-covered trays with means for draining them.

6. All petrol or paraffin oil pipes are to be of annealed seamless copper with flexible bends. Their joints are to be conical, metal to metal. A cock or valve is to be fitted at each end of the pipe conveying the fuel from the tank to the carburettor or vaporiser. The fuel pipes should be led in positions where they are protected from mechanical injury and can be exposed to view throughout their whole length.

7. The engine-room and the compartment in which the fuel tanks are situated are to be efficiently ventilated.

8. An approved fire-extinguishing apparatus must be supplied.

Periodical Surveys.

Section 5.—1. The machinery is to be submitted to survey annually. At these surveys the cylinders, pistons, connecting-rods, crank and other shafts, inlet and exhaust valves and gear, clutches, reversing gear, propeller, sea connections, and pumps are to be examined. The electric ignition is to be examined and the electric leads tested. The fuel tanks and all connections are to be examined and, if deemed necessary by the surveyor, to be tested to the same pressure as required when new. If practicable, the engines should be tested under working conditions.

2. The screw shaft is to be examined annually and drawn at intervals of not more than three years in the cases of shafts fitted with continuous liners, and of shafts fitted with approved glands, or other approved appliances, at their after ends to permit of them being efficiently lubricated. In the cases of other shafts, they should be drawn at intervals of not more than two years. (On the application of owners the Committee will be prepared to give consideration to the circumstances of any special case.)

High Compression Oil Engines.

Rules for the Construction and Survey of Diesel engines and their auxiliaries have been adopted by the General Committee of Lloyd's Register, and can be obtained on application to Registrary, 71 Fenchurch Street, London, E.C. 3.

SECTION XXXI

PART IV

HOT-AIR ENGINES.

In these the working air receives its heat from an external furnace by conduction through the walls of a metal containing vessel; such engines may thus be described as 'External Combustion Engines' to distinguish them from 'Internal Combustion Engines' wherein the air is heated by chemical combustion occurring throughout its mass. In the Stirling engine the diagram consists of two isotherms and two constant volume lines (fig. 33). The contained air is (1) compressed isothermally at (abs.) temperature T_1 from v_1 to v_2; (2) heated at constant volume v_2 to pressure p_3 and temperature T_3; (3) expanded isothermally at temperature T_3 behind the working piston from pressure p_3 and volume v_3 to pressure p_4 and volume v_1; and (4) cooled at constant volume v_1 from temperature T_3 to temperature T_1, the pressure correspondingly falling from p_4 to p_1. The useful work done is represented by the area 1, 2, 3, 4. If r denote the expansion ratio v_1/v_3 we have :—

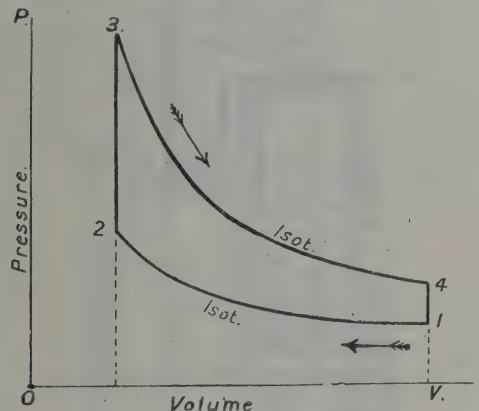

FIG. 33.

$$\text{Heat supplied} = k_v (T_3 - T_1) + c\, T_3 . \text{Log}_e\, r.$$
$$\text{Heat rejected} = k_v (T_3 - T_1) + c\, T_1 . \text{Log}_e\, r.$$

The useful work is the difference of these, viz. :—

$$(T_3 - T_1) . c . \text{Log}_e\, r .$$

And the thermal efficiency is accordingly :—

$$\frac{(T_3 - T_1) . c . \text{Log}_e\, r .}{k_v (T_3 - T_1) + c\, T_3 \text{Log}_e\, r} .$$

This has a value much less than that of the Carnot engine working between T_1 and T_3, viz. $\frac{T_3 - T_1}{T_3}$, on account of the term $k_v (T_3 - T_1)$ in the denominator. The Rev. R. Stirling, in 1827, introduced the regenerator or 'heat-filter' for storing the heat $k_v (T_3 - T_1)$ given out during the period

4, 1, fig. 33, and restoring it to the air during the period 2, 3; by this device the term $k_v (T_3 - T_$ disappears from the denominator and, if perfectly realised, the efficiency would then become equ to that of the perfect Carnot engine, viz. $\frac{T_3 - T_1}{T_3}$. The first Stirling engine (made in 1830) shown diagrammatically in fig. 34. A is a light, bulky displacer filled with brickdust, an fitting easily in its cylinder. The lower portion of the air chamber, B, is situated immediatel over the furnace C, the upper portion being kept always cool by a system of cold-wate circulating pipes W. In the annular space EE, surrounding the cylinder within which works, is a series of very thin metal plates separated by spaces of about ·02 in. width only this is the regenerator. Its upper end is constantly at about the temperature T_1, and lowe end at the temperature T_3; H is the working cylinder, and K its piston.

In the configuration shown, the displacer is at the top of its stroke, while K is at the bottor of its stroke; the contained air is thus at minimum volume and maximum temperature, and th

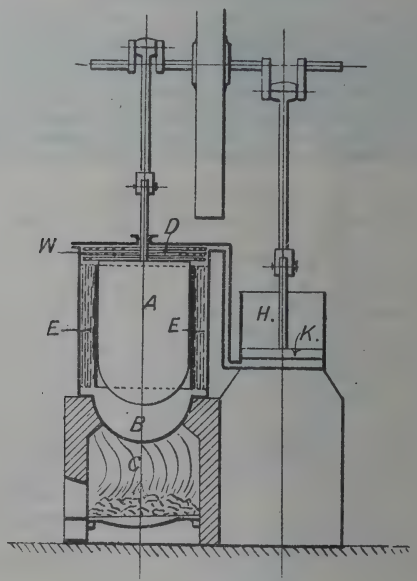

FIG. 34.—The Stirling Engine.

corresponding point on the diagram fig. 33 is 3. The piston next moves out on its working stroke, the pressure falling with expansion and heat being supplied to the working air from the furnace. At the end of the out-stroke of K, A is at the bottom of its stroke and has thus passed the working air from B, through the regenerator EE to the cooled end W of the air chamber; its temperature is now T_1, and pressure accordingly low. The air in passing from B to W through EE gives up to the plates the heat $k_v (T_3 - T_1)$ in the ideal case, and this heat is restored again to the air on its return passage through EE from W to B; by this device the economy was much improved.

It will be noted that there are no valves; the working piston is always in communication with the air chamber, and the air in the working cylinder is always at low temperature. By closing the working cylinder H at the top, and connecting it to a second air chamber and displacer the engine becomes double acting. Though theoretically interesting, the hot-air engine proved so impracticable in any but the smallest powers that it is now quite obsolete. The practical difficulties of rapidly heating a large volume of air; failure of the bottom of the air vessel B; and the great weight and bulk of these engines have combined to effect their disuse. The actual thermal efficiency realised in practice is only from 7 per cent. to 10 per cent.; the mechanical

efficiency is also, in general, low. In the following short table some trial results are given for reference :—

Air Engine.	Date.	Cyl. Bore. Ins.	Stroke. Ins.	Revs. per Min.	Horse Power.		Mechl. Eff. Per Cent.	Lbs. Fuel per Hour.	
					Indic.	Brake.		per I.H.P.	per B.H.P.
Buckett	1883	24·0	16·0	61	20·2	14·4	71	1·8	2·5
Benier	1887	13·4	13·8	117	5·8	4·0	69	3·1	3·6
Bailey	1883	14·6	6·9	106	2·4	1·3	55	4·2	7·6
Rider	1898	6·7	9·5	128	0·66	0·23	35	—	—
Ericsson	1898	8·0	3·9	101	0·23	0·06	27	—	—

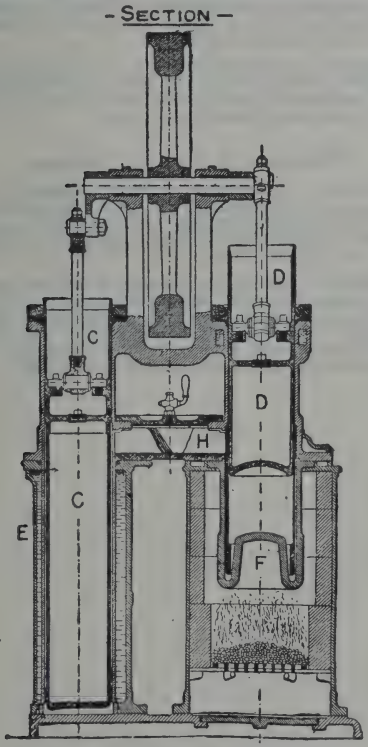

FIG. 35.—The Rider Hot-Air Engine.

Owing to their ease in working and absolute safety, small hot-air engines are still usefully employed in certain situations as, e.g., for driving fog signals on lightships and lighthouses, and for domestic purposes, as pumping, sawing, driving small tools, etc., in cases where only small power is needed.

A pattern of hot-air engine which has been much used is the 'Rider'; it includes all the features of the early Stirling engine except that the working cylinder is in communication with the hot end of the air chamber, and not the cold end as in all Stirling's designs.

In this engine (fig. 35) there are two vertical cylinders, each of which contains a piston
plunger, their strokes and diameters, however, not being equal, that in the power cylinder,
which the air is heated, being the larger. One of these (that to the left hand), lettered C,
the displacer, while that on the right, D, is the power piston. The crankshaft carries a flywhe
in the middle of its length and cranks at each end attached to C and D by connecting-rods,
shown.

The cranks are so placed that when C is at the bottom, D is slightly above the middle of i
stroke. A fire, F, is maintained below the power cylinder, while the displacer cylinder is coole
by a water jacket. The cylinders C and D are constantly in communication through the passage E
in which is contained a regenerator consisting of a number of thin wrought-iron plates place
very close together, whose function has already been explained (*supra*).

The bottom of the power cylinder is maintained at a high temperature by the fire below it
when the power piston D is at the bottom of its stroke the air beneath it, being highly heated,
at pressure and the piston accordingly moves upwards as D is of larger diameter than C. Th
accompanying descent of C transfers air from the cool displacer cylinder through the regenerat
in H—where it becomes warmed up—and delivers it by way of a pendent liner in the pow
cylinder below the rising working piston D when it becomes heated, thus increasing in pressur
and assists in driving D to the top of its stroke.

When this point is reached, the displacer plunger C is at half-stroke upwards, and the subs
quent descent of D transfers air from the power cylinder, via the regenerator, to the cooled dis
placer cylinder, the temperature and pressure consequently falling, and heat being stored up i
the regenerator to be absorbed during the next power stroke.

Efficiency of Hot-Air Engines.

In the best hot-air engines a consumption of 1·8 lb. of gas coke has yielded 1 indicate
horse-power, or 2·54 lbs. of coke per b.h.p., the h.p. being calculated after deducting the wor
required to compress the air. The absolute efficiency is therefore only about 7·9 per cent. referred t
b.h.p. In the smaller sizes of hot-air engine the consumption of fuel is usually very much highe
than this, and is often 20 lbs. or more per b.h.p. hour.

It is practically impossible to construct an air-engine of any great power, as air, like all othe
gases, expands but one volume for each 493° of temperature through which it is raised ; and, i
order to double its volume, we must raise it 493° more, that is, to 986° F., which is much to
high for practical purposes. Even if air could be worked at this temperature, it would b
necessary to have a feed-pump of nearly the capacity of the engine, and the engine itself woul
have to be more than twice the size of a steam-engine of the same power.

SECTION XXXII

AUTOMOBILES.

(Contributed by Ernest W. Birch, A.M.I.A.E.)

ENGINES.

The four-stroke, single-acting, inverted type of engine is in general use.

A few years ago the average power output was 7 b.h.p. per litre of swept piston volume per 1,000 engine r.p.m.; to-day this has been raised to 9 b.h.p. and 10 b.h.p. for racing engines.

There are many factors contributing to this increased output, such as (*a*) carefully designed combustion-chambers without pockets, which allow of the cylinders being machined all-over, thus giving equal capacity and equality of explosion pressure, (*b*) improved design of induction system whereby each cylinder is correctly fed with its right proportion of properly atomised fuel, (*c*) reduction of reciprocating weights due to the use of aluminium alloys.

Other important developments are super-charging, air cooling by blower, evaporative cooling, thermostatic control of cooling system, air cleaners, special alloys for valves, pistons, etc.

The following examples of engines indicate current practice in this country and abroad.

THE MORRIS ENGINE.

(Oxford and Cowley Models.)

This make represents one of the best examples of 'continuous flow' production in this country. Details of 1928 models are as follows (fig. 1.):

THE MORRIS ENGINE.

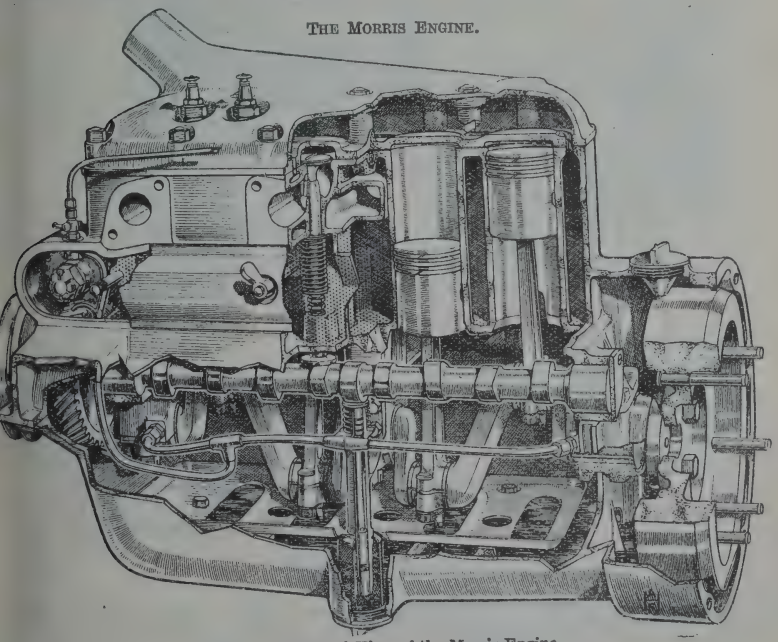

FIG. 1.—Sectional View of the Morris Engine.

Four cylinders cast in one with the upper half of the crankcase, and fitted with detachable cylinder head. The crankshaft has three white-metal bearings carried upon special bearing blocks attached to the cylinder block.

'*Cowley*' connecting rods 'I' section steel with split small end in which gudgeon pin is clamped by set screw, the gudgeon pin taking its bearing in the piston bosses. '*Oxford*' connecting rods of Duralumin, gudgeon pin fitting the same as for '*Cowley*' model. Piston in both models of aluminium with three rings, the upper one being fitted with special spring centering-ring behind it to reduce liability of piston slap. Side by side valves are used. Camshaft and magneto driven by skew-gears at forward end of crankshaft. Thermo-syphon cooling assisted by belt-driven fan. Lubrication is by plunger type oil pump driven from an eccentric in the centre of camshaft.

The '*Cowley*' engine develops 22·3 h.p. at 2,800 r.p.m. and the '*Oxford*' 30 h.p. at 2,250 r.p.m.

A new six-cylinder has been introduced rated at 17·7 h.p. with a bore of 69 mm. and stroke of 110 mm.

The engine is fitted with an overhead camshaft which operates the overhead valves. The crankshaft is carried in four main bearings, and special attention has been directed in the design of the engine to accessibility.

The Lanchester Engine.

The engine illustrated is the 21 h.p. model (fig. 2).

Six cylinders 3·1 ins. bore by 4·5 ins. stroke. Treasury rating 23·1 h.p. Swept volume 203·8 cub. ins. (3,340 c.c.). Power developed at 2,800 r.p.m. is 57 h.p., the brake m.e.p. being 79 lbs. sq. in.

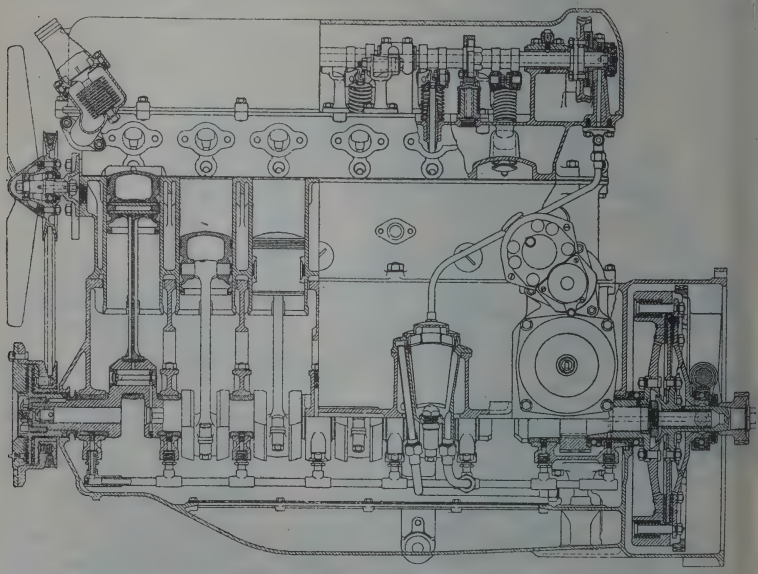

Fig. 2.—Lanchester Engine.

Cylinders cast *en bloc* with detachable head carrying the valves. *Domed* aluminium piston fitted with three light pressure rings and a scraper ring. Hollow floating gudgeon pins with end buttons to prevent scoring of cylinder.

Connecting rods 'I' section with bronze small end bushes and white metal liners for big ends. Crank pin bearings $1\frac{7}{8}$ in. diam. by $1\frac{1}{16}$ in. long. Overhead hollow central camshaft with inclined valves. Camshaft carried on five plain bearings. Damping device provided for damping torsional irregularities. Hollow crankshaft $1\frac{7}{8}$ in. diam. (except for end bearing, which is $2\frac{1}{4}$ in.) carried on seven main bearings of die-cast white metal. Front, middle, and rear bearings $1\frac{7}{8}$ in. long, intermediate journals, $1\frac{3}{8}$ in. long.

Beyond the crankcase proper there is an extension enclosing a vertical shaft and a cross shaft with the gears for driving the overhead camshaft and auxiliaries. An eighth bearing $2\frac{1}{4}$ ins. diam. by $1\frac{3}{8}$ in. long, with white-metal-lined bronze shell, takes the weight of the flywheel.

Daimler Double Sleeve Valve Engine.

This engine operates on the four-stroke, single-acting cycle, but the poppet valves are replaced by cylindrical sliding valves. The piston is enveloped by two open-ended shells which are in turn

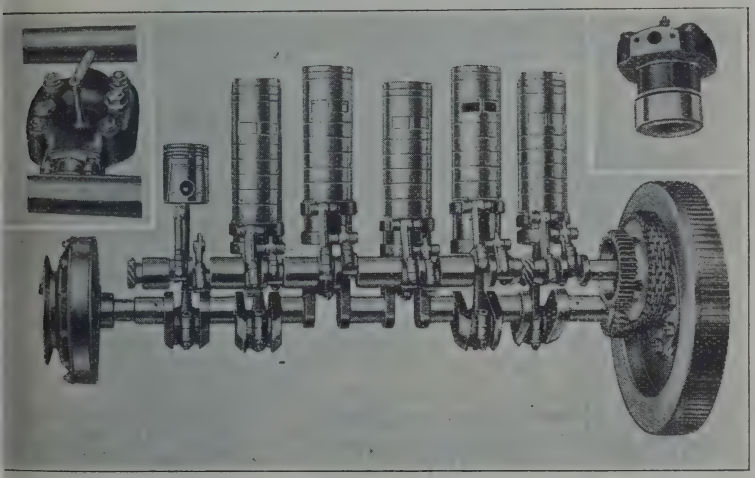

FIG. 3.—Daimler Engine. Sleeve-valve assembly.

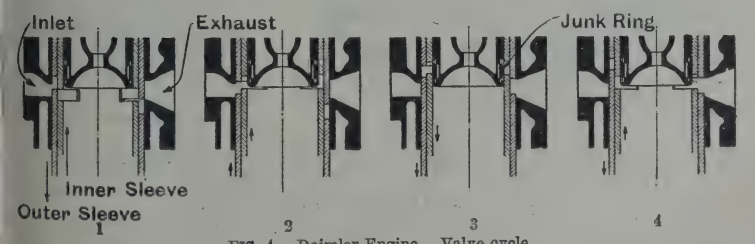

FIG. 4.—Daimler Engine. Valve cycle.

contained within the cylinder casting. These shells are reciprocated in a vertical direction by short links or connecting rods mounted on an independent shaft (fig. 3).

Cycle of Operations.

(Fig. 4, p. 1987.)

Diagram 1 shows the inlet port opening and the exhaust port closing at the beginning of t suction stroke. The inner sleeve is rising and the outer sleeve is descending.

Diagram 2 shows the exhaust closed and the inlet closing at the beginning of the compressi stroke. The ports in the inner sleeve are passing up into the cylinder head, where they are seal by the junk ring during the period of maximum pressure and temperature at the beginning the firing stroke (*see diagram* 3).

Diagram 4 shows the exhaust already well opened at the beginning of the exhaust stroke. T sleeves are now again moving to the position shown in *diagram* 1.

The complete cycle of operations—suction, compression, firing, and exhaust—occupies t revolutions of the crankshaft.

The latest development is the use of steel sleeves made of seamless drawn tubing in place cast iron, which, owing to their lightness and great port area, enable the engine to sustain hi power with perfect balance at high speeds.

The Vauxhall Single Sleeve Valve Engine.

This engine has six cylinders 81·5 mm. bore by 124 mm. stroke. Treasury rating 24·7 h. swept volume 3,880 c.c.

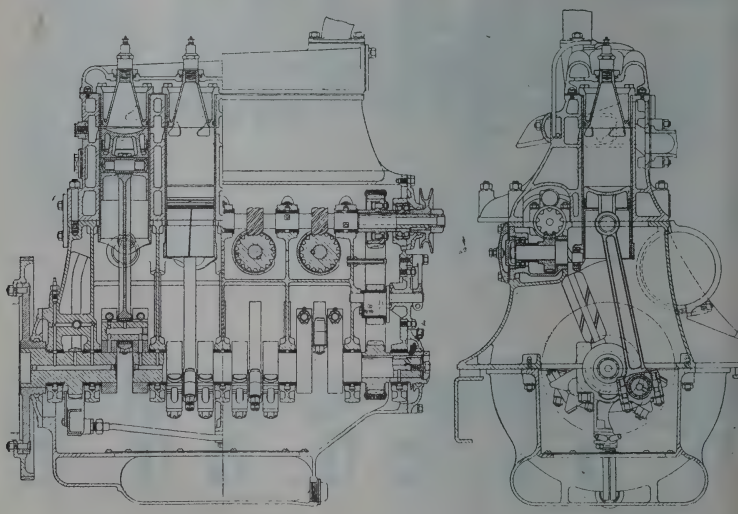

FIG. 5.—Vauxhall Single Sleeve Valve Engine.

There are several special features, such as the built-up crankshaft which is case-hardened, t sleeve driving gear with the spherical bearing in the sleeve, to give the necessary universal moti required by this type, and the shape of the combustion chamber. The sleeve gears are lubricat by troughs, and the sleeves and piston by splash.

Franklin 26 H.P. Air-cooled Engine.

(American.)

Six cylinders 3¼ in. bore by 4¾-in. stroke. A special feature of this engine is the system of air cooling. A Sirocco fan directly connected to the front end of the crankshaft supplies air through a duct over the top of the cylinders, thence through self-enclosing jackets surrounding the cylinders. Deflectors are used to direct the air current in order to secure uniform cooling. At a car speed of 20 m.p.h. the fan absorbs 0·32 h.p. and delivers 1350 cubic feet of air.

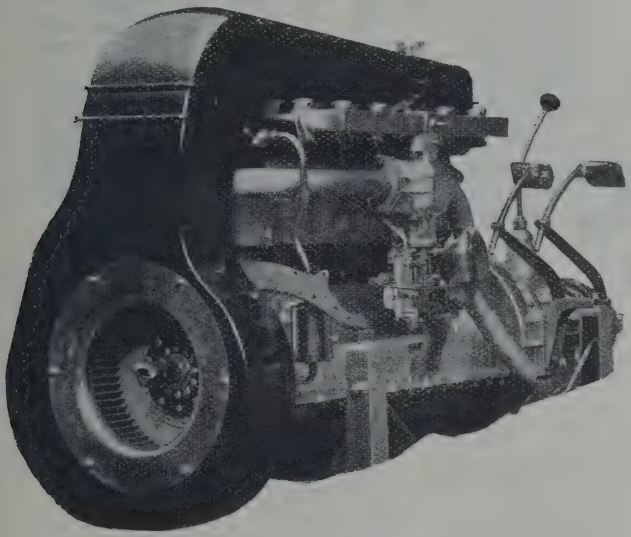

Fig. 6.—Franklin Air-cooled Engine.

Crankshaft case-hardened at the seven main bearings. Camshaft has four plain bearings, with cams forged integral with shaft. Timing gear, oil pumps, and ignition driven off camshaft by helical gears. Connecting rods 'I' section of Duralumin, drilled for lubrication of cylinder walls and piston. Aluminum alloy piston with four rings. Gudgeon pin clamped in small end of rod and chromium plated. Cylinders, unit castings of nickel cast iron with copper cooling flanges cast into cylinder walls.

Packard Engine.

(American.)

Eight cylinders cast *en bloc* with detachable head, 3⅜-in. bore by 5-in. stroke, swept volume 357·8 cub. ins. or 5,865 c.c. 84 b.h.p. at 3,000 r.p.m. (*normal speed*), brake m.e.p. 62 lbs. sq. in. Compression ratio, 4·5 : 1.

Side valves of tungsten steel. Cast-iron pistons with three rings, weight 24 ozs. Gudgeon pins, hand push fit-in piston boss. Connecting rods of 'I' section, bronze bushed at small end, white-metalled at big end (2⅛ in. diam. by 1½ in. long). Firing order: 1, 3, 2, 5, 8, 6, 7, 4, from forward end of engine, main crank bearings 2⅜ in. diam. by 1⅝ in. long. Rear bearing 2½ in. long to support flywheel. Forward end of crankshaft fitted with torsional vibration damper. Hollow camshaft with eight plain bearings, 1⅜ in. diam. Vertical oil pump driven off camshaft by spiral gears. Camshaft and dynamo driven by silent chain.

Water pump mounted on end of cylinder block in which suction passages are cored. Pump impeller fixed by screw to spindle, the other end of which is splined to take fan boss.

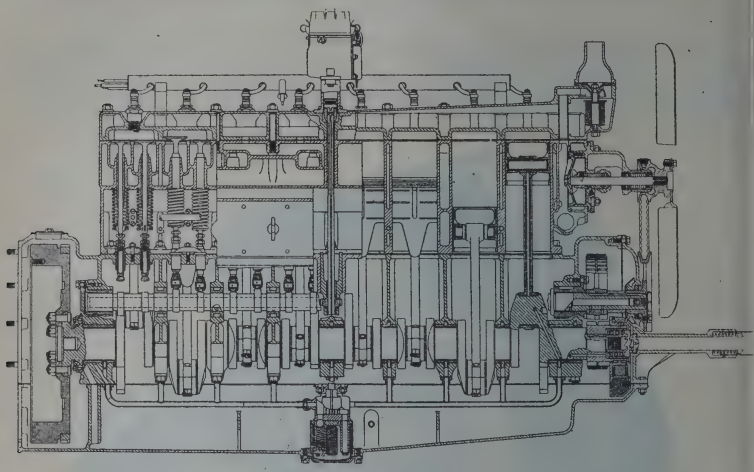

FIG. 7.—Packard Engine.

Thermostatic control is fitted to cooling system. Ignition by coil, the timer being driven by a vertical extension of oil-pump shaft.

THE CITROËN 11·4 H.P. ENGINE.

(French.)

The engine is a four-cylinder monobloc and is in unit with the gear-box. Bore 60 mm. by 100 mm. stroke, giving a swept volume for the four cylinders of 1,453 c.c.

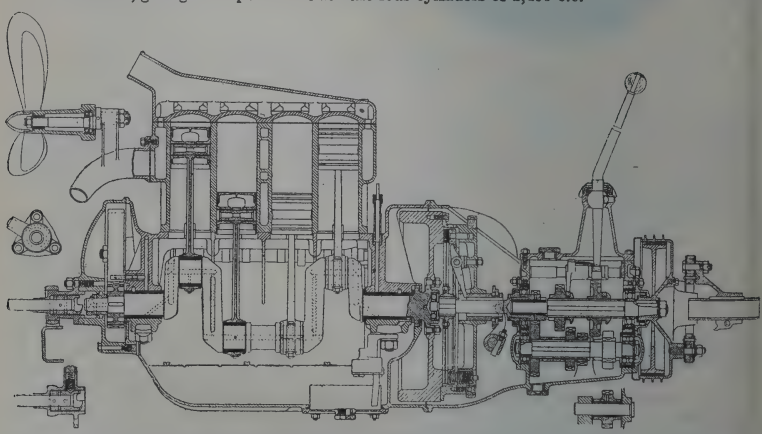

FIG. 8.—Citroën Engine.

The cylinders are bolted to the top in the usual way, the crank case being of aluminium and embodying at the rear the flywheel housing, on which are cast two arms for the engine suspension.

At the front of the crankcase are the helical timing gears, the dynamo being positively driven. The crankshaft is of the two-bearing type, and the camshaft has also only two bearings.

Cast-iron pistons of usual design are fitted with two pressure rings and an oil scraper ring, being fitted in the skirt.

The exhaust manifold is partly formed in the cylinder block, the two middle valves exhausting through a common port and the end ones through single ports. Endwise location of the crankshaft is at the rear bearing, there being a small flange on the rear web. Both crankshaft bearings are split.

The cooling fan is driven by a flat belt from a pulley carried on an extension of the magneto drive spindle.

Bianchi 10–15 h.p. Engine.

(Italian.)

Four-cylinder engine with overhead valves, 64 mm. bore by 100 mm. stroke. Swept volume 1,287 c.c. At 2,750 r.p.m. 27 b.h.p. is developed, and at 3,250 r.p.m. 32 b.h.p. which gives a brake m.e.p. of 99·3 lbs. sq. in.

Cast in one with the upper portion of the crank case, the cylinder barrels have ample jacket spaces, although the outer pair of cylinders are joined. Between the inner pair of cylinders an induction passage is cored through the water space. The crankshaft, which is 40 mm. in diameter throughout, is carried in three white-metal lined bronze bearings. Axial location of the crankshaft is effected by the forward main bearing, hardened thrust washers being interposed between the

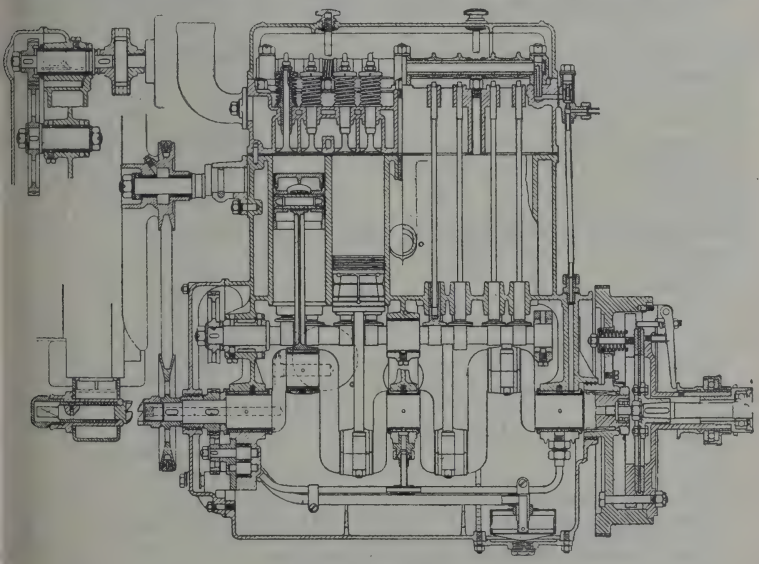

Fig. 9.—Bianchi Engine.

shell and the crank web and timing pinion. Connecting rods are of high tensile steel and have brasses lined with white-metal, and bushes in their small ends. The die-cast aluminium alloy pistons have two-joint rings and a double scraper-ring. The piston skirts are split and relieved.

The ends of the hollow gudgeon pins which work directly in the piston bosses are fitted with buttons. The cylinder bores are ground to a uniform diameter, there being no relief above the working level of the top piston ring. Long studs secure the detachable cylinder head, in which the valves are carried in bronze guides. Plain bronze bushes are used for the three camshaft bearings.

Forced lubrication of the main bearings and big-ends is effected by means of a horizontal gear pump.

Supercharging.

The object of supercharging is to inject a greater quantity of fuel mixture in the period allotted y the timing diagram, thus maintaining the volumetric efficiency at higher engine speeds and ncreasing the power output.

To supply the required quantity of mixture at the necessary pressure, a pump is provided. There are four types in use : (*a*) Roots blower, (*b*) piston pump, (*c*) vane pump, (*d*) turbo-compressor.

The various methods of supercharging can be classified as (*a*) forced induction, (*b*) supplemented nduction, (*c*) scavenging and use of two-stroke cycle.

In system (*a*) the whole of the charge is supplied to the cylinder at a pressure higher than tmospheric, the normal suction of the engine not being utilised.

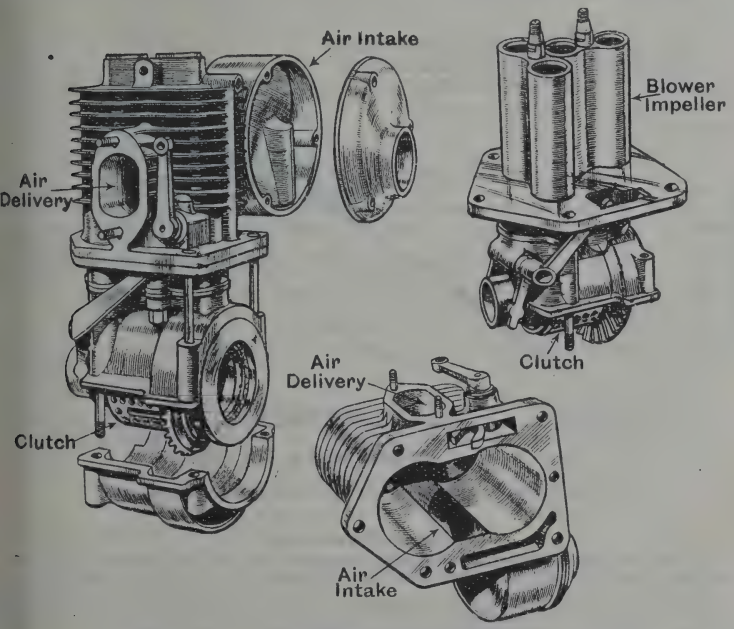

FIG. 10.—Mercedes Supercharger.

(*b*) The normal suction of the engine is utilised to furnish the greater quantity of the mixture, he charge being supplemented by special means.

(*c*) A pump is used that will furnish a volume of air slightly above atmospheric, which is used o free the cylinder and combustion chamber of residual exhaust gases.

Fig. 10 gives details of a Root's blower type supercharger used on the Mercedes engine. It nly becomes operative when the accelerator pedal is depressed past the full open throttle position. This brings into operation a multi-disc clutch that engages a set of bevel gears, and automatically connects the supercharger and closes the normal carburettor intake.

Curve C (fig. 11) represents the power required to propel the car at constant speed, and wher it intersects the horse-power curves A and B indicates the maximum possible speed, which i 75 m.p.h. without, and 87 m.p.h. with supercharger.

Curve A = power output without supercharger.

B = power output with supercharger.

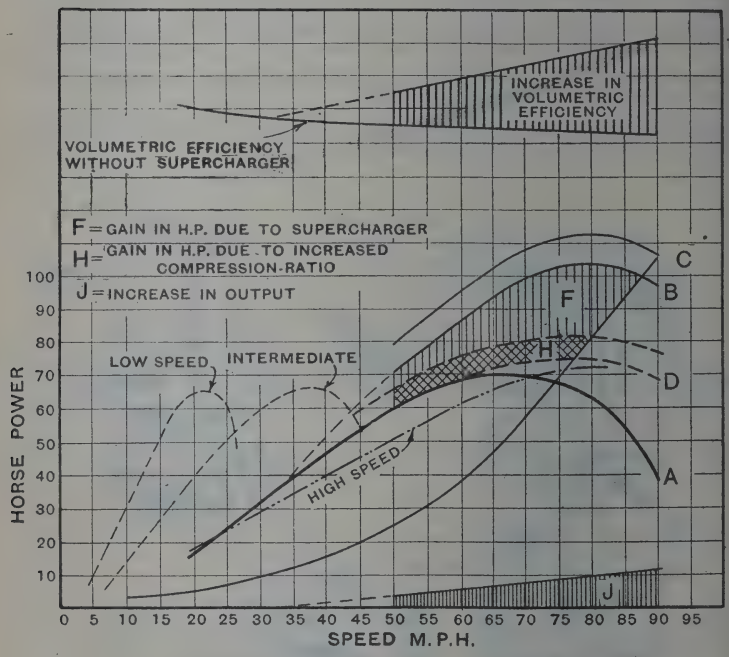

FIG. 11.—Performance Curves* 24–100 h.p. Mercedes Engine.

Engine Governors.

Engine governors as applied to commercial vehicles are used to secure uniform and econom working. There are three main types in use—(*a*) centrifugal, (*b*) velocity, (*c*) vacuum.

Type (*a*) gives close regulation and assurance of full power up to governed speed. Drivi medium must be gears, as other means are unsatisfactory. It requires lubricating and some sk to properly install. Generally placed between carburettor and intake-manifold, and usua connected with the camshaft, the governor controlling a valve in the gas passage.

Type (*b*), installed between carburettor and intake manifold, and as the engine speed increas the speed of the gas going through the manifold is increased. By using a valve in the path of t gas, work can be done on it, due to the force of the impact or gas velocity. By using a valve definite area and adding a spring tension, the speed can be calibrated to any predetermined eng speed. Methods of control—(1) cam to vary spring tension (2) tapered venturi in path of valve

This type is easy to install, compact, and requires little lubrication.

Type (*c*), actuated by alteration in manifold depression. Installed between carburettor a intake manifold and is adaptable to all engines. Full power of engine is given up to point cut-off. Provides close regulation and governs accurately at full or part throttle opening.

* C. W. Iscler, *Proc. S.A.E.*, May 1926.

Characteristics of a Good Governor.

(1) Compactness and sturdiness of construction; (2) dependability; (3) ease of installation nd adjustment; (4) capable of being sealed to prevent tampering; (5) ability to prevent over-peeding; (6) open within 100 r.p.m. of the governed speed to provide quick acceleration; (7) ot increase the engine speed at part throttle opening; (8) not overrun, but cut off sharply t governed speed; (9) not cause engine to surge; (10) not damaged by back-fire.

Fuel Distribution to Cylinders.

Tests made on a standard four cylinder 22·5 h.p. car. showed the following values, the latter eing determined from gas analysis.

Cylinder No.		CO_2 in Exhaust. Per Cent.	Air Fuel Ratio.	Distribution. Per Cent.	Excess or Deficiency. Per Cent.
A.	1	8·1	10·9	28·5	+ 14·0
	2	8·4	11·1	27·4	+ 9·6
	3	12·0	13·5	21·8	— 12·8
	4	11·6	13·3	22·3	— 10·8
B.	1	9·0	11·5	27·2	+ 8·8
	2	9·5	11·9	26·6	+ 6·4
	3	11·4	13·1	23·2	— 7·2
	4	11·9	13·4	23·0	— 8·0

A = tested at 15 m.p.h. up a 4 per cent. gradient. B = tested at 30 m.p.h. up a 4 per cent. gradient.

The tests show that the two front cylinders (Nos. 1 and 2) are subject to 'loading-up,' particularly at the lower speed.

Air Filters.

Measurements of engine wear of two identical 6-cylinder engines after running under similar conditions:—

		With Air-filter.	Without Air-filter.

Pratt	0·719	Rocklight Paraffin	0·825
Carburine	0·720	White Rose Paraffin	0·800
Shell	0·721		

Carburettors.

The function of a carburettor is to provide constant proportions of fuel and air under varying conditions of load, speed and throttle movements.

The jet has two main functions—(*a*) spraying the fuel into the mixture chamber, (*b*) controlling the amount of fuel. There are various types of jets, circular orifice, annulus or slit, the most generally used being the circular orifice. With slow running the air velocities are low, causing erratic behaviour of the jet. It is therefore necessary to (*a*) provide a separate jet for slow running or (*b*) arrange to concentrate the air flow round the jet.

A single jet carburettor cannot meet all the varying demands, hence the majority of carburettors are provided with several jets and choke tubes of different sizes, so that for different engine demands one or other of the jets, or a combination of jets, comes into operation. There are three general types of throttle : (*a*) Butterfly, (*b*) Sleeve or Barrel, (*c*) Valve.

The duty of the float chamber is to maintain a constant fuel level in the carburettor itself, and should be so proportioned that it has sufficient capacity under all conditions. The float, which operates in the float chamber, functions on the same principle as the ball valve in a water cistern. The floats are generally hollow, and the top and bottom should be dished, or serrated, to allow for any 'breathing action' that may take place due to a difference of pressure between the inside and outside of the float. Cork floats are also used, but these should be made up of laminations properly impregnated, and baked.

The float actuates the needle valve, which controls the supply of fuel to the carburetter. It may act direct, lifting the valve on to its seat, or may operate through toggle levers, or in some cases be spring controlled. A filter should be incorporated to prevent the entry of dust and dirt.

In general a carburettor should meet the following conditions :—

(1) Provide constant proportions of fuel and air under varying conditions of load, speed and throttle movement.

(2) Be provided with a means of altering the mean spraying velocity so as to be adaptable to various engine characteristics.

(3) Be provided with a means of maintaining correct mixture strength and fuel disintegration at sudden throttle openings.

(4) Should be able to provide an over-rich mixture for starting purposes and until the engine is sufficiently warm to handle the normal adjustment.

(5) It should be easy to adjust, accessible and non-derangeable.

Sections of typical carburetters are shown in fig. 12.

Paraffin Carburettors.

Paraffin carburettors which have been used on marine motors for a number of years past are now being adopted to a certain extent on motor cars, and particularly on commercial motor vehicles. Although there are many types that have been employed, the general principle is practically the same in every case, namely, heating the mixture on its passage to the cylinder by means of the exhaust gases. The arrangement adopted is to pass the mixture through a vaporiser, around which the exhaust gases have to flow on their way to the silencer. In any case, however, the motor must always be started on petrol. Up to the present time paraffin carburettors have not been entirely successful for automobiles.

Location of Carburettor Intake.

As the result of road tests, the best position appears to be (*a*) on the side of the engine on which the fan blades have a descending motion ; (*b*) about mid-way between the radiator and the dash ; (*c*) about mid-way between the side of the bonnet and the centre line of engine ; (*d*) about one-third of the distance down from the top of the bonnet towards the top of the cylinder head.

Engine Starting.

Within certain limits the richness of the fuel determines the number of revolutions the engine must make before an explosion is obtained. Richness of mixture in the cylinder rather than that of the mixture leaving the carburettor determines whether or not an explosion will occur, and it is suggested that this is a function of delayed vaporisation of fuel left in liquid form in the manifold and cylinder during previous cycles. (*T. O. Eisinger.*)

Detonation and Anti-Knock Substances.*

The phenomenon of detonation appears to be substantially as follows :—When a mixture of hydrocarbon vapour and air is compressed to a high pressure and to a temperature approaching that of its self-ignition temperature, and is then ignited from any one point, the flame at first spreads by the normal process of combustion, compressing before it the unburnt portion of the charge. When the rise in temperature of the unburnt portion due to compression by the burning gases exceeds the rate of heat dissipation by a certain margin, spontaneous ignition of the former takes place, and an explosion wave is set up which strikes the cylinder walls with a hammer-like blow, thus causing the metallic ring, known as 'pinking' on detonating.

* Report of the Empire Motor Fuel Committee, *Proc. I.A.E.*, vol. xviii.

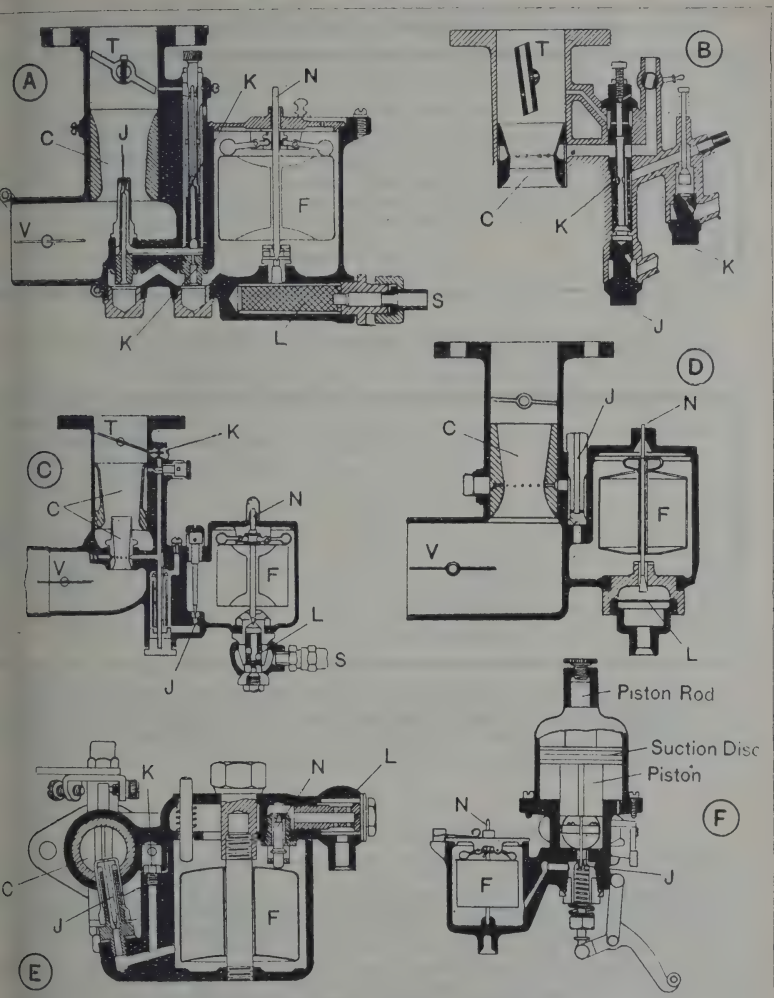

FIG. 12.—Sections of Typical Carburettors.

A. Zenith (Vertical Type).
B. Claudel-Hobson (Power Jet Model). (Float chamber not shown.)
C. Stromberg (Model M).
D. Brown & Barlow. (Auxiliary jets not shown.)
E. Solex (Horizontal Type MH).
F. H.V. Type. Controllable-Jet S.U. Carburettor.

C = Choke Tube. F = Float. J = Main Jet. K = Auxiliary Jet.
L = Filter. N = Needle. S = Fuel supply. T = Throttle Valve.

A number substances will suppress detonation (*anti-knock*), whilst others will induce it.

Element.	Form in which Used.	Effect on Detonation.
Iodine	Element.	Suppresses.
Bromine	Element.	Induces.
Oxygen	Element.	Induces.
Oxygen	Ethyl nitrite or nitrate	Induces.
Nitrogen	Aniline.	Suppresses.
Selenium Tellurium	Di-ethyl compounds	Suppresses.
Tin Lead	Tetra-ethyl compounds.	Suppresses.

'*Anti-knock*' substances are efficient when present in minute proportions, and in the cas of lead-tetra-ethyl, one molecule in 200,000 molecules of air-fuel mixture is sufficient.

Element.	Compound.	Corresponding Per Cent. by Volume.	Corresponding Number of Molecules of Theoretical Air-Fuel Mixture to one Molecule of Anti-Knock.
—	Benzene	25·0	150
Iodine	Ethyl-iodide	1·6	2,150
Nitrogen	Xylidine	2·0	2,600
Tin	Tin-tetra-ethyl.	1·2	7,100
Selenium	Di-ethyl-selenide.	0·4	11,750
Tellurium	Di-ethyl-telluride	0·1	50,000
Lead	Lead-tetra-ethyl.	0·04	215,000

In using lead-tetra-ethyl it is necessary to add some halogen-containing compound to counte act the harmful action on the sparkling plug electrodes. Carbon tetra-chloride, or ethyline d bromide can be used, the function of these compounds being to convert the lead into lead halid immediately after combustion. Lead-tetra-ethyl is a colourless liquid. S.G. 1·62, boiling poi 152° C., miscible with petrol in all proportions and poisonous.

Mechanical Losses in Engines.*

The mechanical losses remain practically constant, irrespective of the torque, for though th friction increases slightly with an increase of load, the work done in filling the cylinder increas as the throttle is closed, and the two practically balance. An 80 per cent. mechanical efficienc at full load becomes only 55 per cent. at 30 per cent. of full torque, while a 90 per cent. efficienc becomes 73 per cent., so that the difference that has to be taken into account is not that betwee 80 per cent. and 90 per cent., but between 55 per cent. and 73 per cent.

Of the gross mechanical losses, piston friction in a well-designed engine accounts for abou 60 per cent. of the total. Pumping losses account for about 25 per cent., while the friction of th bearings and all the auxiliary gear amounts to about 15 per cent. Piston friction can best b reduced by keeping both the weight and bearing surface of the piston down to the minimun Pumping losses are not susceptible of much reduction. A little can be done by the use of larg valves and the most suitable timing, but on reduced loads the losses are mainly due to the r striction through partially closed throttle. These losses are therefore more or less inevitab unless means can be found to work with a weakened instead of a throttling mixture. Unles means be adopted to augment turbulence during the compression the valves must be kept fair

* H. R. Ricardo, *Proc. I.A.E.*

mall and the velocity through them high, or slow and incomplete combustion, with loss of power, fficiency, and excessive heat flow will result. The friction of the bearings is relatively small.

It is almost impossible to assess the losses due to general vibration. However, an engine annot vibrate without absorbing a considerable amount of energy. Every effort should be made o ensure the best possible balance.

Excessive turbulence gives rise to excessive heat losses and a narrowing of the mixture ange.

It gives rise also to excessive roughness of running. The optimum degree of turbulence from he point of view of efficiency corresponds to a rate of pressure rise of 30 to 40 lbs. per sq. in. per legree of crankshaft travel. It is the rate of pressure rise, and not the maximum pressure which ives rise to harshness. A high compression engine, so long as it is not detonating, will be as sweet unning as a low compression one, provided its rate of pressure rise is the same or less.

Heat Losses in Engines.

Heat Flow through Cylinder Walls.

Average Heat Flow. B.Th.U.'s per sq. in. per minute.

Water-Jacketed Engines.	6 Cylinder Passenger Car.	6 Cylinder Motor Coach.	12 Cylinder Aircraft.
Valve position	In head.	L-head.	In head.
Brake horse-power	51	92	415
Heat loss. B.Th.U.'s per min.	2,500	7,400	10,700
Surface, sq. ins.	540	1,150	2,520
Average heat flow B.Th.U.'s per sq. in. per min.	4·6	6·4	4·3

Heat Losses to the Cylinder Jackets.

Type of Cylinder.	Heat Loss. B.Th.U.'s./min/B.H.P.	Water evaporated. Lbs./min./B.H.P.
Aviation	30	0·03
Valve in head	50	0·05
L-Head	70	0·07
T-Head	80	0·08

To guarantee that the cylinder block will always be full of water, it is necessary to pump more water than can ever be evaporated. In practice it has been found desirable to pump 2½ times the maximum evaporative requirements. The water pipes should be large enough to carry this quantity of water without undue pressure drop, or at a velocity exceeding 6 ft. per sec.

Minimum inside diameter, $d'' = \sqrt{\frac{1}{(4 \times 28{\cdot}8 W_p) \div (60 \times 60. \times 12\pi)}} = \sqrt{0{\cdot}0085\ W_p}$.

W_p = weight of water pumped in pounds per min.;

28·8 = volume in cubic inches of 1 lb. of water at 212° F.

For average conditions in a cylinder jacket, the temperature drop through the water film is approximately 20–25° F. The temperature of cylinder walls will increase approximately with an increase in water temperature until it has reached 185–190° F., when no further rise in the cylinder wall temperature will occur so long as the heated surface is wet with water or foam. The effect of a carbon or lime deposit $\frac{1}{32}$ in. thick may cause an increase of inner wall temperature of some 200° F.

Analysis of Heat Losses.

(H. R. Ricardo.)

In the case of a well-designed engine, with a compression ratio of 5 : 1, about 32 per cent. the total heat of the fuel is converted into useful work on the piston, 28 per cent. is carried aw by the cooling water, and the remaining 40 per cent. is lost to radiation, exhaust, etc. Of the to heat carried away by the cooling water, approximately 6 per cent. will be lost to cylinder wa during the combustion period, 7 per cent. will be yielded up during expansion, and 15 per ce during exhaust stroke.

Of the 6 per cent. lost during the combustion period about 40 per cent. appears as useful wo or 2·4 per cent. of the total heat of the fuel. Of the 7 per cent. lost during expansion, abo 20 per cent. will be utilised, or 1·4 per cent. of the total heat of the fuel. Of the 15 per ce lost during exhaust stroke, no part could be utilised.

Although 28 per cent. of the total heat of the fuel is carried away by the cooling water, o 3·8 per cent. could be converted directly into useful work on the piston, and the efficiency of t engine would be increased from 30 per cent. to 35·8 per cent., a gain of barely 12 per cent.

If all the loss of heat to the cylinder walls be suppressed, the temperature of the working flu would be corespondingly higher, with a result that the losses due to the increase of specific h and of dissociation at the higher temperature would be substantially increased, and a net g from 32 per cent. to about 34·5 per cent.

These figures indicate the relatively small part the loss of heat to the cylinder walls plays an internal combustion engine, and how misleading it may be to assess that loss of heat, by t heat carried away by the cooling water. As a first approximation it is fairly correct to assu that, of all the heat carried away by the cooling water of a cylinder, little more than 10 per ce would actually be converted directly into useful work.

Water Pump.

(Gear Type.)

Capacity of gear pumps can be calculated from the volume of the space between the teeth the gears. This space can be assumed to be equal to one-half the volume between the outs cylinder and the root cylinder of the gears. As two gears are working, the theoretical deliv per revolution will be equal to the difference in area between the outside and the root circle one gear times its width. Tests of pumps running at 1500–2000 r.p.m. with boiling water sh that the actual delivery is 20–30 per cent. of this amount.

$$W_p = 0{\cdot}25 \times 0{\cdot}0346 \frac{\pi}{4}(D^2 - d^2)FN = 0{\cdot}0068\ (D^2 - d^2)FN$$

or,

$$\frac{147W_p}{N} = (D^2 - d^2)F$$

where,
d = root diam. of gear-ins.; D = outside diam. of gear-ins.; F = width of gear-ins.; N r.p.m. of pump gears; W_p = weight of water pumped; lbs. per min.; 0·0346 = weight 1 cu. in. of water at 212° F.

(A. G. Herreshoff, 'Proc. S.A.E.' 1926.

Boilerine Radiator Tablets.

These tablets, invented and manufactured only by Boilerine Limited, are for the purpose obviating the fur which forms in radiators and water-jackets. There is nothing in the prepa tion detrimental to the joints or metal parts. Where scale is already in existence 25 tab per gallon of water take the lime into solution, dissolving the particles, thus leaving the w of the cylinder-jackets and radiator tubes perfectly clean.

Following this cleaning process all water put in the radiator should be 'Boilerined' to extent of 2 tablets per gallon, up to 14 degrees of hardness, and one extra tablet for every 7 degr beyond; one tablet per gallon for rain water to prevent rust.

When water is poured into the radiator, it amounts to putting in a quantity of lime or ch or if soft water, a means of producing rust.

If this is done without 'Boilerine' tablets, the lime adheres to the walls of the cylinders radiator tubes until efficiency is choked out of the cooling system.

Boilerine Limited have proved from tests that thirty hours heating of water at 190° F. gi nearly the same amount of deposit as half an hour's boiling, thus, surely, though unseen, the mo is, at the working temperatures, storing up in its cooling system this cause of trouble, consequen the flow of water is reduced, producing overheating, or allowing the impurities in the wate cause rust and corrosion, hence leakages.

These claims are confirmed by the reports given on tests of twelve and six months' durat respectively, made by Messrs. Thomas Tilling, Ltd., and Messrs. W. H. Dorman & Co., L Stafford.

Crankcase Corrosion.

The presence of water in the crankcase is responsible for the corrosion. The quantity of ter present in the products of combustion is dependent upon the hydrogen content of the fuel, e mixture ratio, and the humidity of the air that enters the engine. The amount of water at may be condensed on the cylinder walls or in the crankcase depends upon the effectiveness the piston and piston rings in preventing gas leakage, the temperature of the cylinder walls d crankcase, and the extent of the breather action. Condensation of water from the gases combustion will start at approximately 130° F. when petrol is used, and at 123° F. when 0 per cent. mixture of petrol and benzol is used. The relative freedom of some engines from ter accumulation is due to their higher operating temperatures, or to the better interchange air by breather action, which results in dilution of the gases in the crankcase and consequent luction of the saturation temperature of the gases.

Water alone will cause corrosion, but the action may be accelerated by the formation of weak phurous or sulphuric acid.

In order to reduce water accumulation, pistons must reduce blow-by, and in addition means ould be provided to reduce the warming-up period and ventilate the crankcase. Either air- or am-cooling, with provision for controlled heating of the crankcase, is favourable for the solution the problem.

(*M. A. Thorne*, ' *Proc. S.A.E.*,' 1926.)

Chromium plating of the crankcase has proved an effective measure against corrosion.

Engine Efficiency Constants.*

The following equation for efficiency is recommended by Tizard and Pye, and is based upon 0 per cent. weak mixture, which corresponds very closely to the conditions under which the ximum observed efficiencies are now obtained.

$$E = 1 - \left(\frac{1}{r}\right)^{0.296}.$$

r.	E.	r.	E.	r.	E.	r.	E.	r.	E.	r.	E.
·8	0·3261	4·4	0·3552	5·0	0·3790	5·6	0·3995	6·2	0·4175	6·8	0·4329

Firing Order.

From considerations of balance it is necessary to get as uniform a turning-moment as possible. ur-cylinder engines are so arranged that there is a power impulse every stroke or two power pulses every revolution, the one beginning as the other ends. The crank throws are placed in one plane, the two centre throws being together and at 180° to the two outer throws. ith this arrangement two orders of firing are possible, viz. 1–2–4–3 and 1–3–4–2; both are used, t the latter is the more general.

With a six-cylinder engine the throws are divided into three positions or 120° apart. 1 and 6 always in line, 3 and 4 are always in line, and 2 and 5 are always in line. For a right-hand nk the firing order is 1–5–3–6–2–4 or 1–2–4–6–5–3, and for a left-hand crank 1–4–2–6–3–5 1–3–5–6–4–2.

For an eight-cylinder ' V ' engine :

$$\left.\begin{matrix}8\text{–}7\text{–}5\text{–}2\\1\text{–}4\text{–}6\text{–}3\end{matrix}\right\} \text{ or } \left\{\begin{matrix}1\text{–}3\text{–}4\text{–}2\\8\text{–}6\text{–}5\text{–}7\end{matrix}\right.$$

For an eight-cylinder ' in-line ' :

(*a*) 1–5–3–7–4–8–2–6
(*b*) 1–7–3–5–4–2–6–8
(*c*) 1–3–2–5–8–6–7–4
(*d*) 1–5–2–6–4–8–3–7

* I.A.E. Data Sheet No. 205.

Effect of Changes in the Compression Ratio upon Engine Performance.*

With an increase in the compression ratio there is usually an increase in b.h.p. and a decre in consumption up to a ratio of 14 : 1, provided there is no serious pre-ignition or detonati The changes in indicated thermal efficiency with changes in compression ratio are in close agr ment with those based on the air-cycle efficiencies at the various ratios.

Change in the compression ratio does not produce a consistent change in the friction h volumetric efficiency, or in the range of fuel-air ratios over which the engine can operate. T ratio between the heat loss to the jacket-water and the heat converted into b.h.p. or i.h decreases with an increase in the compression-ratio.

Piston Clearance and Compression Ratio.

Analysis of 100 different makes of engines show the average clearance for cast-iron pistons be 0·013 in. at the top and 0·003 in. at the bottom.

The extreme values were :—Top, max. 0·026 in., min. 0·002 in. Bottom, max. 0·005 i min. 0·001 in.

Average compression ratio 4·42 ; max. value 5·76 ; min. value 3·33. (Compression ratio Ratio of total cylinder volume to combustion chamber volume). In general 4·5 may be c sidered as high compression, 4·0 as medium, and 3·5, or below, as low.

BRAKE M.E.P.

d = diameter of piston. ; s = stroke ; n = r.p.m. of crankshaft ; P = total m.e.p. piston, lbs. per sq. in. ; p = brake m.e.p., lbs. per sq. in.; c = power strokes per revolut of crank.

If d and s are in inches,

$$\text{B.h.p.} = \frac{s.d.^2p.n.c.}{504300}\ ;\ \text{P} = \frac{396000\ \text{b.h.p.}}{s \times c \times n}\ ;\ p = \frac{504300\ \text{b.h.p.}}{s.d.^2n.c.}.$$

If d and s are in millimetres,

$$\text{B.h.p.} = \frac{s.d.^2p.n.c.}{8262 \times 10^6}\ ;\ \text{P} = \frac{\text{b.p.h.} \times 1006 \times 10^6}{s.n.c.}\ ;\ p = \frac{\text{b.h.p.} \times 8262 \times 10^6}{s.d.^2n.c.}.$$

* Report No. 205, National Advisory Committee for Aeronautics, U.S.A.

Pistons.

The material most generally used at present is Cast Iron, but great advances have been made n the use of non-ferrous alloys, and the following, which is an extract from a paper by L. Aitchison, ndicates their advantages.

Light alloy pistons are in general use for aero engines and racing car engines. The main advantages in their use are :—

(*a*) Owing to their light weight, friction is reduced, and also the loading on the connecting-od bearings, due to the reduction of inertia of the reciprocating parts.

(*b*) Owing to the lower temperature of the crown (due to the greater thermal conductivity) ittle or no carbonisation of the lubricating oil takes place on the under-side.

(*c*) Owing to the lower mean temperature of the oil film between the piston and cylinder walls, ess oil may be used without risk of piston seizure.

A disadvantage in their use is due to larger coefficient of expansion, which necessitates ncreased clearance and is the cause of piston-slap.

The Ricardo Piston.

This piston, fig. 13, is a 'slipper' type and aims at securing increased power by the reduction of friction and weight. The contamination of the lubricating oil due to gas leaking past the rings, which takes place in the ordinary form of piston, is reduced by allowing the leaking gas to escape before reaching the piston skirt. Also the lower ring groove is bevelled and drilled to enable the ring to act as a scraper.

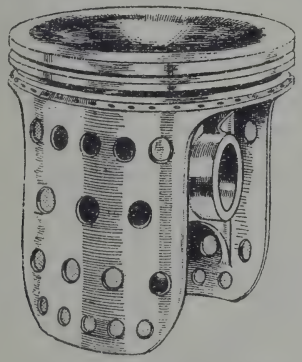

Fig. 13.—Ricardo Slipper Piston.

Features of this piston are: (*a*) Gas pressure is transmitted direct from the crown of the piston to the centre of the gudgeon-pin bosses; (*b*) thrust from the connecting rod is transmitted directly to the bearing surfaces; (*c*) bearing surface is provided only where it is needed: (*d*) gases that pass the piston-rings may escape freely into the crank case; (*e*) no wad is transmitted through the side-walls, or past the piston-ring grooves; (*f*) the lower piston-ring acts as a scraper, so that oil that has worked up past the slippers can be returned through the small holes beneath. Tests made with this piston showed a reduction in oil consumption from 0·06 lbs. per h.p. hour, to 0·035 lbs. At the same time fuel consumption dropped 4 per cent. with about 4 per cent. increase in b.h.p. For cylinder bores ranging from 3½ ins. to 5 ins. the weight of the piston, complete with gudgeon pin and piston rings, can be reduced to 0·1 lb. per sq. in. of piston area.

Cast-Iron Cylinder Liners and Piston Pots.

The advantages in the use of cylinder liners are :—

(*a*) Cylinder blocks can be made of a cheaper and more fluid iron; (*b*) expensive jigs for cylinder grinding unnecessary; (*c*) can be replaced if necessary; (*d*) reduces the rejection of blocks due to flaws discovered during boring.

Liners may be of steel or centrifugally cast iron, and are essential where light alloy cylind blocks are used. Piston pots are generally made of centrifugally cast iron.

The features of centrifugally cast iron are :—

(*a*) Close grain and dense structure, combined with a diminutive formation of the graphi plates ; (*b*) uniform physical properties ; (*c*) superior grinding finish to sand castings.

The dense structure increases resistance to percolation, and since the material receives chilling effect from the dies in which it is cast, it is tougher and harder than sand-cast metal.

It can be machined readily at about 30 ft. per min. Brinell 200–240. The tensile streng based on the B.E.S.A. ring formula is 19–22 tons per sq. in., and owing to the size and dist bution of the graphite plates, grain growth and distortion are reduced.

Design of Piston Rings.

The practice of making eccentric piston rings with the idea of obtaining equal distributi of radial pressure is now being replaced by the use of concentric rings which have been subject to hammering or peening. The effect of peening is to reduce the nominal modulus of elasticit E_n, by about 10–15 per cent. (There is no definite elastic modulus for cast iron, as no part of t stress-strain diagram is straight.) The minimum value for the modulus is given in B.E.S.A. spe fication, No. 5003/1927, as $13 \cdot 5 \times 10^6$ lbs. per sq. in., and the maximum value as $15 \cdot 5 \times 10^6$ l per sq. in. According to the British Piston Ring Co., Ltd., the value of E_n for good pist ring iron varies from approximately 15–17 $\times 10^6$ lbs. per sq. in., but the effect of hammering is reduce this by about $1 \cdot 5 \times 10^6$, so that the value of E_n for the finished rings should be betwe $13 \cdot 5$–$15 \cdot 5 \times 10^6$ lbs. per sq. in.

If

d = diameter of cylinder bore, ins. ;

t = radial thickness of ring, ins. ;

b = width of ring measured parallel to cylinder axis, ins. ;

δ = Free gap in ins. (measured in a straight line tangential to the circumference of ring and parallel to the plane of the ring) ;

p = pressure between ring and cylinder wall per sq. in. of contact area ;

f = calculated maximum stress in tons per sq. in., assuming the material to be truly elastic, and of modulus E_n ;

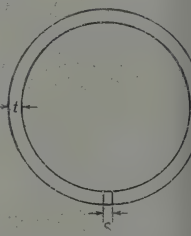

FIG. 14.

E_n = nominal Young's Modulus ;

Q = diametral load in lbs. applied along diameter of ring corresponding to a change gap of δ_1 ins. ;

Then

$$E_n = \frac{5 \cdot 37 \left(\frac{d}{t} - 1\right)^3 Q_1}{b \cdot \delta_1}$$

Minimum thickness of ring $= \frac{d}{30}$

Maximum thickness of ring $= \frac{d}{30} + 0 \cdot 008$ in.

Width of ring varies in steps from $\frac{d}{16}$ for 2-in. size to $\frac{d}{24}$ for the 6-in. s

Tolerance $\frac{-0 \cdot 001 \text{ in.}}{+0 \cdot 000 \text{ in.}}$

Maximum free gap $= \frac{d}{7 \cdot 5}$. Such a gap produces approximately the same stress in the r

during the operation of placing it over the piston as it has when in its closed position in the cylinder, but since the ring is continuously closed in the cylinder it is desirable to use a smaller free gap so as to reduce the stress in the ring under working conditions. A free gap of $3\frac{1}{2}$ times the minimum thickness is more satisfactory in practice.

A ring with a free gap of $3{\cdot}5 \times \frac{d}{30}$ gives a minimum pressure of 9·15 lbs. per sq. in. (taking $E_n = 13{\cdot}5 \times 10^6$ lbs. per sq. in.).

$$\text{Cylinder wall pressure } p = \frac{\left(\frac{\delta_1}{t}\right) E_n}{7{\cdot}08 \left(\frac{d}{t}\right) \left(\frac{d}{t} - 1\right)^3}$$

where δ_1 is the difference in inches between the free gap and the gap when in the cylinder measured in the same manner as δ.

$$\text{Maximum stress } f = \frac{\left(\frac{\delta_1}{t}\right) E_n}{5280 \left(\frac{d}{t} - 1\right)^2} \text{ tons per sq. in.}$$

In a ring having a free gap of $3\frac{1}{2} \times t$, the change of gap (δ_1) is approximately equal to $4\frac{1}{2} \times t$ when putting the ring over the piston, and $3\frac{1}{2} \times t$ when putting it into the cylinder.

The load Q is calculated from $Q = \left(\frac{3\pi}{\pi + 4}\right) p.\, b.\, d.$

where b and d are in inch units, p is expressed in lbs. per sq. in., and Q in lbs.

Horse Power, Treasury Rating (T_R).

$$(a)\ T_R = \frac{d^2N}{2{\cdot}5},$$

where

d = bore in ins.; N = number of cylinders.

$$(b)\ T_R = \frac{d^2N}{1613},$$

where

d = bore in mm.; N = number of cylinders.

The Society of Automotive Engineers (S.A.E.), America, standardised the following formula, based on a piston speed of 1000 ft. per minute:

$$\text{S.A.E., horse-power} = \frac{(\text{Diam. in inches})^2 \times \text{No. of cylinders.}}{2{\cdot}5}$$

Horse Power from Given Working Volume and M.E.P.

$$\text{Horse-power} = \frac{P_m \times Q \times N}{396000},$$

where,

P_m = m.e.p. lbs. per sq. in.; Q = working volume in cu. ins.; N = r.p.m.

Valve Area for Given Volume, Revolutions and Gas Velocity.

$$V_g = \frac{VcN}{360\ \Delta},$$

where,

V_g = gas velocity, ft. per sec.; Vc = volume swept out per cylinder; cu. ins.
Δ = valve area in sq. ins.; N = r.p.m.

Inlet Pipe Diameter.

$$Vg = \frac{QN}{180\pi D_1^2},$$

where

Vg = gas velocity, feet per sec.;
D_1 = diameter of inlet pipe; ins.
Q = working volume per rev.; cub. ins.
N = r.p.m.

Compression Pressure.

$$\left(\frac{V_2}{V_1}\right)^n = R^n = \frac{P_2}{P_1},$$

where

V_1 = volume of clearance space; cub. ins.
P_1 = atmospheric pressure; lbs. per sq. inch.
$n = 1{\cdot}3$;
R = compression ratio.
V_2 = volume of piston displacement + V_1 cub. ins.
P_2 = compression pressure in lbs. per sq. in (absolute).

Calculating Lift of Poppet Valves.

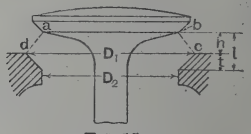

FIG. 15.

The gas passage is the area of the curved surface of the frustrum of the cone *abcd*. V = volume of gas to be discharged in cubic feet, and V_g = mean gas velocity in feet per secon through valve opening, and A = area of valve opening, then,

$$A = \frac{144V}{Vg} \text{ (sq. ins.).}$$

The lift l must be such as to produce this area for the gas to pass through.

$$h^2 = \frac{4A^2}{\pi^2 (d_1 + d_2)^2} - \frac{(d_1 - d_2)^2}{4}.$$

Knowing the value of d_1, d_2, A and t, the lift $l = h + t$ (Fig. 15).

DIMENSIONS OF POPPET VALVES.
(S.A.E. Standard.)

2½–3	0·5595	0·437	0·578	1/16	0·020	0·405	0·206	0·495

The above dimensions are for steel valves; they are considered equally applicable for cast-iron valves, except that it may be desirable to have slightly more metal in the latter under the heads.

Valve stem tips shall be hardened to give a scleroscope reading of 55–65 after finishing. Recommended that length of tips from end of stems to stem-grooves be not less than finished diameter of stem to prevent undue breakage after hardening.

Tolerance on fractional dimensions ± 0·010 in.

Valve Timing.

Analysis of one hundred automobile engines (1927) showed the following average timing:

Inlet opens, 10° A.	Exhaust opens, 47° 50′ B.
Inlet closes, 40° A.	Exhaust closes, 7° 30′ A.
A = after T.D.C.	B = before T.D.C.

In 95 per cent. of the engines the inlet and exhaust valves were of the same diameter.

$$\frac{\text{Diameter of inlet valve } (clear)}{\text{Valve lift}} = 4{\cdot}75. \qquad \frac{\text{Cylinder Bore}}{\text{Valve diameter}} = 2{\cdot}2.$$

Material for Valves.

Valves operate under a tension-impact load, the temperature varying from practically atm spheric at the tappet end to about 1600° F. at the head. The temperature gradient is a functi of the guides in which the valve reciprocates, and for any particular design is affected by t material in the guide, the degree in which it shrouds the stem, and the inner surface of the gui The temperature of the head is affected by the width of valve seat and cross-sectional area stem. The head and upper part of stem are subjected not only to high temperatures, but also the corroding action of the mixture, and the corroding and eroding action of the hot gases passi through the valve at a velocity of 150–200 ft./sec.

The scaling of a valve not only reduces the cross-sectional area, but the loose scale may a become attached to the valve seat.

The strength of the valve material at ordinary temperature is important only in so far as it a function of the hardness. For highly stressed valves the strength at high temperatures important, and it is necessary to select a material which does not show a decrease in the origi strength sufficient to cause distortion or failure.

Bearings.

Crankshaft and big-end bearings are usually white-metal lined ; gudgeon bushes of bron

Corresponding to a maximum explosion pressure of 300 lbs. per sq. in., the bearing pressure lbs. per sq. in. of projected area is as follows :—

For ' big-end ' bearings : 800–1,100 lbs. per sq. in. ; more usually the latter.

For ' gudgeon ' bearings : 1,500–2,700 lbs. per sq. in. ; average about 2,000 lbs. per sq. in.

Gear-Box Gears.

As the result of over ten years' experience in the testing of gear-box gears, H. F. L. Orc summarises his observations as follows :—

(*a*) Gears which are hardened after finishing are always noisy.

(*b*) Gears with teeth accurately finished after hardening are quiet.

(*c*) Gears with teeth finished as accurately as possible may be noisy in the best-finished ge boxes.

(*d*) Gears with teeth roughly finished may be under some conditions comparatively quiet

(*e*) An accurately finished gear is just as essential to cheap and uniform production as accurately finished cylindrical shaft or bearing.

(*f*) In a quiet-running pair of gears the limits of accuracy on the teeth are the finest possi much finer than those which are required in any other conjugate surfaces in the gear-box.

(*g*) In the ordinary gear-box the gear teeth are usually the least accurate of any of the work surfaces.

(*h*) Some ratios run more quietly than others, tooth load and quality of finish being equal

(*i*) The stub gear to run quietly must have extreme accuracy of tooth form, especially pitch spacing. Consequently this gear is more difficult to finish to a degree of quiet running th the full-depth tooth gear.

Strength of Splined Shafts.

From tests carried out on actual shafts, the elastic limit for a splined shaft is substantially l than for a plain round shaft of a diameter equal to the base diameter of the spline. On the ot hand, the ultimate strength of the splined shaft is materially greater than that of the round sh It would appear that the reason the elastic limit is lower in the splined shaft is that the mate in the splines adds very little to the torsional strength, but the strain on the fibres at the outs of the splines will be about the same as if the shaft were of solid round section and equal in diame to the outside diameter of the splines. With fairly elastic material, if the distortion is contin beyond the elastic limit, the splines assume a helical form and gradually come into tension, there adding to the resistance of the shaft to further deformation. If the splines are supported, as in t case of the permanent fitting so that they are in more nearly direct shear from the beginning the load application, their shearing strength is added to that of the body of the shaft.

Analysis of Breakdowns, 1924–1925–1926.

(Royal Automobile Club.)

Cause of Breakdown.

Steering Wheel Position.

The following formulæ (*W. Ferrier Brown*) are for the calculation of the steering-wheel position, a, b, and d, being known factors.

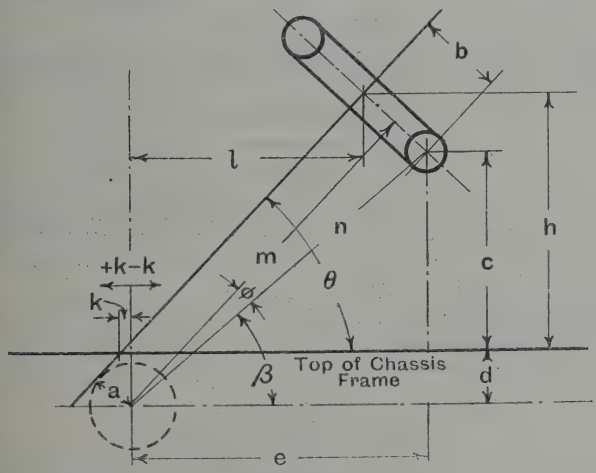

FIG. 17.—Steering Wheel Position.

Given m and θ—to find c and e.

$\phi = \tan^{-1}\frac{b-a}{m}$; $n = \frac{m}{\cos\phi} = m \sec\phi$;

$\beta = \theta - \phi = \sin^{-1}\frac{c+d}{n}$; $e = n\cos\beta$;

$c = n\sin\beta - d$.

Given c and e—to find m and θ.

$\beta = \tan^{-1}\frac{c+d}{e}$; $n = \frac{e}{\cos\beta} = e \sec\beta$;

$\phi = \sin^{-1}\frac{b-a}{n}$; $m = n\cos\phi$;

$\theta = \phi + \beta$ = rake of column.

To find h and l.

$h = m \sin\theta + a\cos\theta - d$; $l = \cos\theta\,(m - a\tan\theta)$.

To find h and l.

$h = c + b\cos\theta$; $l = e - b\sin\theta$.

To find k (which may be + or −

$$k = \frac{a}{\sin\theta} - \frac{d}{\tan\theta}.$$

Lubrication.*

Carbon Formation.—The tendency towards carbon formation is due to an excess of oil worki past the piston rings into the combustion chamber. Special means are used to limit the amou of oil reaching the combustion chamber, such as (*a*) baffle plates between the crank case a cylinder casting, (*b*) scraper ring on the piston, (*c*) effective oil relief groove on the piston or relief holes, (*d*) adequate control of the oil supply to meet the engine's requirements.

Sealing the Piston Rings.—The clearance between the piston and the cylinder wall controls t lubricant to seal the piston rings. When this is small, a light or medium bodied oil is sufficie Larger clearances require a heavier-bodied oil.

Piston clearance must be considered in conjunction with the cylinder bore. A clearance 0·005 in. on a small-diameter piston is relatively large compared with the same clearance on piston of double the size.

Piston material affects the clearance allowed; thus heavier-bodied oils are necessary for al minium pistons compared to cast iron. Other factors are: the number of piston rings and th position on the piston, the presence of oil grooves on the piston to assist in oil distribution, meth of finishing cylinder bore.

Lubrication of Transmission and Differential.

The following characteristics of the lubricant are necessary :—

(*a*) Must be of a character and consistency to coat, follow, cushion, and adequately lubrica the gear mesh.

(*b*) Must be capable of thorough distribution to any ball, roller, or plain bearing, and mu have no corroding effect on the balls, rollers, or raceways.

(*c*) Should be of a body and character to minimise resistance and power loss due to the churni action of the gears. In the case of transmission, it should offer the minimum of resistan to the manual act of gear changing.

(*d*) Should be capable of carrying off the greatest amount of heat, and of exerting a washi action on the gear teeth and bearing surfaces.

(*e*) Should be a body to prevent leakage from the gear-box or back axle under all norm operating conditions.

Chassis Lubrication.

Advantages of Oil for Lubrication.

(C. T. Myers.)

(1) Sustains as heavy a bearing load as grease with less friction.

(2) Fed to one properly located point in a bearing will quickly spread over the entire surfa

(3) Will flow through a very small hole, and can be conducted a considerable distance capillary attraction and surface tension.

(4) Carries much less dust than grease, can be filtered, and not so much exposed to dirt grease, when in bulk or when being applied.

(5) Contains no inert matter to clog holes or channels.

(6) Engine oil can be used.

(7) Easier to apply automatically than grease.

(8) A flow of clean oil tends to clean a bearing, and bearings arranged for oil lubrication c be cleaned with petrol or paraffin.

(9) When oil is used on spring bolts, the seepage works down into the spring leaves, preventi rust.

Weight of Passenger Cars.

(*W. Ferrier Brown, 'Proc. I.A.E.'*)

The total weight of an average car is made up as follows :—

Chassis complete, 65 per. cent; body complete, 30 per cent.; wings, valances, and ste boards, 5 per cent.

For the complete body in detail, the proportionate weights are :—

Body frame (steel), 14 per cent.; body framing complete with head-fittings, 42 per cen panels (steel), 10 per cent.; paint, glass and inside mouldings, 12 per cent.; Trimmi including two extra seats complete, etc., 22 per cent.

	Fine loose macadam	0·60	0·64	—	—

Automobile Brakes.

A common misapprehension is that which assumes that there is no slipping between tyre and road until wheels are locked. Actually slippage occurs immediately upon the sudden application of the brakes, and continues until the car is brought to rest whether the wheels are locked or not. Although the wheels continue to roll, their peripheral speed begins to decrease immediately and is therefore always less than that at which the road surface passes under the car.

The effectiveness of brakes can be determined directly by measuring the breaking force per unit of car weight *i.e.* per lb. per 1000 lbs. or per ton of car weight. The relation between the distance S in feet required to stop, the initial car speed V in m.p.h., and (1) the rate of slowing down in feet per sec.$^2 = a$; (2) the retarding force in lbs. per lb. $= f_1$, (3) the retarding force in lbs. per 1000 lbs. of car weight $= f_2$, is given by

$$(1)\ S = 1{\cdot}08\frac{V^2}{a}; \qquad (2)\ S = 0{\cdot}0336\frac{V^2}{f_1}; \qquad (3)\ S = 33{\cdot}6\frac{V^2}{f_2}.$$

STOPPING DISTANCES FOR DIFFERENT TYPES OF BRAKE APPLICATION.

	Type of Brake.		
	Rear External Band Brake.	Four Brakes Internal Shoes.	Four Brakes, External Bands.
Total weight of car lbs.	6,000	6,000	6,000
Total surface of brake lining, sq. ins.	332·4	308·6	600
Weight per sq. in. of lining, lbs.	18·1	19·4	10
Stopping distance in feet at			
20 m.p.h.	35	23	15
30 ,,	70	45	35
40 ,,	113	74	60
50 ,,	175	114	90

Stopping Tests of Car Fitted with Hydraulic Brakes.

Total weight of car with driver = 4,400 lbs.; Weight on front wheels = 2,000 lbs.; Weigh on rear wheels = 2,400 lbs.
Tyres, cord, size 35 × 5, pressure 65 lbs. per sq. in.;
Road surface—dry concrete.
Speed, 30 m.p.h.
Stopping distance—brakes applied on rear wheels only = 89·2 feet.
" " " front " " = 67·6 "
" " " rear and front wheels = 36·8 feet.

Noisy Brakes.

Tests show that scratching of the brake drum by brass wire in the brake lining, high rive heads, particles of steel from the drum or grit from the road, sets up vibrations in the drum, an that the note given out by these vibrations is of the same tone as the ringing note produced b striking the undamped drum with a hammer. The sound can be damped or muffled by applyin slight pressure at a point diametrically opposite the initial point of vibration. Other recom mendations are :—(a) *drums should be of high carbon steel*; (b) *rivet heads should be sunk* ⅛ in *below the surface of the lining*; (c) *the use of moulded lining containing no wire*; (d) *the bands mu be truly circular.* (*Proc. S.A.E.*, Feb., 1926.)

Laminated Springs.

Size and Number of Plates.

$$\text{Total load on spring W in cwts.} = \frac{sbt^2n}{L},$$

where,

s = maximum stress in plates = 460 cwts. per sq. in.; t = thickness of plates in ins. = breadth of plates in ins.; L = length of spring between eyes in ins.; n = number of plate

Given W and L, and assuming n, values for b and t can be calculated. These must be checke against the rate of deflection, which is determined by :

$$\text{Deflection per ton of load} = \frac{L^3}{40{,}000bnt^3}.$$

From experimental data it appears desirable to so design leaf springs that the plate lengths a proportional to the second moment of area (moment of inertia) of the plate sections, except f strengthening near the eyes to take care of rebound.

Friction in Laminated Springs.

Friction tests show that the friction is a minimum with a lubricant consisting of equal volum of cylinder oil and powdered graphite. The close proximity of the curve for static and slidi friction with this lubricant are of special note. An important conclusion drawn from the tests that with graphite μ is substantially constant.

Values of μ under similar loading conditions.

	Light Oil.	Excess Oil wiped off.	Graphite.
Static	0·24	0·34	0·08
Sliding	0·10	0·18	0·06

Effect of End Taper.

Fig. 18 is a diagram showing the relative liability to fracture of various plates in springs deduced from more than 500 fractures.

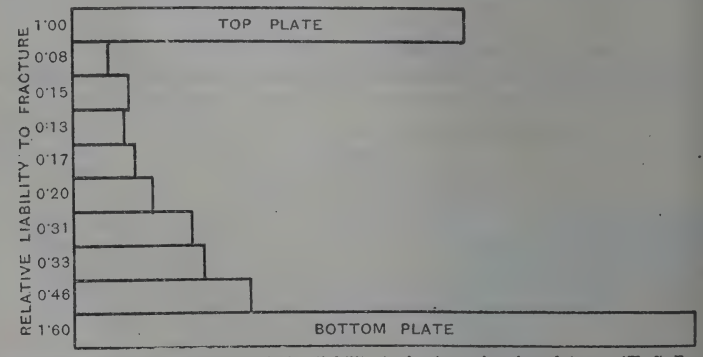

Fig. 18. Diagram showing the relative liability to fracture of spring plates. (*H. S. Rowe*

Plates which are reduced in width only are not appreciably different from square-ended plates, such tapering having no practical effect on the strengths, reactions, stresses, or flexibilities of the spring. On the other hand, taper in the thickness has an enormous effect. A combination of the two tapers—in the width and in the thickness—is sometimes of much importance, but generally the effect of tapering the width is very much less than of a taper in the thickness.

The life or fatigue of a spring is to a considerable extent governed by the stress reversal which occurs on account of nip and flick.

NOTE.—For a very complete survey of the subject, papers by Landau and Parr (*Journal Franklin Institute*, U.S.A.) and Rowell (*Proc. Institution of Automobile Engineers*) should be consulted.

Power Required by Motor Vehicles to Negotiate Gradients.

It is first necessary to determine the maximum engine torque T. If d = engine bore in ins., n = number of cylinders, s = stroke in ins., then $T = 5{\cdot}66d^2sn$ (approx.). Let S_R = total speed reduction ratio between engine and driving wheels and e = efficiency of driving mechanism, then the torque T_1 transmitted to the driving wheels is given by $T_1 = TS_Re$ (e may be taken as 0·9 for top gear and 0·75 to 0·85 for intermediate and low gears).

Total tractive force F in lbs. $= \frac{2TS_Re}{D}$, where D = diameter of driving wheels in ins.

This tractive force is available to overcome (*a*) resistance due to acceleration or gradients, (*b*) road resistance and wind resistance.

AVERAGE VALUES IN POUNDS PER TON FOR ROLLING PLUS AIR RESISTANCE FOR DIFFERENT CLASSES OF VEHICLES ON VARIOUS ROAD SURFACES.*

Road Surface.	Motor Buses and † Passenger Cars.	Commercial ‡ Vehicles.
Best paved surfaces	37	22
Paved surface in average condition	42	30
Best water-bound gravel	55	40
Ordinary gravel	65	50
Best earth roads	65	50
Fair to good earth roads	75	60

The size of tyre appears to affect the rolling resistance very little so long as the tyres conform to good practice as to size and load. Low-pressure cord tyres have somewhat higher rolling resistance than the high-pressure cords, but the difference decreases for the rougher surfaces.

If G = gradient per cent. and R = rolling plus air resistance in lbs. per ton, and W = gross weight of vehicle in lbs., then,

$$\frac{2TS_Re}{D} = \frac{W.G}{100} + \frac{W.R}{2240}; \text{ or, } \frac{4480TS_Re}{D} = W(24G + R);$$

from which the engine torque required to drive a vehicle up a given gradient can be determined; or knowing the engine torque, the maximum gradient that the vehicle can negotiate.

* Report of Committee on the Economic Theory of Highway Improvements, S.A.E. Highway Research Board, 1925.

† Speed 35 m.p.h., high-pressure cord tyres. For low-pressure cord tyres add 10 lbs. per ton.

‡ Speed 15 m.p.h., pneumatic tyres.

The following values of road resistances are given by G. W. Watson (*Proc. I.A.E.*):

Nature of Road.	Resistance, lbs. per Ton.	Nature of Road.	Resistance, lbs. per Ton.
Good asphalt	15	Soft macadam	97
Poor asphalt	29	Small cobbles	60
Good wood paving	30	Medium cobbles	130
Good granite sets	35	Large cobbles	240
Best macadam	43–46	Sand road	360
Ordinary macadam	50–60	Loose sand	560

Tyres.

Comparison of Tyre Sizes.

Range of wheel load, lbs.	675–1,120	1,000–1,500	1,400–1,900
High-pressure tyres, ins.	4	4½	5
Inflation pressure, lbs. per sq. in.	45–6	45–60	45–65
Medium-pressure Tyres, ins.	4½	5½	6
Inflation-pressure, lbs. per sq. in.	30–50	38–54	42–58
Balloon Tyres, ins.	5½	6	6½
Inflation pressure, lbs. per sq. in.	27–35	26–38	30–40

Ideal Load and Inflation Pressure.

The following formulæ are based on the Goodyear Company's tables:

If d = section diameter ins. and P = inflation pressure lbs. per sq. in.:

For cord tyres $P = 12 \cdot 5 + 10d$; For canvas tyres $P = 17 \cdot 5 + 10d$.

The ideal load (lbs.) per tyre, $W = 32 \cdot 4d^{2 \cdot 24}$.

For any given inflation pressure the variation of permissible load with diameter is given by $W = cpd^{1 \cdot 18}$, where $c = 1 \cdot 81$ for cord tyres and $1 \cdot 63$ for canvas tyres.

*Wear of Tyres.**

For high-pressure tyres, road tests show:

(1) Wear increases with speed.

(2) Increased wear with higher temperatures (high temperatures are very destructive to tyres).

(3) Relative wear of rear tyres to front varies from 200 to 118, probable average 150.

For balloon tyres:

(1) Wear is less affected by differences in road surfaces than for high-pressure tyres.

(2) Firm-surfaced roads (*i.e.* asphalt, cement) all have approximately the same effect on tread wear.

(3) Surfaces such as gravel, earth, dry and in good surface condition, cause less tread wear than firm-surfaced roads.

(4) Front tyre wear is greater than rear tyre wear on firm-surfaced roads, and is less than rear tread wear on loose-surfaced roads.

* Highway Research Board, National Research Council, Washington.

RATE OF DEFLECTION OF PNEUMATIC TYRES.*

Standard Pneumatic Tyres.	Inflation Pressure. Lbs. per sq. inch.								
	15	20	25	30	40	50	60	80	100
650 × 65	700	525	450	404	341	302	—	—	—
26 × 3	642	492	420	373	297	232	195	—	—
28 × 3½	488	410	355	315	254	207	182	—	—
815 × 105	488	374	316	275	217	177	158	—	—
880 × 120	420	340	290	248	192	154	138	—	—
895 × 135	335	278	237	207	170	147	130	110	—
36 × 6	—	—	—	—	120	103	88	78	75
38 × 7	—	—	—	—	—	—	82	66	60
40 × 8	—	—	—	—	—	—	78	61	52
Balloon Tyre sizes.									
27 × 4·40	600	464	378	332	275	—	—	—	—
28 × 4·95	584	440	370	322	265	—	—	—	—
30 × 5·25	500	390	318	270	218	—	—	—	—
32 × 6·20	464	354	298	250	192	—	—	—	—
34 × 7·30	400	316	263	228	180	—	—	—	—

The above values represent the rate of deflection when any working load is already applied. The numbers are given in millimetres per cwt. increase in load, and in each case the result has been multiplied by 100 to avoid decimal points.

RATE OF DEFLECTION OF SOLID TYRES.

Solid Tyre Sizes.	Normal Load.	Normal Load less 25 per Cent.	Normal load plus 50 per Cent.
90 × 754	31	36	23
100 × 881	25	28	20
110 × 850	23	29	17
120 × 850	19	24	15
130 × 850	15	17	13
140 × 850	18	22	12
160 × 850	13	16	10
180 × 850	11	13	9
8″ × 850	11	13	10
10″ × 850	7	9	6
12″ × 850	6	7	5

THE MACINTOSH N.A.P. UNPUNCTURABLE TYRE.

This tyre, fig. 19, is so constructed that it possesses a large hermetically sealed core containing uncompressed air. It has a broad and flat base similar to that of the ordinary solid tyre, thick, strong, and abnormally flexible walls, and a narrow tread having a central row of triangular cavities about half an inch deep, which give definite non-skidding and side-slipping properties on slippery surfaces. This form of construction is such that it is claimed to need no attention whatever during the whole life of the tyre, which is guaranteed in the United Kingdom to be a minimum of 10,000 miles or twelve months, whichever expires the sooner. Another important feature is that the walls are entirely of rubber and contain no fabric, with the result that exceptionally cool running is obtained. This tyre seems to combine in a remarkably efficient manner the advantages both of the pneumatic and the solid variety. For such vehicles as Ford one-ton trucks it is particularly well adapted.

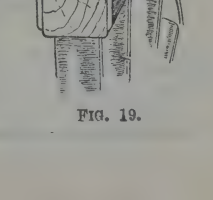

FIG. 19.

Welding Cracked Cylinders without Preheating.

Cast-iron automobile cylinders can be successfully welded without preheating by using bronze welding rod and employing a few ordinary precautions. When the crack is in the water-jacket it is often unnecessary to remove the block from the car. Conduction of heat can be retarded by packing the block with wet asbestos fibre cement two or three inches from the crack on each side. It is not necessary to bevel the edges of the break, but the metal should be carefully cleaned, and preferably ground bright for about 0·5 in. on each side of the break.

The oxy-acetylene blowpipe is used, and the best results are obtained with a welding rod prepared especially for bronze welding on cast iron. It is necesary also to use a good flux.

The temperature at which bronze welding is conducted is quite critical. If the casting is not sufficiently heated, the bronze will not adhere firmly, and if it is raised to too high a temperature the bronze will run off like water on a hot stove. The best method is to practice on a piece of cast iron until the operator can tell from his own experience the correct temperature.

A section of the break should be brought up to this temperature, the metal being heated along both sides of the crack for about 0·25 in. The bronze welding rod should be heated, and then dipped in the flux. Next, the bronze rod should be melted and allowed to run on the heated section of the casting, a very thin layer of bronze metal being allowed to flow on the break.

This first layer should be applied as a tinning layer, and care should be taken to see that the section to be welded is entirely covered by this tinning coat.

After the tinning coat has been applied, bronze weld metal can be added fairly rapidly, usin flux as necessary, until a weld of the proper height has been built up.

Welding should start at least 0·5 in. beyond the visible ends of the crack. If the crack i long, it may be desirable to tack-weld it in one or two places, or to begin welding in the centr and weld towards both ends. It is important that overheating of the base metal or the bronz weld metal should be avoided.

Bronze welding should be done in a well-ventilated shop or in the open air, and the operato should avoid breathing the white fumes of volatilised zinc oxide produced, as otherwise som discomfort may be experienced.

When the weld is completed it can be filed or ground down, but grinding flush with the cylinde wall should be avoided, unless the crack has been bevelled previous to welding.

AEROPLANES — GENERAL DATA — THE ATMOSPHERE — WINGS OF MONOPLANES—AIR SCREWS—AEROPLANE PERFORMANCE — NOTABLE FLIGHTS — AIRSHIPS FOR COMMERCE — STANDARD DATA FOR AIRSHIP CALCULATIONS—OXYGEN APPARATUS—PARACHUTES.

(Revised and amplified by Major D. H. Kennedy, O.B.E., F.R.Aé.S.)

GENERAL DATA.

The Atmosphere.

That the temperature of the atmosphere diminishes as one ascends is obvious from the fact that the summits of high mountains are constantly snow-covered.

The rate of diminution is, naturally, somewhat variable, but for London averages about 3·5°F. per 1,000 feet of height. The mean annual temperature of London is roundly 50°F. Hence, as the average condition a temperature of 50°F. may be taken at the surface of the earth, and a fall of temperature of 3·5°F. per 1,000 feet of height.

At h feet, therefore, the average temperature is assumed as :—

$$t = 50 - 3{\cdot}5 \times \frac{h}{1000} \text{°F.}$$

Or, using absolute temperatures :—

$$T = 510 - {\cdot}0035\ h \text{°F. abs.}$$

Hence the characteristic Equation (1) becomes in this case :—

$$p\ v = c\ (510 - {\cdot}0035\ h) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (53)$$

If at height h feet the pressure be p, then at height $(h+dh)$ feet the pressure must be $(p+dp)$, dp including its sign ; the (negative) increment dp is due to the weight of a layer of air 1 square foot in horizontal section and dh feet high, and is therefore numerically equal to $\frac{dh}{v}$; hence :—

$$dp = -\frac{dh}{v}.$$

From Eq. (53) this becomes :—

$$c\frac{dp}{p} = -\frac{dh}{510 - {\cdot}0035h},$$

hence

$$c\int_{p_o}^{p}\frac{dp}{p} = -\int_{o}^{h}\frac{dh}{510 - {\cdot}0035h}$$

where p_o is the pressure at the earth's surface ; performing the integration, reducing, and taking $p_o = 14{\cdot}7$, we have for determining p, the pressure in lbs. per square inch at height h feet :—

$$\text{Log. } p = 14{\cdot}654741 + 5{\cdot}36.\text{Log. } (510 - {\cdot}0035h) \quad . \quad . \quad . \quad . \quad . \quad (54)^*$$

From this equation the table on page 2024 has been prepared ; in addition, the table gives the absolute and ordinary average temperatures in °F. for heights up to 30,000 feet ; the pressures in lbs. per square inch and in inches of mercury ; the ratio of the pressure at height h to the pressure at the earth's surface, and the volume of 1 lb. of air, in cubic feet, at the several heights. It will be found useful in calculations relating to aeronautics.

The weight of 1 cubic foot of air in lbs. is of course the reciprocal of the figure in column at any given height.

The effect of the fall in temperature with height is to cause the pressure to be slightly *less* tha if the temperature were uniform throughout; thus at 9,000 feet, with uniform temperature 50°F. throughout, the pressure is 21·54 inches of mercury, while with diminishing temperatu (*vide* table) it is 21·32 inches. Actually the atmosphere is very rarely quiescent, and in th uniform condition here assumed; the results obtained are, however, useful for calculation. I particular, for a few hundreds of feet above the surface of the earth the air is usually in a con dition of more or less complex turbulence with eddies, ascending heated currents, etc., due t the nature and configuration of the country beneath.

This table should be regarded as approximate only until further actual observations a to the temperatures and pressures at altitudes are available. The observed temperature o January 2, 1919, at an altitude of 30,500 ft., was −38° F.

Flight of Heavier-than-Air Machines.

The following elementary treatment of the subject furnishes results of some practical interes and exhibits clearly the *rationale* of mechanical flight :—

Air Pressure on a Flat Plate normally to its direction of motion.

Let

A = the area of the plate in square feet;
v = the velocity of the plate, relatively to the air, in feet per second;
G = the weight of the air, in lbs. per cubic foot, or density;
$g = 32·2$;
P = the resulting pressure on the plate, in lbs.

Then in one second a mass (GAv) lbs. of air impinges on the plate and its momentum is

destroyed; the momentum is $(GAv) \times v$, and the momentum destroyed per second measures the force, in absolute units (i.e. poundals); hence we have :—

$$P = \frac{1}{g}(GAv)\, v \text{ lbs.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (55)$$

Actually, however, owing to the air streams formed, and the action at the back of the moving plane, the case is not quite so simple, and it is found necessary to write the equation :—

$$P = f\, GA\, \frac{v^2}{g} \text{ lbs.,} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (56)$$

where f is a coefficient whose value is determined by experiment.

Very numerous experiments have at various times been made to determine f, with somewhat widely differing results according as the size, shape, and material of the plane have been varied. Experimental results of M. Eiffel and Dr. T. E. Stanton suggest that f may be taken for large surfaces, at the value $\frac{5}{8}$ roundly, so that Eq. (56) becomes, putting 32·2 for g :—

$$P = \cdot 0194 \times GA\, v^2 \text{ lbs.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (57)$$

A change in the air velocity, as well as changes in the plate itself, as referred to above, will cause variations in the coefficient f. Experimental results on a square plate are given in the table below, which shows the speed of the air in ft. per sec. and the corresponding pressure on the plate in lbs. per sq. ft.

AIR PRESSURE ON A NORMAL FLAT PLATE AT DIFFERENT AIR SPEEDS.

Air Velocity, ft. per sec.	Pressure, lbs. per sq. ft.	Air Velocity, ft. per sec.	Pressure, lbs. per sq. ft.	Air Velocity, ft. per sec.	Pressure, lbs. per sq. ft.	Air Velocity, ft. per sec.	Pressure, lbs. per sq. ft.

52	4·18	76	8·60	100	14·97		

Power Required to Drive the Plate.

If E be the horse-power necessary to drive the plane at v feet per second in opposition to a resistance of P lbs., we have :—

$$E = \frac{1}{550} Pv. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (58)$$

By aid of Eq. (57) this becomes :—

$$E = \frac{35 \cdot 3}{10^6} GAv^3 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (59)$$

Thus the horse-power necessary varies :—

Directly as the density of the air.
Directly as the area of the plate.
Directly as the cube of the relative speed of plate and air.

Case of a Smooth Plane inclined to the Direction of Motion.

Let the smooth plane be inclined at an angle $\phi°$ to the direction of its motion (assumed a horizontal).

As the plane is smooth, the resultant pressure R upon it must be normal to its surface. may be resolved into a horizontal component H, or drag of the plane, which directly resists t progress of the plane, and a vertical component L which measures the upward thrust of the a or 'lift of the plane.'

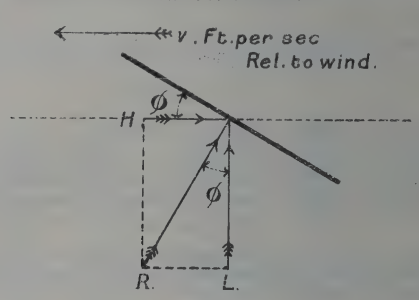

FIG. 1.

From fig. 1 it is evident that :—

$$H = R \sin \phi \quad . \quad . \quad . \quad . \quad . \quad (60) \qquad L = R \cos \phi \quad . \quad . \quad . \quad . \quad . \quad (61)$$

Experiments on the normal pressure of air on inclined planes show that the complete relatio connecting P, H, L, and ϕ is exceedingly complex. M. Eiffel finds that the value of $\frac{R}{P}$ is ind pendent of v; that it increases with the area of the plane; and that for rectangular plates wit the shorter dimension inclined, and for values of ϕ, in degrees, not exceeding 12 :—

$$\frac{R}{P} = \frac{3{\cdot}2 + 0{\cdot}5\, n}{100}\, \phi \text{ (app.)} \quad . \quad . \quad . \quad . \quad . \quad . \quad (62)$$

where n is the proportion of span to chord of the plane, or its 'aspect ratio.'

In general the value of n is about 6; taking this value in Eq. (62) we get as an average cas

$$R = 0{\cdot}062\, \phi \text{ P. lbs.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (63)$$

Hence from Eqs. (57), (60), and (61) :—

$$H = {\cdot}0012\, \phi \sin \phi\, GAv^2 = a\, GAv^2 \text{ lbs.} \quad . \quad . \quad . \quad . \quad . \quad (64)$$

$$L = {\cdot}0012\, \phi \cos \phi\, GAv^2 = b\, GAv^2 \text{ lbs.} \quad . \quad . \quad . \quad . \quad (65)$$

and as $E = \frac{1}{550} Hv$, we have,

$$E = \frac{2{\cdot}187}{10^6}\, \phi \sin \phi\, GAv^3 = c\, GAv^3 \quad . \quad . \quad . \quad . \quad (66)$$

whence, dividing Eq. (66) by Eq. (65) there results :—

$$E = \frac{1822{\cdot}5}{10^6} \tan \phi \times v\, L = k_0\, v\, L \quad . \quad . \quad . \quad . \quad . \quad (67)$$

which connects power, inclination, velocity, and lift.

In order to achieve horizontal flight the velocity v of the plane relatively to the air mus be just so great as to make the lift, L, equal to the weight of the plane, W.

Substitute, then, in Eq. (65), W for L, and we obtain on transposition :—

$$v_{min} = \frac{1}{\sqrt{b}} \sqrt{\frac{W}{GA}} = k_1 \sqrt{\frac{W}{GA}} \text{ feet per sec.} \quad . \quad . \quad (68)$$

Thus the speed necessary for horizontal flight varies :—

Directly as the square root of the weight of the plane.
Directly as the square root of the volume of 1 lb. of the air in cu. ft. (Table, p. 2024, col. 6).
Inversely as the square root of the area of the plane.

The horse-power necessary to just maintain horizontal flight is from Eqs. (67) and (68), putting W for L :—

$$E_{min} = k_0 k_1 \sqrt{\frac{W^3}{GA}} = k_2 \sqrt{\frac{W^3}{GA}} \quad . \quad . \quad . \quad . \quad . \quad (69)$$

Values of a, b, c, k_0, k_1 and k_2 from $\phi = 0°$ to $\phi = 12°$ are given in the following table.

ϕ in Degrees.	a. $\times 10^6$.	b.	c. $\times 10^6$.	k_0. $\times 10^6$.	k_1.	k_2. $\times 10^6$.
0	0	0	0	0	∞	0
1	21	·0012	·038	31·8	28·9	920
2	84	·0024	·1523	63·6	20·4	1,299
3	188	·0036	·3426	95·5	16·7	1,593
4	335	·0048	·6088	127·4	14·5	1,841
5	523	·0060	·9508	159·4	13·1	2,088
6	753	·0072	1·3684	191·6	11·8	2,265
7	1,024	·0083	1·8613	223·8	10·9	2,451
8	1,336	·0095	2·4291	256·1	10·3	2,627
9	1,689	·0107	3·0717	288·7	9·7	2,795
10	2,084	·0118	3·788	321·4	9·2	2,957
11	2,519	·0130	4·579	354·3	8·8	3,113
12	2,994	·0141	5·444	387·4	8·4	3,264

From Eq. (69) it is seen that the power necessary to maintain the plane in horizontal flight varies :—

Directly as the $\frac{3}{2}$ power of the weight.

Inversely as the square root of the density or directly as the square root of the bulkiness of the air as given in table, page 2024, col. 6.

Inversely as the square root of the area.

As the bulkiness of the air increases with the altitude, it appears from Eq. (68) that both the velocity necessary for horizontal flight and also the horse-power must increase as the plane ascends.

If the horse-power developed, E, exceed E_{min} the difference is expended in causing the plane to ascend. In the absence of any vertical resistance, the rate of ascent will be :—

$$\text{Rate of ascent} = \frac{550}{W}(E - E \quad) \text{ ft. per second} \quad . \quad . \quad . \quad (70)$$

When ϕ is small, sin ϕ and tan ϕ are each sensibly the same, and equal to $\frac{\phi}{57{\cdot}3}$, while cos ϕ is practically unity. Hence, as we are here considering values of ϕ not greater than 12°, we may with sufficient accuracy write :—

$$10^6 \times a = 21\ \phi^2. \qquad b = {\cdot}0012\ \phi.$$
$$10^6 \times c = {\cdot}038\ \phi^2. \qquad 10^6 \times k_0 = 31{\cdot}8\ \phi.$$

Accordingly Equations (64), (65), (66), and (67) respectively become :—

$$\text{If} = \frac{21}{10^6}\phi^2\ GAv^2 \text{ lbs.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (71)$$

$$L = {\cdot}0012\ \phi\ GAv^2 \text{ lbs.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (72)$$

$$E = \frac{{\cdot}038}{10^6}\phi^2\ GAv^3 \text{ horse-power} \quad . \quad . \quad . \quad . \quad . \quad . \quad (73)$$

and

$$E = \frac{31{\cdot}8}{10^6}\phi\ v\ L \text{ horse-power} \quad . \quad . \quad . \quad . \quad . \quad . \quad (74)$$

From these equations it is seen that, within the range of inclination taken :—

The horizontal resistance, and the horse-power required, vary directly as the square of th angle of inclination of the plane, while the lift varies directly as the angle simply.

The velocity necessary for horizontal flight, v_{min}, diminishes as ϕ increases agreeably wit the values of k, as given in table, page 2027 ; but the necessary horse-power increases with increas of ϕ, as shown by the increasing values of k_2 (*vide* table, p. 2027), in consequence of th rapid increase in H.

AEROPLANES.

'Aeroplane' is the generic term for landplanes, seaplanes, and amphibians. Seaplanes ar urther subdivided into boat seaplanes and float seaplanes.

Aeroplanes may be broadly classed as follows :—

Monoplanes, having a single main plane, developed from the early Antoinette and Blériot aeroplanes.

Biplanes, having two superposed main planes, developed from the Wright and Farman design

Triplanes, having three superposed main planes, first put into practical form by Mr. A. V Roe.

There are no practical examples of more than three planes, but the development of larg aeroplanes may necessitate some such arrangement.

In general, the biplane gives the best all-round results, being stronger than a monoplan of equal lift and speed, and offering less head resistance than a monoplane of equal strength.

The very small Blériot monoplane which, on July 25, 1909, crossed the Channel from Cala to Dover, covering 31 miles in 43 minutes, had a wing span of only 25 ft. 7 ins., a total lengt of 26 ft. 3 ins., and a gross weight including pilot and in flying order, of only 650 lbs.

The superficial area of the planes was about 150 square feet ; sufficient petrol was carrie for a two hours' flight, and the engine was a 3-cylinder air-cooled 20 h.p. 'Anzani,' driving two-bladed airscrew. The wing frames were of ash covered with water-proofed linen.

The engine was placed in front, below the planes, and the pilot sat above the engine. Th seaplane was caused to ascend by depressing the after ends of the planes ; horizontal steerin was effected by a vertical rudder placed at the rear ; the planes were normally inclined about 8 to the horizontal.

It will be seen that the upward pressure amounted to $\frac{650}{150} = 4\frac{1}{3}$ lbs. per sq. foot of wing are in this case ; from 3 to 6 lbs. per sq. foot is usual, though in races, with shortened planes, th figure is said to rise sometimes as high as 10 lbs. per sq. foot.

A distance of 31 miles in 43 minutes implies an average speed, relatively to the *earth*, o $63\frac{1}{2}$ feet per second. If the Anzani engine developed just 20 b.h.p., the effective horse-powe with an airscrew efficiency of 70 per cent. was 14.

It is of interest to apply the formulæ obtained to the foregoing case. Thus we hav $W = 650$, $A = 150$; and as the flight was not at a great height, we may take $\frac{1}{G} = 13$ (table col. 6, p. 2024) ; also $\phi = 8$. Hence, Eq. (68) gives :—

$$v_{min} = 77 \text{ feet per sec.}$$

relatively to the *air*.

While, putting $L = 650$, Eq. (74) gives :—

$$E_{min} = 12\frac{3}{4} \text{ effective horse-power.}$$

Assuming the airscrew efficiency as 70 per cent., the necessary brake horse-power of the engin must accordingly be, roundly, $18\frac{1}{4}$.

Remembering that the formulæ were deduced for the simple case of a smooth true plan these figures may be regarded as giving a helpful indication. Actually the wings are neithe smooth (see table, p. 2030) nor are they true planes (see fig. 2, p. 2029) ; there is also the re sistance offered by the air to the body, rudder, stays, etc.. etc., of which no account has bee taken in the above investigation.

The velocity of the wind is, in general, least near the earth's surface, and in flying round closed circuit the effect of a wind from any quarter is, on the whole, to retard the aeroplane hence, in aerodrome speed trials (*i.e.* speed relatively to the *earth* pilots usually fly very nea the ground.

It appears from Eq. (69) that the horse-power necessary to maintain horizontal flight slowly creases with the altitude of the plane. Eqs. (68) and (69) show, in fact, that both the velocity d power for horizontal flight must increase in proportion to $\sqrt{\frac{1}{G}}$, that is, in proportion to the uare root of the bulkiness of the air. For example, at an altitude of 20,000 feet we have om table, col. 6 (p. 2024), $\frac{1}{G} = 24{\cdot}44$. Hence, in the case above taken, the necessary elocity at this height must be $77 \times \sqrt{\frac{24{\cdot}44}{13}} = 105{\cdot}5$ feet per second, while the effective orse-power must be $2\frac{3}{4} \times \sqrt{\frac{24{\cdot}44}{13}} = 17{\cdot}5$. Thus both the velocity relatively to the air, and e power, must, in this case, be increased by 37 per cent. to sustain horizontal flight at an titude of 20,000 feet, owing to the diminished density of the air.

For the first two or three thousand feet of ascent as $\frac{1}{G}$ alters but little (see table, p. 2024), ere is, in the example taken, an excess of $17\frac{1}{2} - 12\frac{3}{4} = 4\frac{3}{4}$ horse-power available for causing ascent, that, neglecting all vertical resistances, the plane would rise during the first part of its flight a maximum rate, agreeably with Eq. (70), of $\frac{4{\cdot}75 \times 550}{650} = 4{\cdot}0$ feet per second, or 1,000 feet in 15 minutes.

This, again, is a result of the right order of magnitude; for example, the winning machine the International Air Competition at Hendon on September 27, 1913, attained a height of 700 feet in 13·17 minutes, *i.e.*, at the rate of 1,000 ft. in about 4·9 minutes.

The types of aeroplanes now in general use are:—

Use.	Type.	Name.	Seats.	Engine.
Training	Biplane	Avro	2	100 h.p. rotary, air-cooled.
Reconnaissance	Biplane	Bristol Fighter	2	350 h.p. water-cooled 'V.'
Reconnaissance	Biplane	Panther	2	150 h.p. air-cooled rotary.
Scout	Biplane	Snipe	1	Radial or rotary air-cooled.
Reconnaissance	Biplane	Vimy	3	2–350 h.p. water-cooled 'V.'

Wings of Aeroplanes.

The main planes or wings of aeroplanes are commonly of rectangular form in plan, with a ansverse length, or 'span,' about 6 times the fore-and-aft length, or 'chord'; the ratio of ansverse to fore-and-aft length is termed the 'aspect ratio'; hence the 'aspect-ratio' has ually a value about 6.

The planes on either side of the fore-and-aft centre lines are set at an angle to the horizontal ane, known as the 'dihedral' or 'anhedral' angle, according to whether the planes are above or low the horizontal.

Experiments have shown that a good form of wing section is as indicated in fig. 2, and this known as the R.A.F. 14 wing section. The maximum ordinate—*i.e.* the vertical measurement om the chord—occurs at about one-third of the chord from the leading edge.

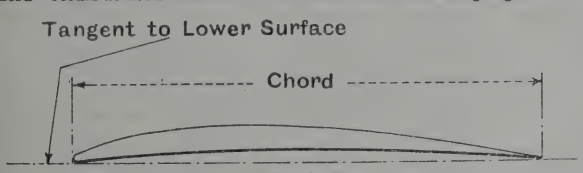

FIG. 2.

The actual shapes and characteristics of this and other wing sections are given in the tables on 2030, which represent the ordinates measured at right angles to the chord at varying distances om the leading edge of the section; the chord being taken as the tangent to the lower points the leading and trailing edges.

The reduction of pressure on the *upper* surface actually contributes the larger portion of the fting force.

The value of the 'aspect-ratio' is important; if the wings be too long in a fore-and-aft rection diminished, performance results; at the Rheims aviation contest, by reducing the ore-and-aft length of the wings of his aeroplane by about one foot, M. Blériot, carrying the same eight as before, flew much faster with the same engine.

The 'Aerial Derby' of 1913 was won by G. Hamel, who, by shortening his wings prior to the ntest, averaged a speed of 76 miles per hour (relatively to the earth). It is obvious from Eq. (68) at a reduction in A causes an increase in v_{min}; the horse-power necessary must also be increased the same proportion, however, as is shown from inspection of Eq. (69). The wing area is now equently reduced for speed contests.

'Skin Friction' of the Planes.

The experiments of Dr. Zahm of Washington led him to conclude that, in proportion their densities, the frictional resistance of air is at least as great as that of water, and at this resistance is an important factor in the problem of high-speed flying. Some of r. Zahm's results are exhibited in table below. He states also that 'the frictional resistance a plane or arched surface soaring at small angles on a horizontal course is equal to the *horizontal rojection* of the surface multiplied by the average friction per square foot as given by table elow.'

Experiments were made to determine the effect of the nature of the surface of the plane upon e frictional resistance; practically no difference was found with dry varnish, sticky varnish, et surface, sheet zinc, glazed cambric, calendered or uncalendered paper, or drawing paper. ith coarse buckram having sixteen meshes to the inch, the friction at 10 ft. per second was, owever, found to be from 10 to 15 per cent. greater than with the uncovered surface.

Calculation of Frictional Resistance and Horse-Power.

In using the above table, it must be remembered that a material plane exposes *two* surfaces the action of the air. For example, the frictional resistance of a material plane of 24 feet span, d with a fore-and-aft length ('chord') of 4 feet, at a speed of 80 miles per hour relatively to e air, is to be estimated as follows:—

From the table the friction per square foot for a fore-and-aft length of 4 feet at a relative eed of 80 m.p.h. is ·0474 lb.; and as there are $2 \times 24 \times 4 = 192$ square feet of total area posed to the action of the air, the total frictional resistance of the material plane is $192 \times 0474 = 9{\cdot}1$ lbs.

Eighty miles per hour $= 1{\cdot}47 \times 80 = 117{\cdot}6$ feet per second; hence the work necessary to vercome friction alone is $117{\cdot}6 \times 9{\cdot}1 = 1070{\cdot}2$ foot-lbs. per second; and thus $\frac{1070{\cdot}2}{550} = 1{\cdot}95$ orse-power must be expended to overcome this resistance. In the practical design of aeroplanes is, of course, necessary to take account not only of the frictional resistance of the wings, but lso that of the body, stays, and other parts of the machine exposed to the relative velocity f the air.

Control of Aeroplanes.

When the Aeroplane is Flying on an Even Keel.

When in flight an aeroplane has freedom of motion in three dimensions about its own cent Its motion in these dimensions is controlled by :—

The Rudder, a movable vertical surface, adjusted by the pilot's feet, controlling the directi of flight in a horizontal plane.

The Elevator, a movable horizontal surface adjusted by a lever in the pilot's hand, controlli the direction of flight in a vertical plane within the limits set by the lift of the main planes a the power developed by the engine.

The Ailerons, small movable planes attached to the outer ends of the main planes, arrang so as to increase or decrease the lift on either side of the aeroplane and adjusted by the sa lever which controls the elevator. The ailerons enable the aeroplane to be kept lateral horizontal, and to be tilted or ' banked ' as required for any manœuvre in the air.

Adjustable Tail Gear.—This gear enables the tail of an aeroplane to be adjusted in flight, a so in effect controls the aeroplane as an elevator. By setting the adjustable tail, an aeropla can be made to climb or to fly in any given attitude without having continually to exert a for upon the control column.

Wing Flaps.—Wing flaps are used to supplement the action of ailerons, but differ slight from ailerons in that the flaps are both moved in the same direction relatively to the aeroplan It is by the use of such flaps that the minimum flying speed of an aeroplane can be adjuste with the result that for a given speed the lift of the main planes can be increased. This is great advantage when an aeroplane is getting off or landing, as in the former case it is enabl to rise from the ground or water much more quickly, while in the latter the speed of contact the aeroplane is considerably reduced.

Stability.

Aeroplanes may be unstable, or inherently stable. The former require constant vigilan on the part of the pilot, or the incorporation of some mechanical device such as the Sper Gyroscopic Stabiliser, which gives them ' automatic stability.' The latter possess a tendency return to their normal flying position after any disturbance.

Inherent stability is obtained by correct proportioning of the main and auxiliary planes a their dihedral angles, and a proper balancing of the couples about the centre of the aeroplan due to the lift and resistance of the planes, the mass of the aeroplane, and the thrust of th airscrew.

Unstable aeroplanes can be manœuvred more rapidly and accurately than can highly stab aeroplanes : they are therefore more suitable as fighting machines, whilst the latter have a wid application for commercial purposes.

Airscrews.

Airscrews are now constructed either of wood or metal. In the former case, laminations hard wood, usually walnut or mahogany, are glued and pegged together and shaped to the corre pitch and blade section. In the case of metal airscrews, these are made of sheet steel, shape to the correct blade section, the details of manufacture being greatly varied. Some met airscrews are constructed with hollow steel blades which are welded at the root to a suitab metal boss.

The tips of wooden airscrews are sometimes sheathed with metal, usually brass or copp to protect the thin portions of the blade. This metal tipping is often adopted for seaplane and where airscrews are liable to be sprayed with water while running at high speed.

For the sake of efficiency, airscrews should be of large diameter, and should run at a lo speed. In large engines, a reduction gear is usually incorporated so as to allow the engine t run at a higher speed than the airscrew. With modern airscrews, an efficiency as high a 77 per cent. and over has been obtained.

Colonel Dorand has found that the diameter of the airscrew should be proportional to th weight supported per h.p. and to the square root of the total weight of the aeroplane. Also, tha the r.p.m. of the airscrew should be inversely proportional to the square of the weight supporte per h.p. and to the square root of the total weight.

The loss in the efficiency of airscrews running at a high speed is serious, and has been foun greater than any gearing loss ; therefore, for engines running at high rotational speeds, it i

ecessary to fit reduction gearing to allow the airscrew to run at about 1,200 r.p.m. Tip speeds p to 800 ft. per second have been used, but it is better for the speed not greatly to exceed 00 ft. per second.

An exhaustive treatise on aviation is that of Mons. G. Eiffel, entitled 'The Resistance of the ir and Aviation' (Eng. Trans. by J. C. Hunsaker, Constable & Co., 42*s*.); the subject is treated s completely as is at present possible, and the work may be studied with advantage by ngineers interested in the design and construction of aircraft.

Windmills.—Windmills are reversed airscrews, and are used considerably for driving secondary ower units on aeroplanes. Their aerodynamic features follow very much on the lines of air- crews, and a suitable aerofoil section is adopted for the blades. The characteristics of windmills re such that they can give a certain power at two distinct speeds, and if power be plotted against otational speed for a given forward speed, it is found that the power increases to a maximum nd then falls off. The limiting conditions of no power are when the rotational speed is zero, nd when the rotational speed is such that there is no slip of the windmill relatively to the air.

The conditions of use of windmills decide that they should be restricted in size, and conse- uently most of the windmills now used are of a comparatively small diameter with wide blades.

Resistance of Wood to Reversals of Stress.

The limiting resistance of spruce (used for aeroplane wing spars) to alternate tension and com- ression was proved by experiment to be above 1,600 lbs. per sq. inch, and below 1,970 lbs. per sq. nch. For spruce of this quality the safe range of stress under reversals of bending would be pproximately ± 1,800 lbs. per sq. inch, or one-quarter of the ultimate stress, which was found to e 6,800 lbs. per sq. inch. In this respect spruce appears to be at a slight disadvantage compared ith mild steel, in which the safe limit of stress under similar circumstances is generally about ne-third of the ultimate stress. (*The National Physical Laboratory.*)

Resistance of Tension Members of a Structure to Lateral Vibrations.

In cases in which the tension members of a structure are attached to the pin joints of the ame by means of a screw connection unaccompanied by a universal joint, it has been found hat the screws are liable to the development of fatigue cracks at the bottom of the threads, and o ultimate failure.

It has been found that if a universal joint be provided at both ends of a wire subjected to lateral ibrations, a load of one-third of the breaking load will in the case of high class material be borne or an unlimited number of vibrations, but that if only a single joint be used fracture takes place nder one-sixth of the breaking load after a few hours. (*The National Physical Laboratory.*)

Rivet for Aircraft Construction.

This rivet, the invention of Lieutenant J. W. Iseman, is for use in Duralumin construction ork in positions where it is difficult to hammer at one end and support the other, but it is also daptable for other purposes, and is a very ingenious arrangement.

The rivet is shown in fig. 3 in position both before and after riveting. A hole ending in a

Fig. 3.

onical point is drilled through the head of the rivet in the direction of the axis, as shown at **A**. The base of the cone starts at the end of the nominal grip length of the rivet, this being equal to he thickness of the riveted plates. The end of the rivet is slotted up to the grip with two slots at right angles.

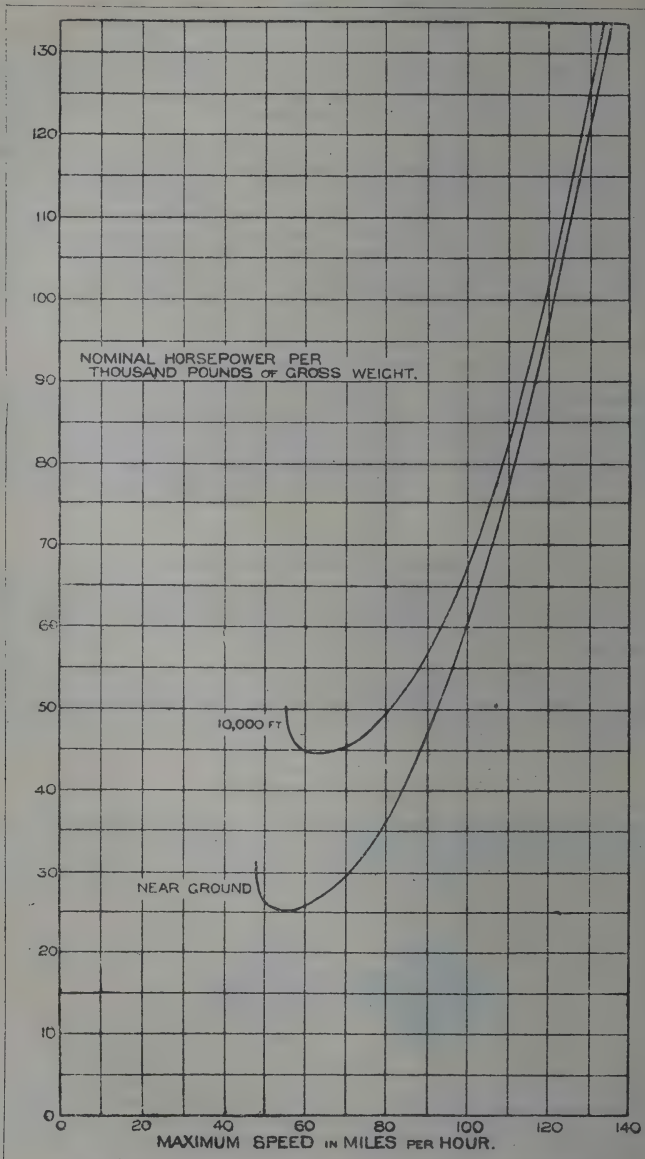

FIG. 4.—Curves showing how speed varies with ratio of H.P. to gross weight.

A pin of the same diameter as the hole and ending in a similar cone is tapped into the rivet ıtil the end is flush with the head, as shown at **B.** This pin causes the slotted end to spread ı as the straight side of the pin travels along the side of the cone. When the pin is home, the ies of the cone are parallel to the axis of the rivet as at **B.**

It is found that friction and binding between the rivet and the pin are quite sufficient to hold e latter in place.

Tests of these rivets have shown that with an outside diameter of 0·127 in. and a pin 0·053 in. diameter, a shear strength of 450 lb., of 35,500 lb. per square inch, can be developed.

Rough Prediction of Aeroplane Performance.*

The curves (fig. 4) show how the speed of flight near the ground and at 10,000 ft. depends ı the nominal power of the engine and the gross weight of the aeroplane. The ratio of horse- ıwer to weight is used. Regarded as an empirical curve, however, it is found that the rformances of the smallest and largest aeroplanes are equally well predicted. Like all general- ıtions it has its limitations, and a designer who has given special attention to one type will ; able to give a closer prediction. On the other hand, any record of performance showing riking departure from the curve may be regarded with mistrust.

The curves illustrate the aerodynamic disadvantages of high speed. It is to be noted that a oss weight of 1,000 lbs. can be carried by an aeroplane of modern type for an expenditure of ı h.p., but there is no reserve and the pilot could not climb or cope with down currents. His eed would be about 55 m.p.h. The necessary horse-power for the same load could be reduced ı providing bigger wings and flying slower, and it has been pointed out by various writers that e most economical design aerodynamically requires speeds of flight below those of commercial ility.

Using the curves of fig. 4, it can be seen that the aerodynamic quality of the aeroplanes the beginning of the war was not appreciably less than those of the present day, for all give rformances indicated by the curve. Progress has followed the development of the aero-motor hich now permits the use of one horse-power for each 8 lbs. of gross weight, whereas in 1914 e same power was yoked to a load of nearly 25 lbs. The most recent of our large aeroplanes rries nearly 20 lbs. per horse-power, and its performance on speed and ceiling is not greatly fferent from that of the 'Avro' or B.E.2C. It is now accepted as a fundamental truth that the eight-carrying aeroplane cannot be the fast aeroplane, and the rate at which the horse-power rve is rising shows that the conditions become progressively worse. It needs little imagination see that increase of top speed beyond present limits will not easily be attained, and that no eat increase such as that during the war period is within the limits of reasonable expectation. ıe table given below is instructive in the economics of aeroplane carriage.

Speed of flight, m.p.h.	Gross weight, lbs. per h.p.	Percentage of gross weight available for passengers and merchandise.
60	38	45
70	35	44
80	28	41
90	21	38
100	17	33
110	13	27
120	10	20
130	8	10

It will be seen that the choice lies between a time of six hours and a useful load of 40 per cent. the total and a time of four hours and 20 per cent. of the load useful. Only the particular need the moment can determine a final choice. (*Leonard Bairstow, F.R.S.*)

Storage of Aircraft.

To maintain good efficiency and reliability considerable attention must be given to aircraft uring the time they are not actually in flying condition, as storage in an indiscriminate manner ads to rapid deterioration of the aeroplane structure, with consequent financial loss, and the troduction of factors which may be dangerous when the aeroplane is afterwards flown.

* Extract from the Wilbur-Wright Lecture, 1919, 'Progress in Aviation in the War Period,' elivered before the Royal Aeronautical Society by Leonard Bairstow, F.R.S., C.B.E.

Many of the methods used for the storage of aeroplanes have up to the present been formulated by a process of trial and error, but by experience it is now possible to say which are the best methods.

It is necessary that care should be taken not only with the storage of the aeroplane, but also with the selection of the storage building. Such buildings should be weatherproof, ample size, and, if possible, be equipped with plant for maintaining fairly constant atmospheric condition

Given a suitable building, each complete aeroplane or its component must be stored so that no heavy parts are allowed to hang on weak points of structure. Loads thrown on the centre of an unsupported span should be avoided, as such loads may produce permanent deformation of the structure and may be sufficient to render the aeroplane or its part unserviceable. Stored aircraft should be subjected to periodical inspections in order to detect deterioration; to permit these inspections the aeroplane shed should be arranged so as to give access to all the principal components such as main planes, engines, and controls.

Methods of Storage.—There are three methods of storage which may be adopted, namely,

(*a*) Aircraft fully erected but with tanks empty. In the case of large aeroplanes, with the main planes folded.

(*b*) Aircraft dismantled into its principal parts and the parts located together.

(*c*) Aircraft dismantled into its principal parts and the parts stored separately.

Method (*a*) is adopted when the aeroplane is likely to be required for flight at short notice as it is only necessary to take the aeroplane from the storage shed and make the appropriate rigging adjustments in order to place the aeroplane in flying condition.

Method (*b*) is used where an aeroplane will not be required for immediate use, and the method is devised principally to ensure that the association of the various parts of each aeroplane may be maintained.

In method (*c*) the procedure follows much on the lines of (*b*), but in this case instead of the components of each aeroplane being kept together they are placed in common storage with similar parts of other aeroplanes.

Stored aeroplanes should be screened from strong sunlight, either by colour washes on the roof lights of shed, or by employing non-actinic glass in the roof lights, as it has been found that sunlight has a deteriorating effect on the doped fabric, causing the doped film on the latter to crack, and so allow moisture direct access to the fabric; rubber is also affected by sunlight, and cracks after prolonged exposure.

In the case of storage by methods (*a*) and (*b*) a film of oil should completely cover all the internal surfaces of the engine, and as a further safeguard this oil should be renewed at intervals of about one month. The oil used should be a high-class mineral oil, and after being injected through the sparking-plug holes the engine should be turned a few times to distribute the oil over the interior surfaces. When renewing the oil, all the old oil should first be drained from the engine.

Rigging of Aeroplanes.

Before an aeroplane is flown, it has to be erected so that its principal parts bear a definite relation to each other.

The features which are special to rigging are, principally, angle of incidence, dihedral angle, gap, chord, stagger, tail plane incidence and setting of controls.

The angle of incidence is limited to the value of the angle which the chord of the main plane makes with a horizontal or datum line when the aeroplane is in rigging position.

A typical design may be taken in the form of a single-engined tractor biplane:

Fuselage.—The fuselage is first erected and trued up, and where longerons and struts with cross bracing are used, it is necessary to adjust the bracing so that the whole structure conforms to its designed shape. The structure may be symmetrical, either in plan or elevation, or both, and when this obtains, the condition of symmetry is checked by reference to a centre line stretched along the length of the fuselage. Each bay of the fuselage is then adjusted until the members are in correct position, particular care being taken to see that the fuselage does not become twisted. After this preliminary truing up the engine, upper centre section, tail plane, fin and other such fittings may be attached to the fuselage.

With the fuselage thus erected, it is supported on suitable trestles, one being placed under the front portion and another under the tail, and adjustments made until the fuselage is in rigging position, *i.e.* until a datum line (usually fixed by the designer) is horizontal; this line is sometimes indicated by points on each of the struts of the fuselage, or alternatively, it may be obtained by stretching a line between certain fixed points at each end of the fuselage.

Undercarriage.—Taking an undercarriage of the ordinary Vee strut type, this is assembled and attached to the fittings on the fuselage. In this position it will really be slung from the fuselage so that the wheels, if fitted, will be just clear of the ground. Where Vee struts are used, longitudinal adjustments cannot be carried out, and it remains for the undercarriage to be symmetrical about the centre of the fuselage when viewed from the front. Adjustments in this direction are usually obtained from cross bracing wires which extend from near the axle end to the point of attachment of the front undercarriage struts to the fuselage; by making these bracing wires of equal length, the correct position of the undercarriage is obtained.

In this position the weight of the undercarriage may be taken by placing packing blocks under the axle ends or where the axle meets the Vee struts.

Main Planes.—The main planes are usually treated in pairs on each side of the aeroplane, and for aeroplanes with two pairs of interplane struts on each side and of span up to 30 feet, each pair of planes is assembled on the ground with the struts and bracing wires loosely attached. The whole is then lifted into position on the fuselage and the bracing wires connected up. The weight of the planes is then carried by the bracing wires, but to augment this support, trestles are placed under the lower main planes below the outer interplane struts and packed up until they meet the spars of the lower main planes. The fittings for the lower main plane spars are rigidly attached to the lower portion of the fuselage, so that the chords of these main planes will be at a definite angle to the datum line on the fuselage, this angle being the angle of incidence. Apart from 'wash in,' 'wash out,' or other refinements, this angle of the chord will be maintained throughout the span of the main plane and, in the case of planes without décalage, the chords of the upper planes will be parallel to those of the lower. The lengths of the interplane struts will determine the attitude of the upper main planes, and if struts of the proper length are used, the incidence of the upper main planes will be approximately correct. The interplane bracing wires are then adjusted to give the designed dihedral angle which is varied by raising or lowering the tips of the planes. In a similar manner, the stagger, or forward displacement of the upper plane relatively to the lower, is obtained, but, in this case, the bracing wires between the interplane struts are used for adjustment. When all the settings of the planes have been correctly adjusted, all the bracing wires are carefully tightened and locked, undue tightening being avoided as it has a tendency to bend the interplane struts. The angular settings of the planes may be checked by a measuring device such as an inclinometer, and the symmetrical arrangement of the planes by taking measurements from the top of the front outer interplane strut to the root of the front spar of the lower plane on each side and seeing that these measurements are equal.

Tail Plane.—The tail plane is set in the centre of its travel, and this position used as a basis for rigging. In this position the centre line of the tail plane will be inclined to the datum line of the fuselage at a small angle, and this setting may be obtained by altering the zero setting of the adjusting mechanism.

Controls.—The control surfaces consist of the ailerons, rudder, and elevators, and these are hinged to the main planes, stern post, and tail plane, respectively. After attachment, the cables from the pilot's controls are connected and the setting of each surface is arranged as follows:—

Ailerons.—With the pilot's control column in its central position, the trailing edges of the ailerons should droop approximately $\frac{1}{4}$ inch.

Rudder.—With the rudder bar square in the fuselage, the rudder should point directly fore and aft.

Elevators.—These are usually considered to be a continuation of the tail plane when in its normal position, and in this position the pilot's control column may be slightly out of the vertical and lean forwards or backwards according to the requirements of the design.

Autogyros.

Autogyros embody some of the features of the standard type of aeroplane coupled with certain characteristics of a helicopter. The chief features of the design consist of an aeroplane fuselage which is lifted by rotating wings that form a windmill over the fuselage. The fuselage is fitted with a power unit of the usual type and the rotation of the windmill occurs by a process known as 'auto-rotation.' A flying machine of this type has been constructed by Señor de la Cierva and successfully flown. The fuselage is that of a standard Avro type 504 biplane and the power unit consists of a 100-h.p. Le Rhône engine with a standard wooden airscrew. The fuselage has the usual type of tail unit and is supported on an Avro under-carriage. The rotating windmill, from which the lift is derived, is formed with four blades, and the central pivot for the windmill is carried on a vertical mast which is rigidly attached to the fuselage. Each blade of the windmill is set to provide a small angle of incidence, and an up-and-down movement of the blade is allowed for by a pin joint at the root end of the blade. To prevent the blade from dropping

while the windmill is stationary, the weight of each blade is carried by a length of shock absorb elastic, which has its end fixed to the top of the vertical mast, so that it can rotate with the blad The machine has the usual flying controls of the ordinary type of tail unit. Lateral control effected by two small stabilisers, one on each side of the fuselage. Each stabiliser is carried the end of a spar that projects from the side of the fuselage much in the same way as a spar the standard wing system. Before commencing a flight, the wings of the windmill are rotat by man-power, and owing to the inertia of the system, and the small bearing friction, the rotati continues for some time. The rotation is effected by first winding a cable round pegs on t lower side of the wings and then pulling on the cable to unwind it and so spin the windmill. T machine is then taken into the air in the normal manner, *i.e.* by running along the ground, a when the necessary speed of the windmill has developed, the machine lifts into the air and co tinues to fly by the forward force provided by the airscrew and the upward force derived from t rotating windmill. The maximum flying speed with the expenditure of 90-h.p. is about 1 kilometres per hour, and the slowest forward speed at which the machine has been flown is abo 54 kilometres per hour. Owing to the nature of the design, a very steep landing angle can used, and when descending at an angle of 30°, the landing speed is about 4 metres per seco horizontally and 2 metres per second vertically. The rotational speed of the windmill remai practically constant at about 130 r.p.m. throughout the range of flying conditions. The ma dimensions of the rotating wings are: span 35 ft., chord 3 ft., incidence 2°, and the weight of t complete machine is roughly 1,400 lbs.

Notable Flights.

Atlantic Flights.

The first crossing was made by the seaplane N.C.4, piloted by Commander Read, which acco plished the journey from Newfoundland to Plymouth in three stages, as follows:—

Newfoundland to Azores	1,381 miles	15 hours	19 mins.
Azores to Lisbon	1,034 ,,	9 ,,	42 ,,
Lisbon to Plymouth	895 ,,	5 ,,	1 ,,

The attempt made on May 18, 1919, by the late Mr. H. G. Hawker and Lieut.-Command Grieve in a single-engine Sopwith machine failed, the aviators being picked up 1,000 miles fr land by the small ship *Mary*.

Three weeks later the direct crossing was successfully accomplished from St. John's to Galw Bay, Ireland, by a Vickers-Vimy double-engined (Rolls-Royce) aeroplane (fig. 5), piloted Captain John Alcock, D.F.C., and navigated by Lieut. Arthur Whitten Brown. The 1900 nauti miles were compassed in 15 hours, 57 minutes. For this performance the airmen were knighted His Majesty the King.

In the following month, a British airship, R34, starting on July 2, 1919, from England, cross the Atlantic to Newfoundland, and went on to New York, whence it returned direct to its starti point, arriving on July 13. This flight was remarkable for the fact that the airship was, duri the whole of its six-thousand-mile trip, in wireless communication with the Air Ministry in Londo Moreover, it was furnished with continuous information as to weather conditions ahead of and was able to modify its route in order to avoid storm-swept areas.

In 1927 the Atlantic was flown several times. On May 20, at 8 A.M., Capt. C. Lindbergh s out from New York on a Ryan monoplane fitted with a 220-h.p. Wright Whirlwind engine, wi the object of flying the distance of 3,600 miles to Paris. Le Bourget was reached at 10.22 P. on May 21. The pilot was single-handed, and he had neither wireless nor the special navigati instruments usually employed for such purposes. The fuselage of the machine was of st construction, and the wings were braced by sloping struts to the fuselage. The landing gear h a wide track with no axle. The gross weight of the machine with 425 gallons of fuel and 28 gallo of oil was 4,750 lbs., and the speed range with full load was 69–123 m.p.h.

Another of the Atlantic crossings was made by Commander Byrd on June 29. A total cr of four and extensive equipment were carried. A machine called the 'America' was used, bei a Fokker monoplane with three Wright Whirlwind engines. The start was made at dawn fr Roosevelt Field, Long Island, and after leaving Newfoundland the machine ran into fog whi caused the crew to lose sight of sea and sky for nineteen hours. On reaching France at nightfa on June 30, the weather became adverse and the crew were lost for some hours. Eventually was decided to find the coast and alight on the water, and in doing this at 2.30 A.M., near t village of Ver-sur-Mer, between Cherbourg and Havre, the machine was damaged but the cr were unhurt.

Anglo-Australian Flight.

The Australian Government prize of 10,000*l.* for a flight from England to Australia, in a heavier-than-air machine of British construction, was also won by a Vickers-Vimy aeroplane, piloted by Captain Ross Smith, accompanied by his brother, Lieut. K. M. Smith, and two sergeant mechanics. This wonderful journey, commenced on November 12, 1919, was completed in twenty-eight days, the total flying time being only 124 hours. This makes it evident that by organising relays of aeroplanes it would be possible to provide a mail service to Australia with a transit time of less than one week.

FIG. 5.—Atlantic Flight: Vickers-Vimy Rolls-Royce Aeroplane. (Now in Victoria and Albert Museum.)

Length 47 ft.
Span 70 ft.
H.P. 700 (2 Eagle Rolls-Royce of 350 h.p.)
Total weight 16,000 lbs.
Time crossing Atlantic 15 hrs. 57 mins.
Carried 867 galls. of petrol. (Used two-thirds of this.)
Cruising speed 80 m.p.h.
Maximum speed 105 m.p.h.
Climbs to 25,000 ft.

First Flight across Asia.

Lieuts. Ferrarin and Masiero started from Rome on February 14, 1920, and flew across Asia to Japan, arriving at Tokyo on May 31. Intermediate stops were made at the under-mentioned cities: Adalia, Bagdad, Bunder Abbas, Delhi, Calcutta, Rangoon, Bangkok, Canton, Tsingtao, Peking, Seoul, and Osaka.

London to Turin, Direct Flight.

On May 31, 1920, Mr. Bert Hinkler, an Australian pilot, left Croydon at 4.50 A.M., flying a Baby Avro with a 35 h.p. Green engine—which engine had been built in 1910.

Passing over Dover, Paris, Lyons, and clearing the Alps, he arrived, without an intermediate stop, at Turin at 2.20 P.M. on the same day.

Six hundred and fifty miles in 9½ hours on twenty gallons of petrol.

For fuel economy this flight brings the aeroplane into competition with the motor-car.

London to Rangoon.

In November 1924 a flight was made by Mr. A. J. Cobham, with Air Vice-Marshall Sir W. Sefton Brancker as a passenger, from Croydon Aerodrome to Rangoon, and the return journey was completed on March 18, 1925.

During the flight 17,000 miles were covered in a flying time of 220 hours, and the aeroplane used was a D.H. 50 fitted with a 230 h.p. Siddeley Puma V. engine.

During one portion of the journey the aeroplane was forced to land in a snowstorm, and it had to be dismantled, transported 50 miles by road, and re-erected by unskilled personnel, all of which was accomplished in 36 hours.

London—Cape Town—London.

On March 12, 1926, Mr. Alan Cobham (Sir A. Cobham) completed a successful flight from Stag Lane aerodrome in London to Cape Town and return. The aeroplane used was a D.H. 50 J. fitted with a 385-h.p. Armstrong Siddeley Jaguar engine (see p. 2061), and the total distance flown was 17,000 miles. The homeward journey was accomplished in 15 days.

England—Australia—England.

Between June 30 and October 1, 1926, Mr. Alan Cobham (Sir A. Cobham) accomplished a successful flight from England to Melbourne and return. The journey covered a distance of 28,000 miles and was performed on a D.H. 50 J. aeroplane fitted with a Siddeley Jaguar engine (see p. 2061) of 358 h.p.

It took 37 days to fly from England to Port Darwin, Australia, a distance of approximately 11,380 miles, and then another 8 days to fly to Melbourne, a further distance of 2,650 miles. On the homeward journey it took 5 days from Melbourne to Port Darwin, and then 28 days to reach England. The total flying time was 320 hours.

Round Australia.

On June 29, at 14·45 hours, Mr. Kingsford Smith and Mr. Ulm arrived at Mascot aerodrome Sydney, after having flown round Australia in ten days on a Bristol Tourer (240-h.p. Puma engine)

The Longest Oversea Flight.

On June 29 Lieuts. Maitland and Hegenberger, of the U.S. Air Corps, arrived at Honolulu after having flown across the Eastern Pacific from San Francisco in a Fokker F. VII-3m. (three 200-h.p. Wright Whirlwind engines).

The distance of 2,400 miles was covered in 25 hours 13 minutes. This is the longest flight made entirely over the sea.

BRITISH SPEED RECORDS.

In December 1921, at Martlesham Heath, Mr. J. H. James achieved a maximum speed of 212 m.p.h. over the measured kilometre, and averaged in four trials 196 m.p.h. This was accomplished on a Bamel machine with Napier 'Lion' engine.

AERIAL DERBY, 1923.

The 1923 Aerial Derby was won by L. Carter on a 'Gloster' aeroplane built by the Gloucestershire Aircraft Company, with a 450-h.p. Napier 'Lion' engine.

The speed of the winner for the two-circuit 200-miles route worked out at 192·4 miles per hour

There was no race in 1924.

FLYING BOAT TROPHY, 1923.

The International Flying Boat Trophy—open to all flying boats in the world—was won for U.S.A. by Lieut. David Ruttenhouse on a Curtiss Navy Racer with Curtiss D 12 465 h.p. engine

The speed of the winner averaged 177·38 miles per hour.

KING'S CUP RACE, 1923.

His Majesty the King presented, in 1912, a cup to the Royal Aero Club for competition in an air race around Britain.

Croydon was the starting-point, and calls had to be made at Birmingham and Newcastle *en route* to Glasgow, where the aviators stayed over night, completing the circuit on the second day via Manchester and Bristol.

Twenty-two competitors started, and eleven completed the circuit. The first prize was won by Captain F. L. Barnard on a war-time D.H. 4A., with a 350 h.p. Rolls-Royce Eagle VIII engine. His average speed for the whole circuit of 180 miles was 123 miles per hour.

F. P. Raynham, in a Martinsyde F. 6, with a 200 h.p. Wolseley 'Viper' engine, was second; average speed 105 miles per hour; and Alan J. Cobham, in a D.H. 9B., with 230 h.p. Siddeley 'Puma,' was third, average speed 810 miles per hour.

In 1925 the race was flown on two consecutive days over a circuit of Britain commencing and finishing at Croydon and passing the following places:

Harrogate, Newcastle, Renfrew, Blackpool, Shotwick, and Bristol.

On the first day the competitors went in the direction of Croydon to Harrogate, and the second day from Croydon to Bristol. The total distance of each circuit was 804 miles, and the result of the race was as follows:

	Aeroplane.	Engine.	Pilot.	Net Flying Time. First Day.			Second Day.		
				Hrs.	Mins.	Secs.	Hrs.	Mins.	Secs.
1.	A. W. Siskin V.	395 h.p. Jaguar	Barnard	6	11	17	5	18	58
2.	D.H. 37 Sylvia	275 h.p. Falcon	Hemming	9	59	14	6	43	51
3.	A. W. Siskin IV.	395 h.p. Jaguar	Jones	7	1	51	5	41	3

King's Cup Race, 1926.

In 1926 it was a handicap race, and was flown on July 9 and 10 over a total distance of 1,464 miles. The course for each day consisted of two triangular laps, each being flown twice, with the start and finish at Hendon. One of the laps was via Martlesham and Cambridge, a distance of 166 miles, and the other was via Coventry and Cheltenham, a distance of 200 miles. At Hendon a compulsory stop of either 30 minutes or 1 hour was made between each lap, and competitors were not to land at any other points.

There were sixteen entrants for the race, two of which proved non-starters. During the race nine machines retired, and the final result was as follows:

Position.	Identification Letters.	Machine.	Engine.	Pilot.	Total Time, 732 miles.	Total Time, 1,464 miles.	Average Speed.
					h. m. s.	h. m. s.	m.p.h.
1	G-EBMO	D.H. 60 Moth	27-60 Cirrus I.	Capt. H. S. Broad.	8 5 53	16 22 20	90·4
2	G-EBIP	Vickers Vixen	450 Napier Lion.	Flt. Lt. E.R.C Scholefield.	5 11 51	10 25 0	142·2
3	G-EBKL	Martinsyde A.D.C. 1.	395 Siddeley Jaguar.	Sqd. Ldr. H.W.G.Jones	4 54 12	9 45 14	151·9
4	G-EBLW	D.H. 60 Moth	27-60 Cirrus I.	Capt. W. J. McDonough	8 55 58	18 13 6	80·25
5	G-EBLI	D.H. 60 Moth	27-60 Cirrus I.	Capt. F.G.M. Sparks	9 14 51	18 9 38	80·4

King's Cup Race, 1927.

In 1927 the race was flown on July 30. It consisted of a total distance of approximately 540 miles, composed of three courses of approximately 180 miles each. The first course, which was flown twice, covered the counties of Leicestershire, Rutlandshire, Huntingdonshire, Cambridgeshire, Norfolk, and Lincolnshire, and the turning-points were at Spittlegate, Huntingdon, King's Lynn, and Cranwell. The second course passed over Nottinghamshire, Yorkshire, and Lincolnshire, with turning-points at Howden (Yorks.) and Skegness. The start and finish of each course was at Hucknall, Notts, and the competitors had to alight at the aerodrome after each course and make a compulsory stop of 30 minutes. All the competitors were handicapped according to the assumed capabilities of their machines.

There were 26 entrants for the race, 10 of which proved non-starters, and 6 machines finished the race.

The times and speeds of the first three machines to finish were as follows :

Position.	Identification Letters.	Machine.	Engine.	Pilot.	Handicap Allowance.	Total Flying Time.	Average Speed.
					h. m. s.	h. m. s.	m.p.h.
1	G–EBME	Moth	Cirrus I.	W. L. Hope	3 25 9	5 50 14	92·3
2	G–EBRL	Widgeon III.	Cirrus II.	Capt. Mac-Donough	2 14 28	5 15 49	102·8
3	G–EBIP	Vixen	Lion	Flt.-Lt. Scholefield	1 3 32	3 49 23	141·6

The International Schneider Cup Seaplane Race.

The International Schneider Cup Race has been an annual event to determine the highest speed attainable among international aircraft. In 1925 the race was won by the United States of America, and in accordance with the conditions of the race the next contest had to be held in America. In 1926 this event was flown in Hampton Roads, U.S.A. Only two nations—Italy and America—were represented.

Italy was the winner, with an average speed for the course of 246·49 m.p.h.

The Italian seaplane, Macchi M39 monoplanes fitted with 800 h.p. Fiat engines, which won the race, was of the monoplane type with twin floats. The fuselage was supported on an inverted 'V' formation of struts, the lower ends of which were attached to the floats. The floats were connected by cross struts and also carried the ends of bracing wires, which in conjunction with other bracing wires in the top of the fuselage, assisted to hold the main planes in position.

In 1927 the race was at Venice, over a course of 218 miles laid out on the Lido. Again, only two countries were represented, but this time it was Italy and Great Britain. Unfortunately, the Italian machines failed to complete the course and the race was won by Great Britain. The winning machine—a Supermarine S. 5 Seaplane with Napier engine—was piloted by Flight Lieutenant S. N. Webster, R.A.F., and its average speed was 281·49 m.p.h. This was not only a record for the course, but was the highest speed ever recorded for any mode of transport.

Light Aeroplane Trials.

Trials were carried out at a meeting organised by the Royal Aero Club and held at Lympne in September of 1926.

The types of light aeroplanes which were entered for the competition were, in general, similar to those used in the competition of the previous year.

The results were as follows :—

Lympne Open Handicap.

Place.	Machine and Engine.	Speed, m.p.h.
1st	R.A.E. Cygnet (Cherub III.)	78·2
2nd	Pixie III. (Cherub III.)	75·25
3rd	Brownie (Cherub III.)	76·4
4th	Avro 'Avian' (Genet)	97·8

Grosvenor Cup Race.

Place.	Machine and Engine.	Speed, m.p.h.
1st	Blackburn 'Blue Bird' (Genet.)	84·95
2nd	Parnall 'Pixie' (Cherub III.)	75·18
3rd	R.A.E. Hurricane (Cherub III.)	84·79

Daily Mail Competition.

In this competition the machine had to fly over prescribed courses on six consecutive days, covering in all 1,994 miles. No replacements were allowed. A prize of £3,000 was awarded to the winner.

The first three places in the race were awarded as follows :—

Machine and Engine.	Average Speed, m.p.h.
Cygnet (Cherub III.)	64·98
Cygnet (Cherub III.)	55·68
Brownie (Cherub III.)	69·71

Notes on Airships for Commercial Purposes.

(Published by the Air Ministry.)

(*Abstract.*)

The airship is essentially a long-distance weight-carrying craft as compared with the short-distance high-speed aeroplane. An airship with a speed of 77·6 m.p.h. can be considered slow only relatively to the aeroplane, being fast in comparison with land and sea methods of transport.

An airship is not liable to forced descent in case of engine failure, as is the aeroplane. Quite large repairs to engines, such as the changing of a cylinder, are possible in an airship.

The airship can be used over land of a wooded or broken nature, such as to be unsuitable for the landing of aeroplanes, and on journeys involving non-stop flights of 1,000 miles and upwards. It can be used in flying at night or in fog or clouds, and the great lift permits of much more comfortable accommodation being provided than is possible in an aeroplane. In the case of a rigid airship, for example, a walk of 400 or 500 ft. may be taken along the keel.

Official statistics show that only one airship has been lost in this country owing to catching fire in the air, although 83,360 hours have been flown and over 2½ million miles covered during the war. In the case referred to the flight was an experimental one with a new type of ship, and the cause has since been ascertained and eliminated.

For commercial purposes large rigid airship stations should be established at distances of 2,000–3,000 miles apart, mainly for trans-oceanic traffic, while the aeroplane would be used for bringing passengers and merchandise to these from the neighbouring countries.

Although airships are generally considered to be fair-weather craft, up to the end of November there were only nine days in 1918 when no airship flight took place in the British Isles—which are notorious for possessing almost the worst weather conditions of any country in the world.

The latest German rigid airship has a disposable lift available for crew, fuel, merchandise, etc., of over 38 tons, which gives her a theoretical endurance (if all the available lift be employed in carrying petrol) of 177·5 hours (7 days) at a cruising speed of 45 m.p.h.—the maximum speed being 77·6 m.p.h.—during which 8,000 miles would be covered.

An airship has been successfully moored out for six weeks in a perfectly open expanse to a specially designed mast. Only two or three men are required to look after the ship, and winds of up to 52 m.p.h. have been ridden out without any damage resulting.

A system of recovering water-ballast during flight would obviate waste of hydrogen by preventing the ship becoming 'light,' owing to the consumption of fuel during a long voyage.

Increase in size of aeroplanes brings many difficulties in its train with no compensating improvement in efficiency, but increase in size of airships results in a reduction of the difficulties experienced at present, and gives improved efficiency.

PROGRESS IN HEAVIER-THAN-AIR (H/A) AND LIGHTER-THAN-AIR (L/A) MACHINES: 1914–1918.

In 1914 the average endurance of a German rigid at cruising speed was under one day, and the maximum full speed about 50 m.p.h. In 1918 (German L.70 class, 2,195,000 cub. ft. capacity) the endurance at 45 m.p.h. has risen to 177·5 hours (7·4 days) and the maximum full speed to 77 m.p.h. The ceiling has correspondingly increased from 6,000 ft. to 23,000 ft. The British R.38 class (2,720,000 cub. ft. capacity) has an estimated cruising endurance at 45 m.p.h. of 211 hours (8·8 days), 34 hours greater than the German L.70 class.

The D.H.10A has been taken as the best all-round aeroplane in August, 1918. Although the two-engined Handley-Page and Caproni have greater endurance and weight-carrying capacity their all-round efficiency appears inferior to the D.H.10A. The Handley-Page V gives promise of having a slightly better performance than the D.H.10A.

Tables 1 and 2 give the progress in L/A and H/A since 1914. Table 3 shows the differences in performance between corresponding L/A and H/A craft of 1918.

TABLE 1. L/A.

—	August, 1914. Average figure for German Naval Zepp.	August, 1918. German L.70.	Progress.
Maximum speed at 10,000 ft.	50 m.p.h.	77·6 m.p.h.	55%
Endurance at 45 m.p.h.	20 hours	177·5 hours (7·4 days)	787·5%
Total lift.	30 tons	66·64 tons	122%
Disposable lift	8·5 tons	38·84 tons	357%
Efficiency ratio	27·3%	58·3%	113·5%
Static ceiling	6,000 ft.	21,000 ft.	250%
Indicated H.P.	800	2,100	162·5%

TABLE 2. H/A.

—	August, 1914. Avro.	August, 1918. D.H.10A.	Progress.
Speed at 10,000 ft.	70 m.p.h.	125 m.p.h.	78·3%
Endurance	4 hours	10 hours	150%
Total weight loaded	·737 tons	4·02 tons	445%
Useful load	·268 tons	1·45 tons	445%
Efficiency ratio	36·3%	36·1%	0·55% (Decrease)
Ceiling	14,000 ft.	22,500 ft.	35·7%
Indicated H.P.	80	810	913%
	August, 1914. Avro.	**August, 1918. Handley-Page.**	**Progress.**
Speed at 10,000 ft.	70 m.p.h.	85 m.p.h.	21·4%
Endurance	4 hours	12·5 hours	212·5%
Total weight loaded	·737 tons	5·97 tons	524%
Useful load	·268 tons	2·17 tons	709%
Efficiency ratio	36·3%	36·4%	0·28%
Ceiling	14,000 ft.	15,000 ft	7·1%
Indicated H.P.	80	720	800%

It will be seen that at the present time the largest rigids in commission have over 10 times the total lift of the corresponding H/A, and that the disposable lift is about 25 times greater.

The proportion of useful lift compared to gross lift is much higher in airships than in aeroplanes. An approximate figure for an aeroplane of average engine power is $\frac{1}{3}$, while in a rigid the useful lift available for fuel, crew, passengers, freight, etc., is well over $\frac{1}{2}$. In the case of L.70 the figure is 58·3 per cent., although this ship is the most heavily engined and fastest airship yet built.

TABLE 3. COMPARISON OF EXISTING H/A & L/A MACHINES.

August, 1918.	H/A. D.H.10A.	L/A. German L.70.	Percentage Superiority.
Speed at 10,000 ft.	125 m.p.h.	77·6 m.p.h.	H/A. 61·1%
Cruising endurance	14 hours	177·5 hours	L/A. 1,167%
Total lift (=weight loaded)	4·02 tons	66·64 tons	L/A. 1,557%
Disposable lift (=useful load)	1·45 tons	38·84 tons	L/A. 2,580%
Efficiency ratio	36·1%	58·3%	L/A. 61·5%
Ceiling	22,500 ft.	21,000 ft.	H/A. 7·1%
Indicated H.P.	810	2,100	L/A. 159%

It cannot be too strongly emphasised that many of the advantages apparently possessed y H/A at the present time result from their relatively small lift. Thus, an aeroplane of 60 tons otal lift, if found to be possible at all, would certainly be very much less convenient to land and andle on the ground than aeroplanes of existing sizes and would require overall dimensions bout twice those of the largest existing machines.

It is important to note that in H/A there is no automatic improvement in efficiency resulting rom greater dimensions. In L/A, on the other hand, such an automatic improvement takes lace to a very marked degree. The reason for this difference is as follows:—In similar H/A achines of different dimensions, the total lift, air resistance, and b.h.p.—other things being qual—all vary nearly as the plane areas, *i.e.* as the square of the linear dimensions.

It follows that the ratio $\frac{\text{weight of machinery}}{\text{total lift}}$ does not vary much with size of aircraft. The atio $\frac{\text{weight of structure}}{\text{total lift}}$ tends to increase with size of aircraft. Unit area of wing surface can ly exert a definite lifting effect, and as the aeroplane increases in size it is necessary to increase roportionally the weight of each preceding unit area of wing surface to make the aeroplane roportionally strong. A point is finally reached where every additional unit of wing surface sults in as much increased weight as its lifting effect, so that any further increase in size will volve a definite falling off in the total lifting capacity of the aeroplane. A further small increase size can be effected by increasing the number of planes; but, owing to the inefficiency of iddle plane surfaces, due to the blanketing effect of the top and bottom planes, the resulting ain in endurance will not be large, and it will only be effected at the price of a loss in efficiency.

A 10,000,000 cub. ft. capacity rigid has five times the lift of the present 2,000,000 cub. ft. apacity rigid, but the length of the former is only 1·7 times greater, and therefore the weight of e structure only five times greater $(1{\cdot}7)^3$—*i.e.* the weight of the structure is directly proportional the total lift.

This theoretical property of structure may, to a certain extent, be modified by the material ed. Thus, for ships of 2,000,000 to 4,000,000 cub. ft. capacity duralumin is the most suitable aterial for the hull structure, while for ships of 8,000,000 to 10,000,000 cub. ft. capacity, a ving in weight can be effected by the use of steel.

In H/A, therefore, all-round efficiency, as measured by the ratio of $\frac{\text{disposable lift}}{\text{total lift}}$, tends to crease with greater dimensions. Greater efficiency will, therefore, not result from increase size, but, on the contrary, great increase in size will not be attainable until greater ficiency has been first obtained by progress in design and materials.

In L/A, the total lift varies as the cube of the linear dimensions, while the air resistance and h.p.—other things being equal—vary as the square of the linear dimensions. Hence the ratio eight of machinery / total lift decreases automatically. Values for this 'coefficient of tractive resistance' r airships are given in Table 4 (p. 2046).

It will be seen that they vary from ·9 per cent. for a large rigid at 45 m.p.h. to 7·7 per cent. r a small rigid at 80 m.p.h., compared with 15 per cent., which may be taken as an average gure for H/A.

It will further be seen that as the size of the rigid increases, the coefficient of tractive resistance creases to a marked extent. With a proportionate increase in h.p., it is easier and proportionately more economical for a 10,000,000 cub. ft. capacity rigid to fly at 80 m.p.h. than for a 000,000 cub. ft. capacity rigid to fly at 60 m.p.h. In the case of H/A craft, however, increase size effects no decrease in the coefficient of tractive resistance.

TABLE 4.

Gross Lift of Rigid.	Coefficient of Tractive Resistance at		
	45 m.p.h.	60 m.p.h.	80 m.p.h.
	Per cent.	Per cent.	Per cent.
60 tons	1·9	3·8	7·7
80 ,, ...	1·7	3·4	6·7
100 ,, ...	1·5	3·0	6·0
150 ,, ...	1·3	2·5	5·0
200 ,, ...	1·1	2·2	4·4
250 ,, ...	1·0	2·0	4·0
300 ,, ...	0·9	1·8	3·6

The figures for tractive resistance are based on the German L.33 streamline form, and fro the experimental results already obtained by the National Physical Laboratory it is reasonat certain that a more efficient streamline form can be obtained which will appreciably reduce the figures.

As the ratio $\frac{\text{weight of structure}}{\text{total lift}}$ is, in airships, fairly constant, it follows that the ra $\frac{\text{disposable lift}}{\text{total lift}}$ increases with dimensions. The natural tendency will, therefore, be towards larg airships, in order to secure the benefit of the resulting gain in efficiency.

A further point of great importance emerges from the above. As the total lift varies (dimensions)^2 in H/A. and as (dimensions)^3 in L/A, increase in total lift is secured in the latt with less increase in dimensions than in the former. Thus, to secure five times the total lift must increase the dimensions 124 per cent. in H/A and only 70 per cent. in L/A.

If total lift is increased indefinitely in both types, the dimensions of the H/A will therefo ultimately pass those of L/A, when almost the last remaining advantage of the former over t latter will disappear.

The proportion of useful lift compared to gross lift is much higher in airships than in aeroplan An approximate figure for an aeroplane of average engine power is 33 per cent., while in a rig the useful lift available for fuel, crew, passengers, freight, etc., is well over 50 per cent. In t case of the German L.70 the figure is 58·3 per cent., as has already been mentioned.

It is concluded that the outstanding characteristics of H/A will remain as at present: h speed, handiness, moderate lift, independence of all weather conditions except the worst.

As regards L/A, the functions now performed by the smaller airships will be usurped more a more by H/A. Airships may be expected to develop in the direction of increased size to a lir which is not yet in view. The outstanding characteristics of L/A will be reasonably high spee very long endurance, great weight-carrying capacity for freight, stores, passengers, etc.

The line of policy to be adopted is to develop the aeroplane for transport over distances und say, 500–800 miles, and the rigid airship for trans-oceanic and possibly trans-continental flig of over this length.

Table 5 shows the approximate dimensions of a series of airships similar in form to R.33.

TABLE 5.

Capacity in cubic ft.	Gross lift in tons.	Length.	Diameter.
2,000,000	60·7	643′	79′
3,000,000	91·1	736′	90·4′
4,000,000	121·4	810	99·5′
5,000,000	151·8	872′	107·2′
6,000,000	182·2	927′	113·9′
7,000,000	212·5	976′	119·9′
8,000,000	242·8	1021′	125·4′
9,000,000	273·3	1061′	130·4′
10,000,000	303·6	1100′	135·1′

It will be seen that although a 10,000,000 cub. ft. capacity rigid has five times the gross and over five times the disposable lift of the present 2,000,000 cub. ft. capacity rigid, the dim sions of the large ship are only 1·7 times greater, and it could be docked in a shed of no m than one-third larger dimensions than those at Killeagh, *i.e.* 1,150′ long × 160′ high × 180′ wi compared with 850′ long × 130′ high × 150′ wide, for Killeagh.

As regards constructional sheds, the most economical method of accommodating such la airships would perhaps be to lengthen existing constructional sheds, which are sufficiently w

) at least 1,150 ft. long (present length 700 ft., and lower the floors as necessary to secure the equired height. A somewhat similar course could probably be taken with existing housing sheds.

If the endurance of a rigid is increased to a sufficient extent, it will be possible to carry out ights with a regularity comparable to that maintained by surface craft. The range is almost nlimited, and the weight-carrying capacity large. A 10,000,000 cub. ft. capacity rigid will ave a disposable lift of over 200 tons, which is available for petrol, ballast, crew, passengers, nd freight.

There is no other type of vessel which is so efficient.

With a rigid of about 10,000,000 cub. ft. capacity, and endurance of approximately three eeks at 40 to 45 m.p.h., with a maximum speed of 70 to 80 m.p.h., a ceiling of some 30,000 ft. an be obtained, and a maximum range of over 20,000 miles.

Standard Data for Airship Calculations.

(1) *Lift of Hydrogen* to be taken as 68 lbs. per 1,000 cu. ft. of gas space at sea level.

The variation of lift with height to be taken as proportional to the density of the 'Standard tmosphere.'

(2) *The Volume of Gas* assumed in lift calculations to be as follows :—

For rigids, the total volume of the gasbags when filled with a slight pressure not exceeding mm. at the bottom.

For non-rigids, designed volume of the envelope with ballonets empty, plus an allowance f 5 per cent. for stretch.

(3) *Gross Lift*, at sea level, is defined as the volume, determined as in para. (2), multiplied y the lift per unit volume, as given in para (1).

(4) *Standard Flying Height* to be taken as 2,000 ft. above sea level in the case of rigid airships, nd 1,000 ft. above sea level in the case of non-rigid airships.

Values of atmospheric density, pressure, and temperature at sea level and standard flying eight are :—

	Density. Lbs. per cu. ft.	Relative Density. Per cent.	Temperature. ° C. Abs.	Pressure. Mb.	Pressure. Lbs. per sq. in.
Sea level	·0782	100·0	282·0	1,014·0	14·70
1,000 ft. above sea level .	·0757	96·8	281·0	978·0	14·18
2,000 ft. above sea level .	·0733	93·8	279·7	943·4	13·68

(5) *Fixed Weights* are defined as all constant and non-consumable weights which an airship ould carry under all conditions of service, including :—

Structure.
Fabric.
Cars.
Machinery—including liquids in the system and radiators (not petrol or oil in service tanks or float tanks, or water in radiator headers intended as a reserve supply).
Gun mountings (ex guns and ammunition).
Wireless telegraphy equipment.
Approved navigating equipment (including instruments).
Approved allowance of handling and mooring ropes, etc.
Internal gassing hose.
All fixed tanks.
All pipe systems.
All electrical systems.

In the case of commercial ships, all passenger cars and car fittings should be taken as fixed eights.

(6) *Disposable Weights* are defined as all weights other than fixed weights, and therefore nclude :—

Crew and effects.
Food and fresh water.
All water ballast.
All fuel and oil.
All reserve water for radiators.
All slip containers.
All bedding.
Parachutes.
Life-saving jackets.
Oxygen apparatus.
Spares and tools.
Water ballast bags and all other approved gear and equipment not included in the fixed weights.
Passengers, merchandise, guns, ammunition, and bombs.

(7) *Dischargeable Weights* are defined as :—

All fuel and oil except reserve as defined in para. (9).
All ballast except emergency as defined in para. (9).
All slip containers (except such as may be necessary to contain reserve fuel, oil, and ballast).
Bedding.
All other loads which may have been raised by the 'Useful Lift' (see para. (9)).

(8) *Maximum Static Height or 'Static Ceiling'* to be calculated on the following assumptions :—

(*a*) The ship to be lightened by removal of all dischargeable weights (para. 7), and no others.
(*b*) All other disposable weights to be carried in accordance with approved complement and equipment (see para. (9)).
(*c*) The variation of lift with height to be taken in accordance with the standard atmosphere, as in para. (1).

(9) *Useful Lift* is defined as the lift available for :—

Fuel and oil,	Food and drinking water,
Passengers and merchandise,	Guns, ammunition, and bombs,

and to be determined by deducting from the gross lift at sea level the following :—

All fixed weights.
Ballast necessary to reach the standard flying height, amounting to :—
For non-rigids . . . 3·2 per cent. of gross lift (at 68 lbs. per 1,000 cu. ft.).
For rigids . . . 6·2 " " " " "
(See para. 4.)
Emergency water ballast, amounting to 3 per cent. of the gross lift at sea level.
Reserve fuel and oil for two hours' flight at normal full speed at standard flying height.
All tanks and containers not already included in the fixed weights.
Approved reserve of water for radiators.
Crew : Approved complement, the weight of each member being taken as 180 lbs., including clothing and personal kit.

All approved spares and tools.

Approved equipment :

Bedding.	Oxygen apparatus.
Parachutes.	Fire extinguishers.
Life-saving appliances.	Emergency ration (iron ration).

All other approved disposable equipment, *e.g.* First Aid equipment, which would be taken on board at commencement of flight under all conditions of service.

(10) *Speed* to be stated in knots, *i.e.* nautical miles (6,080 ft.) per hour, for all classes.

Speeds in all cases to be calculated under the standard atmospheric conditions corresponding to standard flying height, as laid down in para. 4.
Maximum speed.
Normal full speed, to be defined as 90 per cent. max. speed.
Cruising speed, to be defined as 80 per cent. max. speed.
Comparison speed. 40 knots.

(11) *Endurance* to be calculated on the following assumptions :—

The whole of the useful lift (para. 9) to be employed for fuel, oil, food, and drinking water.
Rate of fuel and oil consumption to be the approved figure for the ship at the speed in question and at the standard flying height (para. 4), with corresponding atmospheric conditions.

Rate of consumption of food and fresh water to be taken as 10 lbs. per day for each member of the approved complement of crew ; that is as $\frac{\text{complement} \times 10 \text{ lbs.}}{24}$ per hour.

Thus if 'A' be the total fuel and oil consumption in lbs. per hour at a given speed, and if 'B' be the consumption of food and fresh water in lbs. per hour : the endurance in hours at that speed $= \frac{\text{Useful Lift}}{A + B}$.

Helicopters.

Details of Air Ministry Competitions.

In 1923 the Air Ministry announced a competition for the design of helicopters or equivalent types of flying machines, and offered prizes to the total value of £50,000 for successful designs. The machines had to comply with certain conditions, which took the form of four tests to which the designs had to be subjected for competition purposes. The first test required that the machine should carry a pilot, fuel for one hour's flight, and 150 lbs. of military load, and thus loaded it should make a vertical flight from the ground to a height of 2,000 ft., afterwards descending and landing without damage. For this test two wind conditions were specified, one in which the ground wind did not exceed 5 m.p.h., and the other in which the ground wind exceeded 10 m.p.h. but did not exceed 20 m.p.h.

In the second test the machine was required to rise from the ground and remain in the air for half an hour at 2,000 ft. over a certain prescribed ground area, the ground wind being not less than 5 m.p.h. and not greater than 20 m.p.h., and subsequently landing without damage.

The conditions for the third test were similar, except that in this case the machine had to r over a prescribed closed circuit not less than 20 miles in length, at an air speed of not less an 60 m.p.h.

In the fourth test the machine had to be manœuvred in the air into a position over a given point a the ground, and had to descend from a height of not less than 500 ft. with the engine off, and ight without damage within a 100 ft. of the given point.

The prize for the first-mentioned test was £5,000, and sums of £15,000, £20,000, and £10,000 spectively were offered in respect of the other three tests.

In 1925 the Air Ministry announced that no machine had been submitted for test in accordance ith the above conditions, but as the provision of the original competition allowed for a second mpetition, the latter is to be arranged with a final date of test of April 30, 1926.

Use of Helium for Airships.

Next to hydrogen, helium is the lightest gas known. It is both non-inflammable and non-plosive, and possesses 92 per cent. of the lifting power of hydrogen, so that it is a most suitable ling for airship envelopes. By the use of helium, the engines of airships can be placed within e gas envelope if desired. A further advantage of helium over hydrogen is that the buoyancy n be increased at will by heating or cooling the gas by electric or other means. Moreover, the ss of gas from diffusion through the envelope is less with helium than with hydrogen by about) per cent.

The weight of 1,000 cu. ft. of dry air (reckoned at a barometric pressure of 29·5 ins. and a mperature of 55·5° Fahr.) is 76·03 lbs.; of the same bulk of pure hydrogen, 5·284 lbs., and of lium 10·46 lbs. The 'lift' of hydrogen per 1,000 cu. ft. is, therefore, 76·03 less 5·284 lbs., 70·746 lbs., and of helium 76·03 less 10·46—*i.e.* 65·57 lbs.

High-flying Oxygen Breathing Apparatus.

High-pressure Apparatus.

In this apparatus the oxygen in gaseous form is stored in a specially constructed seamless ld-drawn steel tube charged to a pressure of 2,250 lbs. per sq. in. (150 atmospheres).

The tubes were produced during the war in two sizes, one capable of holding 500 litres at the ove-mentioned pressure and the other 300 litres. They are extremely light, weighing 4 lbs. d 6¾ lbs. respectively for the smaller and larger sizes.

The tubes before being passed by the Aeronautical Inspection Department are subjected to internal pressure test of 3,750 lbs. per sq. in., being inserted in suitable water-jackets for easuring any increase in volume. The cylinders are rejected if the permanent increase of lume (after the hydraulic pressure is removed) exceeds the increase of volume under pressure 20 per cent. Two per cent. of each batch of tubes after manufacture are also subjected to proof pressure test to destruction, and if the bursting pressure is less than 4,250 lbs. per sq. in. rther samples are selected and treated in like manner, and if these fail under destruction test e whole batch is rejected. They may, however, be heat-treated again.

The final test (flattening test) is carried out on the uninjured portion of those selected from itches in previous destruction test, and the cylinders are flattened until the inner surfaces are in. apart. If cracking results from this treatment, as before, the rest of the batch are scrapped, though they may be re-heat-treated.

In the necks of the cylinders are sweated valves with forged bronze bodies and parallel-readed shanks, with screwed inlet and outlet connections, each valve weighing approximately ozs. All valves are tested hydraulically to 2,250 lbs. per sq. in. The cylinders when valved e subjected to a final compressed air test at about 1,000 lbs. and immersed in water to ensure perfect joint between cylinder and valve.

The cylinders are fixed in the aeroplanes in convenient positions by means of specially constructed spring clips, and from the cylinders the gas is led through fine copper tubing some 10 ft. length to the oxygen regulator, which performs the double function of reducing the gas from gh to low breathing pressure and at the same time regulating the flow to the airmen.

The regulator consists in the main of a pressure gauge for indicating the pressure of gas ceived from the cylinders already described; a reducing valve for reducing the pressure of gas om the pressure in the cylinder to a normal breathing pressure of between 1 and 2 atmospheres solute; a control valve for regulating the delivery according to the height of the aeroplane id a flow indicator to indicate that gas is flowing.

An improved indicator has a graduated tube introduced which has the additional function recording the exact rate of flow of gas.

There are two distinct types of control valve, an automatic control by means of a diaphragm alve in one model and a hand-controlled valve in the other model. In aerial combat the hand-ntrolled instrument was preferred, whereas on long-distance flights the automatic valve was voured. In the former case the airmen were able to inhale any quantity and cut off at leisure otherwise engaged, and in the latter case, where long duration was necessary, the oxygen was nsumed economically.

The low-pressure gas after leaving the regulator passes along a flexible tube to the breathin mask, which in the latest type is embodied in the pilot's headgear, being readily detachab by means of a separate strap on the main portion of the helmet. The pilot inhales the oxyge by means of a pipe-mouthpiece which is swivelled and can be easily discarded.

The 300-litre cylinder at altitudes between 10,000 ft. and 15,000 ft. is capable of supplyin oxygen at an average rate of flow of 1·35 litre per minute continuously for approximatel 3½ hours, but between altitudes of 15,000 ft. and 20,000 ft., where an increased rate of flow necessary, owing to decrease in atmospheric pressure, the same quantity of gas at an averag rate of flow of 2·55 litres per minute would only be available for approximately two hours.

Liquid Oxygen Breathing Apparatus.

In this type of apparatus the liquid oxygen is first placed in a vaporiser, which has an inn spherical chamber varying in sizes to accommodate from 1 to 5 litres, according to the lengt of flight and altitude.

The vaporiser embodies the ordinary vacuum flask principle where an inner and outer vess are constructed and the space between the two rarefied down to about 1/1000 mm. of mercur vacuum.

A small quantity of specially selected charcoal is placed in a tube in the inner vessel to absor any moisture. The ends of the tube which terminate in the vacuum space are covered wit gauze. The vaporisers vary in weight, the largest, of 5 litres capacity, weighing approximatel 12 lbs. when empty and capable of holding 12 lbs. of liquid oxygen when charged.

The vaporiser thus consists of inner and outer vessels, neck, and charcoal receptacle, and i the neck is a syphon tube which passes into the body of the vessel. The oxygen in liquid for passes up this tube into the heating and evaporation coils, which are bent round the neck i the form of solid drawn copper tubes. The oxygen after leaving these tubes passes into a flas boiler which, not being evacuated, is at a much higher temperature than the liquid oxyge and in consequence the latter is converted into the gaseous state.

To cause additional radiating surface a number of blind tubes are added underneath the flas boiler.

The oxygen then passes along to the pressure gauge which indicates the pressure of the oxyge from the vaporiser, and is graduated to accommodate pressures from 0 to 25 lbs. per sq. in.

From experiments it has been ascertained that the best results are obtained when the oxyge passes from the vaporiser at a pressure of about 5 lbs. per sq. in.

The oxygen from the vaporiser passes by means of a rubber connection to the control fittin the function of which is to control the supply of oxygen to the airmen. The fitting consist simply of control valve and pressure release valve, which is used to indicate the quantity o oxygen passing to the airmen's breathing masks. The flow of oxygen is indicated by the impac of a jet of gas upon a pivoted vane provided with a pointer moving over a dial. The calibratio of the flowmeter is from 0 to 6 litres per minute, and the quantities of oxygen required for airme at varying altitudes are as given in the description of the high-pressure breathing apparatus.

Liquid oxygen storage vessels known as containers, and capable of holding approximatel 27 litres of the liquid, are also specially constructed on the vacuum principle and used for chargin the vaporisers. The container forms a convenient means of storing the liquid, and owing to th very high vacuum which is created between the inner and outer vessels the loss of liquid oxyge due to evaporation is brought to an absolute minimum.

The liquid oxygen apparatus has one great advantage over the high-pressure type in tha there is no danger in connection with the use thereof in aerial warfare, owing to high-pressur gas being non-existent. In the case of the gaseous oxygen apparatus, the very high pressure t which the steel tubes are charged creates a source of danger which frequently results in damag to pilot and aeroplane when the tubes are struck by enemy bullets.

Liquid Oxygen Plant.

The plant as manufactured by Messrs. Société L'Air Liquide, Boulogne-sur-Seine, Paris was designed for the purpose of mounting on a railway truck and capable of delivering at leas 15 litres of liquid oxygen per hour with 96 per cent. purity. The plant, fig. 6, works on the well known Claude principle and is made up of the following components :—

1. Petrol engine to supply motive power (the particular engine used was the 100 h.p Ricardo engine).

2. Air compressor.

3. Water separator.

4. Purifier and drier to decarbonise the air.

5. Liquefaction and rectification column, each in itself comprises:—(a) A temperature xchanger to cool the compressed air. (b) An expansion engine which is responsible for rapid rop in temperature. (c) Brake dynamo and rheostat to absorb the power given out by the xpansion engine which would be otherwise wasted. (d) Liquefying column embodying rectifier.

The air is first drawn into the two-stage compressor (A), fig. 6, from the atmosphere, and assed at a high pressure of about 45 atmospheres to the separator (B) where moisture absorbed om the injection water in the cylinders of the compressor is removed. The air then passes uccessively through the purifying chambers (C, C), filled with caustic soda or caustic potash, om whence it emerges perfectly dry and free from CO_2.

The dried and purified air passes into the temperature exchanger (D) and traverses the nest small tubes (E) therein, which are cooled by expanded and cold gas flowing in the opposite irection. The air, considerably cooled, leaves the temperature exchanger, part entering the xpansion engine (F) and the other part a nest of tubes (G) in the liquefier (H). The air enter- ig the expansion engine does external work on the piston and is expanded and thus cooled.

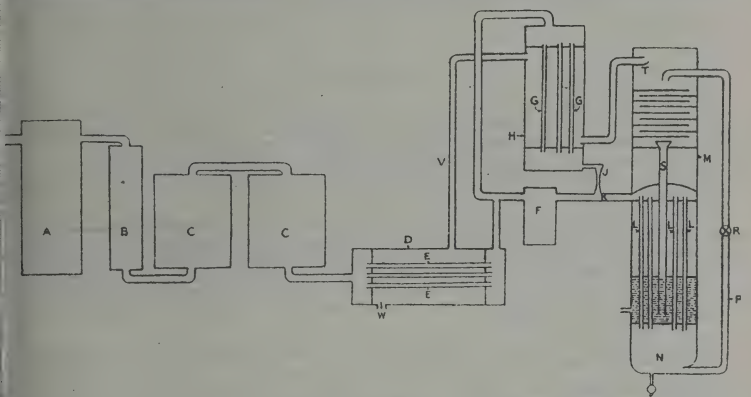

FIG. 6.—Diagram illustrating Liquid Oxygen Plant.

The air in the nest of tubes (G) in the liquefier is cooled by expanded and cold gas flowing i the opposite direction, and, under the continued action of cooling and pressure, liquefies, nd, passing through the needle valve (J), mixes in the pipe (K) with the cold and expanded ir issuing from the expansion engine. The cold air and the liquid air enter the top of another est of tubes (L) called the vaporiser, which is contained in the rectification column (M). On aving these tubes the mixture of gas and liquid enters a sump (N) at the bottom of the column, nd from thence rises through the pipe (P) and regulating valve (R) to the top of the column. he top portion of the rectifying column contains a series of staggered and perforated trays. he liquid in the mixture descends through the trays and enters the vaporiser by means of the ipe (S). The gas in the mixture, which contains a large quantity of nitrogen, since nitrogen as a lower boiling point than oxygen, leaves the top of the column by the pipe (T), entering the quefier in the space surrounding the nest of tubes (G), thus cooling the compressed air in the ubes, and from thence enters the temperature exchanger (D) by the pipe (V) in the space rrounding the nest of tubes (E). Thus it fulfils the same function of cooling the compressed ir flowing in the opposite direction; it ultimately leaves by the pipe (W) warmed, but still at ome degrees below the temperature of the incoming air.

When the liquid air supply is sufficiently large for liquid oxygen to be formed, the valve (R) slowly closed down, but not completely shut. The exhaust pressure in the expansion engine hen rises to the same as that of the liquid air in the nest of tubes (L) in the vaporiser, and causes he surrounding liquid to boil. The gas thus formed, and consisting mainly of nitrogen, rises hrough the plates, while all the liquid formed rises through the valve (R) and flows into the top f the column; the liquid thus descends through the trays, while the gas ascends and eventually nds its way into the atmosphere through pipe (W). Thus it will be seen that the continued ction of progressive refrigeration gradually purifies the liquid in the column (M) and which pproaches pure liquid oxygen. In the same manner the gas, passing through pipe (T) and ventually through pipe (W), gradually becomes richer in nitrogen and with greater cooling effect n the oncoming compressed air in the temperature exchanger.

At a test, the first signs of liquid were not observed until two hours after the starting of the plant. It was not possible to analyse the purities of the liquid oxygen directly, although the purity of the evaporated gas was taken. The relative density of the liquid oxygen was found to be approximately 1·11, and the flow of liquid per hour was never less than 17·2 litres.

The original specification called for 18 to 22 litres. At a second test, the liquid was produced one and a half hours after the plant was re-started, and a further two hours realised the total of 43·6 litres, giving an increased average per hour of 21·8 litres.

The compressor was running at an average speed of 245 r.p.m., and in two stages compressed the gas to a maximum of 45 atmospheres.

The expansion engine was running at about 160 r.p.m., and the dynamo for absorbing the waste energy from the expansion engine was able to give an average output of 35 amps. at average pressure of 70 volts. The average purity of the oxygen gas was 92 per cent. and the average purity of oxygen liquid 97 per cent.

Parachutes.

In the early days of the war the use of man-carrying parachutes was confined entirely to kite balloons and proved of very great service in life saving. It is estimated that at least six hundred of our balloon observers effected their escape by this means.

At this very early period on the Western front the parachute then in use was of Spencer manufacture, known as the 'conical' type, afterwards superseded by another Spencer type, known as the 'flat-case' type.

The conical type of parachute consists of a silk body having a flattened hemispherical form with 48 cords attached to its periphery at equal distances and terminating in a single rope. In the centre of the body there is a hole 9 ins. in diameter through which the current of air escapes as the parachute descends. This gives stability to the parachute, which would otherwise swing violently, although the swinging to a certain extent cannot be prevented in any parachute. The parachute and cordage are packed into a conical canvas case which is hung mouth downwards from the basket of the kite balloon.

The flat-case type of parachute is another method of packing and consists of a flat case fastened to the side of the basket and into which the parachute is packed.

It was towards the end of the war before parachutes were seriously considered by the Air Ministry for use with aeroplanes. The urgency for aeroplane man-dropping parachutes was so apparent that a special parachute department of the Air Ministry was created. When this section was formed there were in existence several types of parachutes, of which perhaps three stood out prominently from the rest as being very suitably adapted for aeroplanes.

When an aeroplane is under control and flying on a level keel, exit by parachute is comparatively safe provided always that ordinary precautions are taken, but with an aeroplane on fire or completely out of control escape is always problematical and dangerous. The parachute does however, provide the airman with a chance of saving his life, whereas without this chance he would otherwise go to almost certain death.

The 'Guardian Angel' type of parachute differs from other types in that it has the advantage of a 'positive opening,' which means that the parachute on delivery always leaves its case with its mouth open. This is effected in the A1 type by the following means—The silk body is pleated until it forms a cube and is then folded down upon a disc of Duralumin some 24 inches in diameter, another similar disc being placed above it. The two discs are separated by a Duralumin distance tube of about five inches diameter. The rigging lines (in the form of stout tapes) are folded in fillets below the discs and fastened by boxwood toggles to the periphery of the parachute and the whole is covered and kept weathertight by a waterproof cover. The parachute when folded resembles in outline an ordinary plum cake with a handle on the top, the lower extremities of the tapes, twelve in number, being fastened to a central bolt of Duralumin, which is ultimately attached to the harness of the aviator. When the aviator leaves the aeroplane and his weight comes upon the centre bolt the lower portion of the cover comes away, the tapes are pulled out to their full extent, and the parachute body is pulled out over the lower disc in the form of a pleated silken tube 2 ft. in diameter and 14 ft. long filled with air. The parachute, continuing to descend in this condition, cannot fail to expand to its full extent, and this fact gives great confidence to the user. This parachute when packed weighs 30 lbs. and measures 24 ins. in diameter and about 12 ins. through, and its cost is considerable, being in the neighbourhood of 100*l*. The rate of descent averages 15 ft. a second for a 12-stone man, a perfectly safe rate of

ged. From 80 to 90 yards of silk are required for the manufacture of this parachute. In its est form the parachute is packed upon a bent wood ring, the Duralumin discs done away with, d other modifications made, so that the 'Guardian Angel' D4 type with Taylor-shaped body w weighs 18 lbs., measures 20 ft. across, and is compressible into about 5 ins. in depth. The st is also proportionately reduced.

Drops from an aeroplane going at 130 miles per hour have been made.

The 'Guardian Angel' parachute invariably opens in the first 100 ft. of falling.

The 'Mears Knapsack' type is a Spencer parachute pleated and folded in such a way as to ake its opening a practical certainty.

It has never been known to fail to open, but has no mechanical means of extending its mouth on delivery. After longitudinal pleating of the body a strip of canvas ending in a length of bbing is placed upon it and is rolled up with the silk in much the form of a snail. The para- ute with rigging is then placed in a weather-proof knapsack with the webbing protruding, hich is attached to the aeroplane. The knapsack is worn by the aviator either on his back or ached to his harness in front. When the aviator jumps, the reaction between his falling weight d the moving plane causes the webbing to pull the parachute out of the knapsack, and the rachute then unfolds and expands, leaving the strip of canvas and the webbing still attached the aeroplane. This parachute has many good qualities in that the aviator is well clear of the ving plane before the parachute unfurls and is, therefore, more or less free from the danger fouling. It is also cheap, and easy to pack and comparatively light in weight.

The 'Smiths Salvus' parachute also possesses the good quality of the positive opening like D4 and also is better adapted for the forward positions in large machines such as Handley- ge or Vickers-Vimy, as the distance of fall before the body inflates can be regulated according the type of aeroplane it is to be used for. In this parachute the periphery of the body is held a wooden ring, making it a positive opening type until a certain distance from the aeroplane s been covered, when the periophery is released automatically and the body expanded to its l extent.

The weight of this parachute is about 19 to 20 lbs., the diameter packed, 21 ins., and the pth about 8 to 10 ins. It is a very good and reliable appliance.

SECTION XXXIII

PART II

AERO ENGINES.

(Contributed by Ernest W. Birch, A.M.I.A.E.)

Engines for Aircraft are either air- or water-cooled, and operate on the four-stroke cycle. The various types in use are Vertical, Vee, Radial, and Rotary. The majority of engines are water-cooled, but the air-cooled engine is receiving great attention and has the following advantages: (*a*) Less sensitive to sudden heat or cold; is easier to start and requires less warming up in cold weather; the oil does not heat unduly, and remains at working temperatures. (*b*) Top overhauls are easier to make. The grinding of valves involves only the removal of a cylinder, with no alteration to the timing—water-cooled engines, as a rule, require either the removal of the engine, or the dismantling of the camshafts and valve mechanism, and the whole engine requires retiming on assembly. (*c*) Due to the reduction in the number of parts, the radial air-cooled engine can usually be built cheaper than the water-cooled engine. The tendency in water-cooled engines is towards block construction to give a more rigid and lighter structure; this, however, involves the rejection of an entire block for the defect of a single cylinder.

Air-cooled engines are not confined to fixed-radial and rotary types. In America the 'Liberty 12,' which is normally a water-cooled engine, has been developed as an air-cooled engine, and as such has developed slightly more than its rated output as a water-cooled engine.

The most successful engines at the present time are really refinements of types available for some years past. Some of these improvements are greater compactness, resulting in lighter weight and increased rigidity; higher crankshaft speeds; improvements in valve operating mechanism, valve cooling and valve materials; improvement in bearing design, and improvement in volumetric efficiency. The success of the inverted 'Vee' type, and the static radial air-cooled engine, of reduction gearing and of the rotary inductor supercharger, has contributed a large share to recent progress in engines.

ROLLS ROYCE ENGINES. ('EAGLE' SERIES.)

This engine is of the 12-cylinder water-cooled 'Vee' type, fitted with an epicyclic reduction gear, magneto ignition, and complete with propeller-hub, and engine supporting brackets suitable for tubular bearers.

The leading particulars for 'Eagle' Series IX. engines are:—

Number of cylinders, 12; bore, 4½ ins.; stroke, 6⅞ ins.; normal b.h.p., 360; normal speed (crankshaft), 1,800 r.p.m.; maximum speed (crankshaft), 2,000 r.p.m.; normal speed (propeller), 1,080 r.p.m.; gear ratio, 0·60.

Petrol consumption on the ground at normal b.h p. and normal r.p.m., 25 galls. per hour.

Oil consumption, 1 gall. per hour.

Weight, including reduction gear, propeller-boss, exhaust pipes—less radiator, water and oil, 965 lbs.

Cylinders.—Two rows of six at 60° with each other of built-up all steel construction, being machined from 0·6 per cent. carbon steel forgings with the heads integral with cylinder barrels. Water jackets, die pressed sheet steel, acetylene welded at joints. Valve seatings machined in cylinder heads.

Valves.—One inlet and one exhaust per cylinder, operated by overhead camshafts and rockers. Valves made from high chromium steel forgings, working in phosphor-bronze guides.

. *Camshafts.*—Driven by means of inclined tubular shafts with bevel gear at upper and lowe ends. Out-of-alignment and expansion effects are allowed for by hardened serrated coupling Each camshaft has five phosphor-bronze bearings which are in halves, and bolted together. Valv rockers provided with hardened steel rollers and adjustable tappets.

The gears for driving the camshaft and all auxiliaries are driven from the rear end of crank shaft, through the medium of a spring-controlled friction damped pinion, in order to eliminat from all auxiliary drives any torsional crankshaft vibration.

Connecting Rods.—' H ' section of the articulated type, machined all over. Big end of mai rod is white-metal lined, the small end being fitted with phosphor-bronze bush. Both ends o the articulated rod fitted with phosphor-bronze bushes. All bearings positively lubricated b oil under pressure.

Crankshaft.—Six-throw, all journals and crank pins being bored for lightness and to conve oil to bearings and connecting rods. The crankshaft is carried in seven bearings of ampl proportions.

Pistons.—Of ' Zephyr ' type, with five piston rings, arranged as four compression rings abov the gudgeon pin, and one scraper ring below, at the base of the skirt. Gudgeon pins locked t prevent axial and rotational movement.

Crankcase.—Made in two halves of box section, suitably ribbed. The main bearings are hel in the top half by steel caps, these being held by long bolts which pass through the top half o the crankcase. The bearings are in halves and consist of phosphor-bronze shells, white-meta lined.

Propeller Hub.—Provided with internal serrations engaging similar serrations on the propelle shaft. To locate the hub radially and to secure it against any axial movement two opposed tapers are utilised, one consisting of a split conical phosphor-bronze ring on the propeller shaft and the other of a conical nut on the extremity of the shaft, each engaging conical seats in th hub. The loose flange is fitted on serrations of the hub, the whole being provided with a numbe of hollow bolts which pass through the propeller.

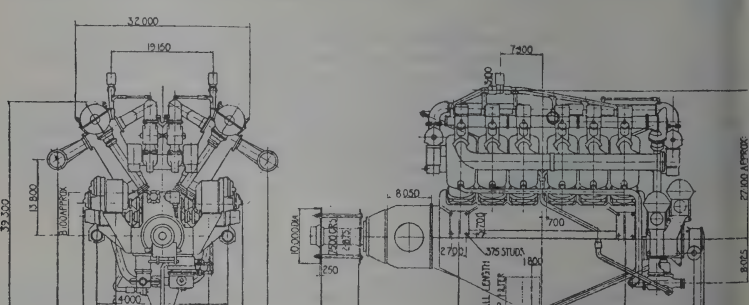

FIG. 1.—Rolls Royce ' Eagle ' Engine (Series VIII.).

Reduction Gear.—A compound epicyclic reduction gear is fitted on the front end of the crank shaft, through which is transmitted the drive to the propeller. The annulus driving gear is fixed on the flange of the crankshaft, which rotates the three sets of planet gears round the sunwheel. The latter is the fixed member of the gear and is prevented from rotating by means of a friction anchorage in the form of a multi-plate clutch, the plates being anchored to the casing and the sunwheel alternately and pressed together by springs.

This arrangement limits the maximum torque which may be imposed on the gears, the clutch being designed to slip if a certain torque is exceeded, due, for instance, to periodic stresses set up by propeller vibrations or pre-ignition. Lubrication of all working parts is effected from engine

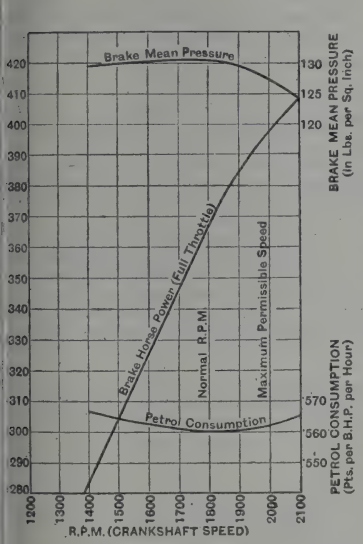
ankshaft, and the whole gear is totally enclosed in a casing carried from the front end of the ankcase.

Four 6-terminal high tension magnetos are fitted, and two sparking plugs per cylinder.

The lubrication of the engine is on the ' dry sump ' system, the bulk of the oil being carried a service tank separate from the engine. The ' scavenger ' and ' pressure ' pumps are arranged a unit, being bolted to the under side of the engine timing gear case, and driven from the ing gear.

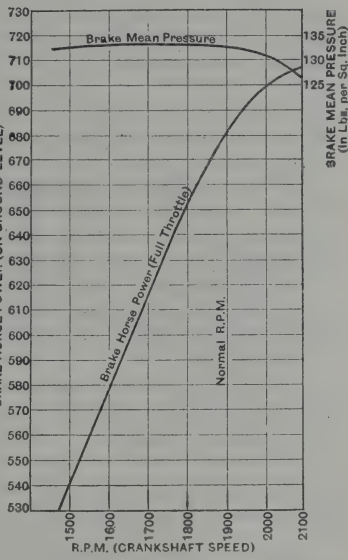
Materials Used in Construction.

Cylinders, 0·6 per cent. carbon steel forgings ; *valves*, high chromium steel ; *camshaft*, 5 per nt. nickel case hardening steel ; *valve rockers*, 3 per cent. nickel steel forgings ; *gears*, 5 per cent. kel case hardening steel ; *pistons*, aluminium alloy ; *connecting rods*, 3½ per cent. nickel steel ; *nkshaft*, nickel-chrome steel forging ; *propeller hub*, 3½ per cent. nickel-steel forging.



Rolls Royce ' Eagle,' Series IX.

Compression ratio = 5·22.
Atmospheric temperature = 16° C.
Atmospheric pressure = 29·97″ Hg.



Rolls Royce ' Condor,' Series III.

Compression ratio = 5·3.
Atmospheric temperature = 16° C.
Atmospheric pressure = 29·97″ Hg.

FIG. 2.—B.h.p. and Consumption Curves for Rolls Royce Engines.

ROLLS ROYCE ENGINES. (' CONDOR ' SERIES III.)

The ' Condor ' engine is of the 12-cylinder water-cooled ' Vee ' type, fitted with a spur drive duction gear for the airscrew.

The leading particulars are :—

Number of cylinders, 12 ; bore, 5½ ins. ; stroke, 7½ ins. ; normal b.h.p., 665 ; normal speed ankshaft), 1,900 r.p.m. ; maximum speed (crankshaft), 2,100 r.p.m. ; normal speed (propeller) th 0·582 reduction gear, 1,106 r.p.m.

Fuel consumption at normal power and speed, 45 galls. per hour.

Oil consumption, 1·9 galls. per hour.

Weight of engine, 1,154 lbs. (including carburettors, magnetos, engine feet, distributor an pipes for power starter, etc., but excluding reduction gear, exhaust boxes, radiator, airscrew oil, fuel and water).

Weight of engine as above, but including reduction gear, 1,310 lbs.

Rolls Royce Engines (Series F10).

This is the latest type of engine built by Rolls Royce, Ltd. It is a twelve-cylinder V engin 5 ins. bore by 5½ ins. stroke, and develops 485 h.p. at 2,100 normal r.p.m., corresponding to b.h.p. M.E.P. of 140 lbs. sq. in.

The leading particulars are as follows :—

Two banks of six cylinders, each bank being formed from one aluminium alloy casting, wit inserted steel cylinder barrels, in direct contact with the cooling water. Cylinder heads and g passages formed integrally with the cylinder castings, and inserted seatings are used for the tw inlet and two exhaust valves in each cylinder. Cylinder blocks secured to crank chamber by lor studs passing through the complete depth of the cylinder casting, and abut on the crank chamb by means of flanges formed on the cylinder liners.

Pistons of forged aluminium alloy. Crankshaft arranged to be coupled at the driving en either to a propeller shaft carried in an extension piece bolted to the crank chamber or to th pinion of a spur-type reduction gear. Steel connecting rods of the superimposed type.

Valves actuated by single overhead camshaft carried in each cylinder block, operating throug the medium of rockers. Valve mechanism lubricated by low-pressure oil, and is complete enclosed. Inlet valves situated towards the inside of the Vee between the cylinder blocks, which space is carried two double carburettors, each throat feeding three cylinders.

Ignition by two completely independent 12-cylinder magnetos driven by a cross shaft at th wheel-case end of the engine, one magneto dealing with the plugs on the inlet side of the engin and the other dealing with the plugs near the exhaust valves on the outside of the cylinder block

Two scavenging and one pressure pump for the lubricating system placed within the oil bas One scavenging pump evacuates oil from the front end of the engine and delivers into a well the rear end, where the whole of the drainage oil is then ejected from the engine by the secon scavenger pump. The pressure pump delivers high-pressure oil to the crankshaft journals an connecting rod ends.

The overflow from the high-pressure system is led through two blow-off valves in series bac to the crank chamber, the cavity between these valves forming a source of low-pressure oil fo lubricating the valve gear and any other low-duty bearings not dealt with by splash.

This scheme provides that in the event of an engine being partly disabled the first bearin to be starved of oil will be the low-duty ones.

A water pump is carried on the bottom of the wheelcase at the engine rear, having a doub volute with a lead to each cylinder block. The whole of the cylinder outlet water is carri serially through the two induction pipe jackets, with the exception of two small water lea provided to maintain circulation at the rear end of the blocks.

A petrol pump of the gear pattern fitted on wheelcase, also a gun gear, the drive of which c be readily adjusted for timing.

A hand-starting gear is provided and provision is made for fitting a gas starter.

Napier Engine. (Lion.)

The leading particulars are as follows :

Number and arrangement of cylinders, 12, three blocks of four each, one vertical, two 60° ; bore, 5½ ins. ; stroke, 5½ ins. ; Compression ratio, 5·8–1 (high), 5·0–1 (low) ; norm b.h.p. and speed, 450 b.h.p. at 2,000 r.p.m. (high compression) ; normal b.h.p. and spee 425 b.h.p. at 2,000 r.p.m. (low compression) ; direction of rotation of crank, anti-clockwis viewed from front ; direction of rotation of air screw, clockwise, *i.e.* L.H. tractor or R.H. pushe ratio of gear reduction to airscrew, 41–27 ; oil pressure, maximum 70 lbs./sq. in., normal 55– lbs./sq. in., minimum 40 lbs./sq. in. ; oil consumption, 6–12 pints per hour ; type of carburett special Napier Claudel Hobson, single and double (see page 2067).

Fuel consumption, 235 pints per hour at normal load near ground.

Type of magneto, two B.Th.H. A.V. 12E (dual ignition).

Firing order, 1, 5, 9, 3, 7, 11, 4, 8, 12, 2, 6, 10.

Numbering of cylinders, airscrew { 12, 11, 10, 9 / 5, 6, 7, 8 / 4, 3, 2, 1.

Speed of magneto, 1½ engine speed.

Magneto timing, 40° before t.d.c. at full advance on exhaust side, 45° before t.d.c. on ·t side.

Inlet valve opens (deg. on crank), 10° after t.d.c.

Inlet valve closes (deg. on crank), 51° 15′ after b.d.c.

Maximum lift of inlet valves, 0·344 ins.

Clearance of inlet valve, 0·018–0·022 in.

Exhaust valve opens (deg. on crank), 48° before b.d.c.

Exhaust valve closes (deg. on crank), 10° 44′ after t.d.c.

Maximum lift of exhaust valves, 0·354 in.

Clearance of exhaust valve, 0·018–0·022 in.

Weight of engine complete without water, fuel, or oil, 910 lbs. (approx.).

Maximum speed, 2,200 r.p.m.

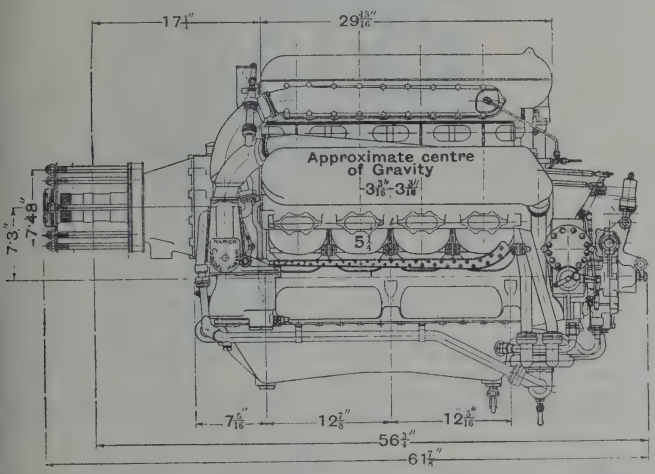


FIG. 3. Napier 'Lion' Engine.

Weight per h.p., 2·1 lbs. on rated power, 1·89 lbs. on average power at maximum speed.

Oil consumption on Air Ministry 2-hour endurance test, maximum 0·036 lb. per b.h.p. ır; average, 0·0235 lb. per b.h.p. hour.

Fuel consumption, 0·527 lb. per b.h.p. hour with fuel of a specific gravity of 0·765 at full d and normal speed. Average fuel consumption at 90 per cent. full load = 0·49 lb. per ı.p. hour.

Cylinders.—Steel forgings machined all over. Water jackets of steel. Detachable aluminium inder head containing inlet and exhaust passages, valves and valve actuating mechanism.

Pistons.—Of aluminium alloy, fitted with two gas and two scraper rings. Hollow gudgeon as of large diameter, fixed in steel bushes.

Valves.—Two inlet and two exhaust per cylinder, each fitted with two coil springs and erated direct by overhead camshaft driven through bevel gearing by vertical shafts from the ankshaft.

Connecting Rods.—The master rod, coupled to the pistons of the vertical block of cylinders, formed with lugs on either side, to which are attached the short auxiliary rods for the pistons the right and left groups of cylinders. The big ends are white-metal lined, anchor pins and ıer parts work in bushes.

Crankshaft.—Machined from solid steel forging. The four throws are in one plane and journals, bearings and crankpins are of large diameter and bored out. The shaft is carried five substantial roller bearings and a large plain bearing at the forward end.

The method of assembly of the roller bearings on the crankshaft is shown in fig. 5.

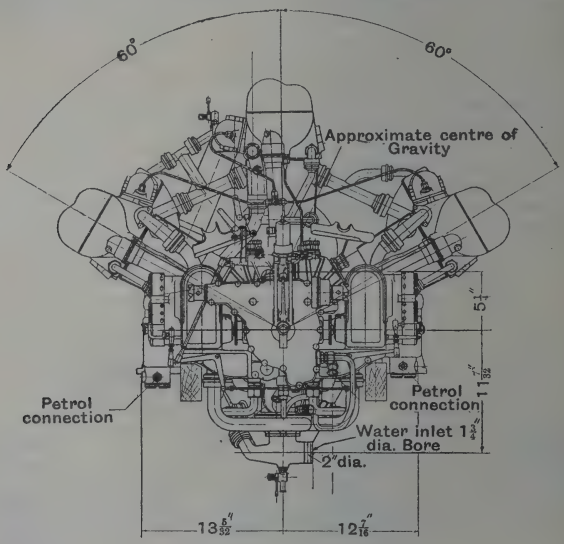

FIG. 4.—Napier 'Lion' Engine (Rear View).

Airscrew Shaft and Drive.—Shaft rotates clockwise when viewed from the airscrew end. is carried on two roller bearings and fitted with a large double thrust ball bearing, to take t thrust of either a 'Tractor' or 'Pusher' airscrew.

Water Pump.—Centrifugal type, mounted at rear end of engine and running at cranksh speed. Water is delivered through a separate outlet to each of the three cylinder blocks.

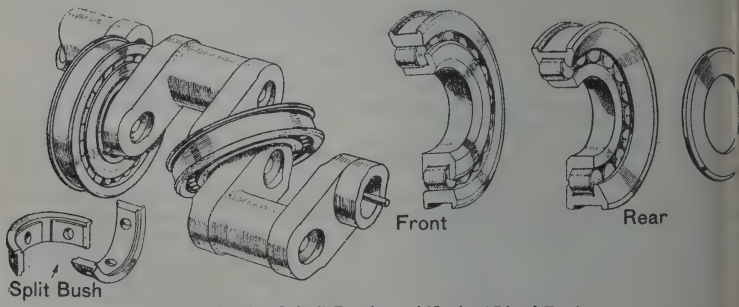

FIG. 5.—Crankshaft Bearings of Napier 'Lion' Engine.

Oil Pumps.—Two suction and one pressure type; the suction pumps scavenge the oil sur and return the oil to the supply tank. The pressure pump takes the oil from the supply tank a delivers to the working parts of the engine under pressure.

Lubrication.—By pressure throughout to big ends, gudgeon pins, bearings of camshaft and ward bearing of crankshaft. Reduction gears lubricated by oil projected on to the teeth. re tappets and cams lubricated by oil escaping from the camshaft bearings.

Armstrong Siddeley 'Jaguar' Engine.*

Air-cooled static radial type, having 14 cylinders arranged in two banks of seven, and king on two cranks set at 180° to each other. Normal rated h.p. 385; maximum h.p. 425 1870 r.p.m. Total weight, 770 lbs.

The body of the engine consists of a cast aluminium crank case B, which is attached to the oplane by means of a pressed steel bearer flange F, and which is bored to receive the

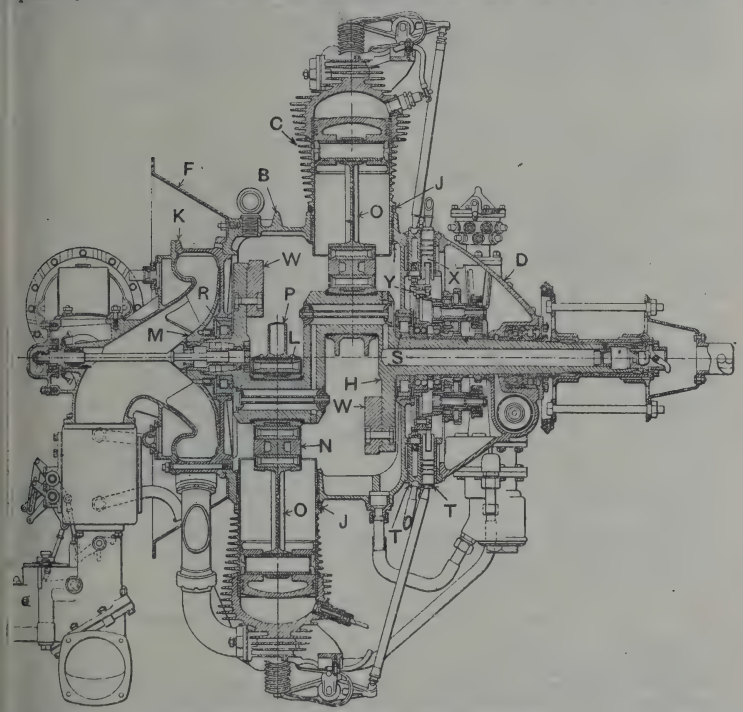

Fig. 6.—Armstrong Siddeley 'Jaguar' Engine.

inders C, and the valve tappet guides T. A back cover attached to the engine body carries magnetos and carburettors, and also the rear crankshaft bearing R. The inside of the back rer forms a casing for an induction fan M, which is attached to the crankshaft.

The crankshaft is a one-piece alloy steel forging and is balanced by weights W, which are tachable. A master connecting-rod O is rigidly attached to a master ring N, and is attached the piston of the top vertical cylinder in the front bank of cylinders and to the bottom vertical linder in the rear bank.

There are six auxiliary tubular connecting-rods P, which are free to hinge in the master ring, ing attached to it by the hardened steel pins L.

Hollow floating gudgeon pins are used in the piston, the pistons being of aluminium alloy th two cast-iron gas rings and two scraper rings. A hardened steel ring, Y, embodies three et and three exhaust cams, and is operated by planetary reduction gearing which drives it at e-sixth engine speed in an opposite direction to that of the crankshaft.

* *This type of engine was used by Sir Alan Cobham in his flight to Australia and back.*

Lubrication is on the dry-base system, two gear type pumps being fitted, one to feed s the other to scavenge the oil. Oil is supplied to the feed pump from a supply tank, and is th forced through a filter to the hollow crankshaft at a rate of about 2½ galls. per minute. released from the engine the oil drains back to the sump, and is returned to the supply tank the scavenge pump through oil-jackets surrounding the induction-fan casing and heater b By these means the oil is cooled, and the incoming gas heated.

Armstrong Siddeley 'Genet.'

This is a low-powered engine, the general design of which is similar to the 'Jaguar.'

General characteristics are: Five cylinder, air-cooled radial. Steel cylinders, screwed s shrunk on aluminium heads with inclined valves operated by push rods. One piece cranksh with counterbalance weights. Forged 'Y' alloy pistons. Oil pumps and magnetos mounted front cover of crankcase, carburettor at back communicating with induction chamber contain a mixing fan. Dry sump lubrication and provision for dual ignition.

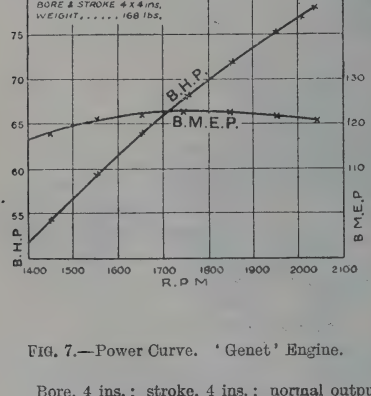

Fig. 7.—Power Curve. 'Genet' Engine.

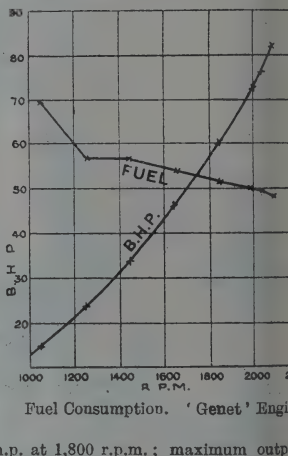

Fuel Consumption. 'Genet' Engi

Bore, 4 ins.; stroke, 4 ins.; normal output, 60 b.h.p. at 1,800 r.p.m.; maximum outp 72 b.h.p. at 2,035 r.p.m.; weight, 168 lbs.

Fuel consumption, 0·57 pint per b.h.p. hour.

Wright 'Whirlwind' Engine. Model J–5 Series.

This engine (fig. 8) is of the air-cooled, static radial type.

The leading particulars are as follows:—

Number of cylinders, 9; bore, 4½ ins.; stroke, 5½ ins.; displacement, 788 cubic ins.; co pression ratio, 5·2 : 1; guaranteed h.p. at sea level, 200 h.p. at 1,800 r.p.m. Average weig (dry), 508 lbs. Length overall (ex. starter), 34 ins. Diameter overall, 45 ins. Distance, mou ing flange to end of propeller hub, 27$\frac{17}{32}$ ins. Fuel consumption at rated power, 0·60 lb. h.p. hour. Oil consumption at rated power, 0·025 lb. per h.p. hour.

The cylinder consists of a head H with integral fins cast in aluminium alloy screwed a shrunk on to a forged steel barrel B with integral fins and holding-down flange. Combust chamber hemispherical with valves inclined at 35° to cylinder axis. Two sparking plugs cylinder located in bronze bushings, diametrically opposite in the sides of the combustion chamb at an angle of 10° to crankshaft axis. Cylinder head contains two ports, the axes of which at right angles to each other, one for attachment of inlet pipe, and the other for attachment exhaust manifold. Cylinder attached to crankcase by eight studs.

Crankcase built up of five aluminium alloy castings. Front section S_1 includes thrust bear housing, magneto brackets, magneto and cam-driving gears. Intermediate section S_2 conta cam and valve tappet mechanism and housing for front crankshaft bearing. Main section S_4 provided with pads for attachment of cylinders and contains the flange for mounting t engine, and the housing for rear crankshaft bearing and intake passages P. Rear section contains drives for oil and fuel pumps, gun synchronisers and tachometers. It also provide mounting for engine starter and housing for main oil strainer.

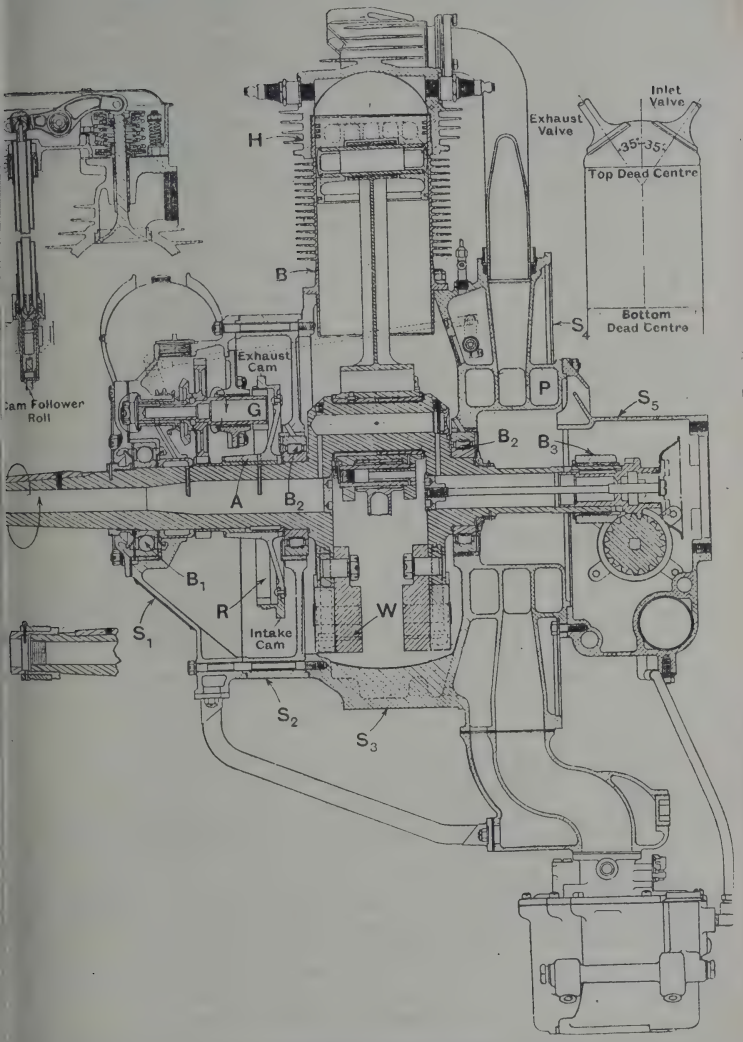

FIG. 8.—Wright 'Whirlwind' Engine.

Model J–5 Series.

Crankshaft, single throw, counterbalanced type, chrome-nickel steel forging machined over and hollow throughout its length. Counterweights W bolted to extensions of crank chee Shaft runs in four bearings, ball thrust bearing B_1, two main ball bearings B_2, and a plain bear B_3 in rear crankcase section.

Valve-operating mechanism actuated by cam located in intermediate crankcase section, a consists of a hardened steel ring R with eight lobes on the outside, and an internal gear G on inside, which is riveted to an aluminium hub A riding on the sleeve portion of the cam dr gear, which is keyed to crankshaft. Cam followers of roller type. Push rods of nickel st tubing with hardened steel balls pressed into either end. Valve gear enclosed by rocker a housings, which form the support for rocker arm pins. Connecting rods consist of one mas and eight link rods machined from chrome nickel steel forgings, master rod provided with st backed babbit-lined bearing at big end. Gudgeon and knuckle pin bearings of bronze.

Pistons cast aluminium alloy with three compression rings above gudgeon pin and one scraper ring at bottom of skirt.

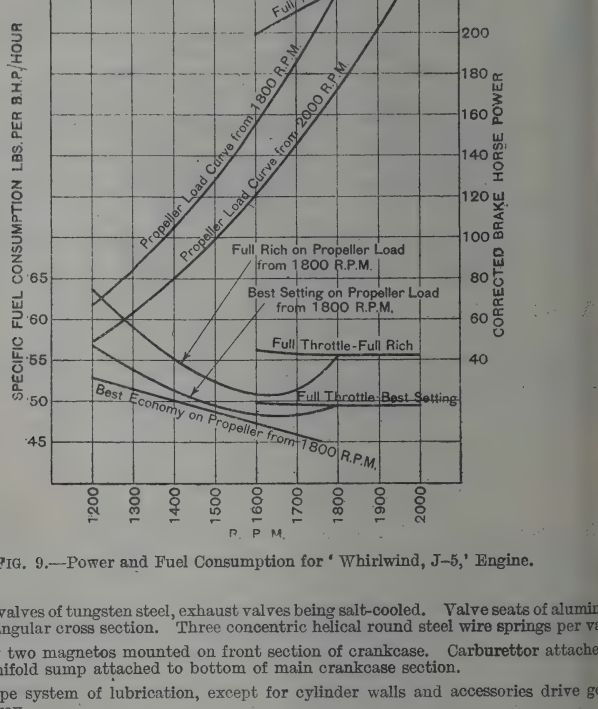

FIG. 9.—Power and Fuel Consumption for 'Whirlwind, J–5,' Engine.

Tulip-type valves of tungsten steel, exhaust valves being salt-cooled. Valve seats of alumini bronze of rectangular cross section. Three concentric helical round steel wire springs per val

Ignition by two magnetos mounted on front section of crankcase. Carburettor attached oil jacket, manifold sump attached to bottom of main crankcase section.

Pressure-type system of lubrication, except for cylinder walls and accessories drive ge which is by spray.

A.D.C. AIRCRAFT CO.'S 'NIMBUS' ENGINE.

This engine is one of the lightest of its type yet produced. It has six water-cooled vert cylinders, with three valves per cylinder, one large inlet and two exhaust. The inlet valves operated by short rockers, while the exhaust valves are operated directly from the overh camshaft. Aluminium alloy pistons are used.

No gear reduction is employed, the air-screw being direct driven.

Bore, 152 mm.; stroke, 190 mm.; normal output, 305 b.h.p. at 1,450 r.p.m.; maximum put, 335 b.h.p. at 1,600 r.p.m.; petrol consumption at normal output, 0·52 pint per h.p. hour; consumption, 0·017 pint per h.p. hour; compression ratio, 5·4 : 1; b.m.e.p. 132 lbs. per in.; weight dry (complete with airscrew boss, but less radiator and water), 670 lbs. ± 10 lbs.

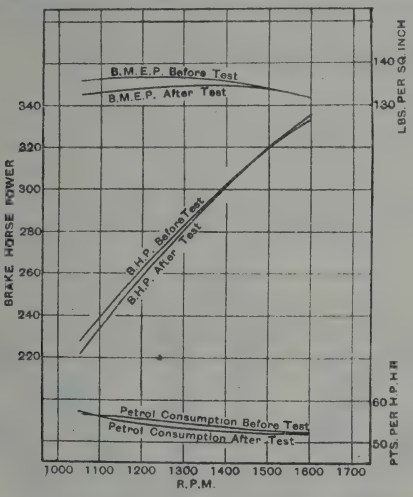

FIG. 10.—Power and Fuel Consumption Curves. 'Nimbus' Engine.

A.D.C. AIRCRAFT CO.'S 'AIRDISCO' ENGINE.

This engine is suitable for training or light commercial machines.

Air-cooled, 8-cylinder 'Vee' type, with cylinders set at 90°. Cylinders of cast-iron with olling fins with detachable head of aluminium alloy, the whole assembly being secured to the nkcase by four long studs passing through lugs on the cylinder heads.

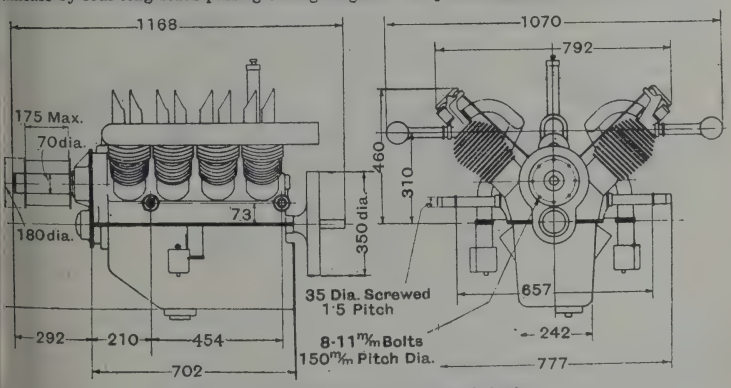

FIG. 11.—Main Dimensions of 'Airdisco' Engine.

Aluminium alloy piston with two cast-iron rings; gudgeon pin fixed in small end of rod and ating in piston.

The valves are both of the overhead type, operated through rockers by push rods, the rockers ing supported by brackets cast on the cylinder heads.

Connecting rods of the main and articulating type, the articulating rod running on a harden steel pin in a phosphor-bronze bush. The big end bearing is white metal and cast direct in the main rod.

Power transmitted from crankshaft to propeller shaft by gears with a 2 : 1 reduction ratio.

Bore, 105 mm.; stroke, 130 mm.; normal output, 128 b.h.p. at 1,800 r.p.m.; maximu output, 140 b.h.p. at 2,000 r.p.m.; weight (less fuel and oil), 452 lbs.; weight per h.p. (at norm output), 3·53 lbs.

Petrol consumption at normal output, 0·62 pint per h.p. hour.

Oil consumption at normal output, 0·04 pint per h.p. hour.

'Bristol' Jupiter Series VII. Engine.

The 9-cylinder 'Bristol' Jupiter engine is of the air-cooled static radial type with gear-driv blower, and is manufactured by the Bristol Aeroplane Co.

Leading particulars are as follows :—

Number of cylinders, 9; bore, 5¾ ins.; stroke, 7½ ins. Total swept volume, 1,753 cubic in Normal r.p.m., 1,775 above 12,000 ft., maximum r.p.m. 1,950 above 15,000 ft. Dry weigl 770 lbs. Fuel consumptiom, 0·59 pint/b.h.p. hour. Direction of rotation, L.H. tractor.

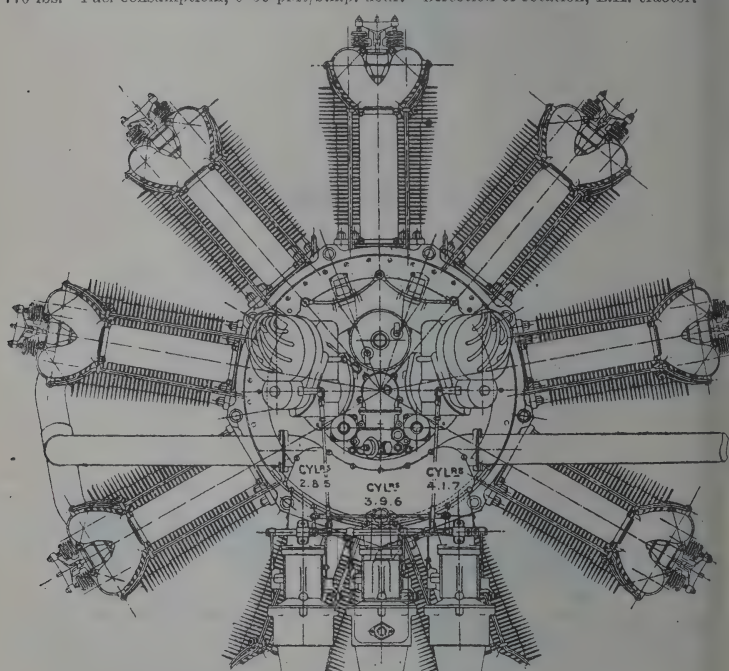

Fig. 12.—The 'Bristol' Jupiter Engine (Rear View).

Rating.

Ground.—Engine throttled to 370 b.h.p. at 1,535 normal ground r.p.m.

Climbing.—Throttle opened up progressively to full at 12,000 ft., normal r.p.m. increasi progressively to 1,775 r.p.m. at this altitude, engine developing 440 b.h.p.

Level Flight.—Maximum full throttle r.p.m. of 1950 not permissible till 15,000 ft. altitud engine then developing 460 b.h.p.

The airscrew is direct driven, but the engines can be supplied fitted with epicyclic ge reduction to drive the airscrew at 1,200 r.p.m.

The crankcase is an aluminium alloy casting in two sections, held together by long bolts, ich also hold the engine to the fuselage.

The steel cylinders are machined from solid billets, and are bolted to the crankcase. Three burettors are fitted, each feeding three cylinders.

'BRISTOL' JUPITER SERIES VII. ENGINE (with bevel type reduction gear).

Leading Particulars.—9 cylinders, air-cooled radial; bore, 5¾ ins.; stroke, 7½ ins. Total oke volume, 1,753 cubic ins. Compression ratio, 5·3 : 1 (commercial type 5 : 1). Normal ine speed, 2,000 r.p.m. Maximum engine speed, 2,200 r.p.m. Gear ratio, 0·5 : 1. Propeller, H. tractor. Normal propeller speed, 1,000 r.p.m. Maximum propeller speed, 1,100 r.p.m. rmal power, 485 b.h.p. at 2,000 r.p.m. (commercial type 465 b.h.p.). Maximum power, 5 b.h.p. at 2,200 r.p.m. (commercial type 505 b.h.p.). Oil pressure, 40 lbs./sq. in. Tachometer ve ½ engine r.p.m. Fuel, standard service, 80 20 petrol-benzol. Oil, Castrol 'R' or pure ated pharmaceutical castor. Dry weight, 830 lbs.

A 3-cylinder, air-cooled radial engine developing 100 h.p. is also made. This engine runs 1,600 r.p.m., and has steel cylinders 5¾ ins. bore × 6¼ ins. stroke, with aluminium heads. e smallest engine made by this company is the 'Cherub,' Series III. This engine has two posed cylinders of 90 mm. bore, stroke 96·5 mm., and a capacity of 1,288 c.c. It develops a ximum output of 36 b.h.p. at 3,200 r.p.m. and weighs 95 lbs., or 2·88 lbs. per b.h.p.; normal put, 34 b.h.p. at 2,900 r.p.m.

Fuel consumption, 2 galls. per hour; oil consumption, 1 pint per hour.

The cylinders have steel barrels and aluminium alloy heads carrying the screw-in alloy steel ve seats, guides, valves, inlet and exhaust passages. Inlet and exhaust valves of cobalt-chrome el are interchangeable, and have three concentric springs each. The camshaft lies across the nkcase below the crankshaft and is driven by spur gears, and operates the valves through ker shafts which run parallel to the cylinder axes from crankcase to cylinder head.

Aluminium alloy pistons, with three rings, are used.

Carburation.

With radial and rotary engines it is usual to fit a simple type of carburettor, there being no t chamber, the petrol flow being hand adjusted to suit engine speed and atmospheric conditions.

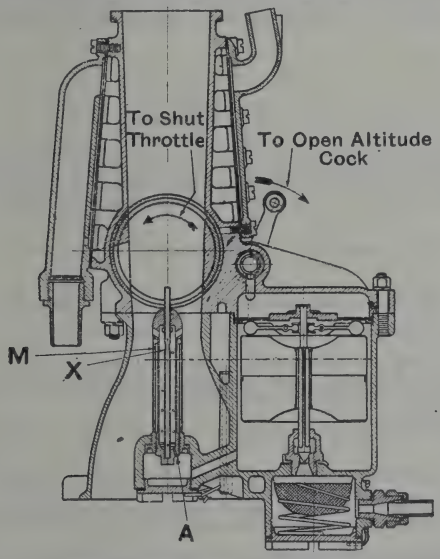

FIG. 13.—Napier Claudel-Hobson Water Jacketed Carburettor.

th stationary engines two or more carburettors are fitted according to the size of the engine presentative types are the Zenith and Claudel-Hobson, which are fitted with float chambers

and designed to give a practically constant mixture under the usual variations of load and spee These carburettors require to be carefully adjusted to each engine so as to give the same resul the operation of adjusting being known as ' synchronising.'

Aero engine carburettors must operate under variable circumstances. As the machine ris the density of the atmosphere decreases, and the quantity of fuel required per cu. ft. of free becomes less. The desired reduction in petrol flow is controlled by hand adjustment, either throttling the supply to the jet or, in the case of carburettors with float chambers, by reduci the pressure difference between the float chamber and the jet.

The Napier-Claudel Water Jacketed Carburettor is shown in fig. 13, and is designed for u with the ' Lion ' engine. It operates on the standard Claudel diffuser principle, the holes A a X being the main and pilot jets respectively. Water is delivered into the jackets on t induction pipes through pipes connected to the outlet flanges on the cylinder heads. Fr the induction jackets the water is led through short pipes to the water jackets of the carburetto and thence through a return pipe to the water pump.

On tractor type engines the series parallel type main and slow running jets are used, where on pusher type engines the series type jets are used.

The jets shown in fig. 13 are the series type; the series parallel type main jets have additional pilot jet hole drilled through their base central with the pilot jet, the pilot jet bei specially calibrated to function correctly with this type of main jet.

The altitude compensation is of the ' Vacuum control ' type. The areas of the various passag are specially proportioned for the ' Lion ' engine. The functioning of the pressure balance a altitude control systems depends on the maintenance of an air pressure or depression above t petrol in the float chamber.

The arrangement of the induction piping is a most important factor in getting go carburation; sudden changes in the speed of the charge, and sharp bends, cause a considera loss. Also there must be no dip in the pipes. The usual methods of heating are by wat circulation, by exhaust gases, and by hot air taken into the carburettor. The purpose of t choke tube is to obtain the correct velocity of air around the jets in order to get the best mixtu at all speeds. The main jet has most influence at high speeds, and the compensator, whi corrects the irregularities of the main jet, has the greatest influence at low speeds.

Water Cooling.

Water cooling of aircraft engines has followed automobile practice in general principl but there has been great diversity of opinion as to radiator design. The honeycomb type m now be considered as standard, with round tubes and hexagonally bulged ends. This gives maximum cooling surface with minimum solid frontal area and therefore minimum he resistance.

From a series of tests on different radiators (Aeronautical Research Committee R. & M. No. 9 it was found that:

(*a*) Heat dissipation can be represented as a function of the cooling area ratio ($i.e.$ $\frac{\text{cooling area}}{\text{frontal area}}$) and drag as a function of cooling area ratio and diameter.

(*b*) A round bulge gave a better performance than the hexagonal, mainly on account of t smaller drag. For tubes of the same length : diameter ratio, large diameters a better than small, mainly on account of the drag.

(*c*) Shutters have comparatively little effect on heat dissipation until they are more th half shut.

(*d*) The shuttered results suggest the use of longer tubes in order to cut down the frontal ar

(*e*) Geometrical considerations suggest the development of hexagonal tube radiators, as th would have greater cooling area for the same tube length and a smaller capacity.

Opinions of designers vary greatly as to the best position of the radiator. The ' nose ' positi in which the radiator is placed immediately behind the propeller, has many adherents, but excelle results are also obtained when the radiator is placed in two halves on the sides of the fusel or below the fuselage. The radiator may also be placed in the top plane centre section.

Radiator Shutters.

In machines designed for flying at high altitudes, it is necessary to provide a variable cooling rice to obviate the danger of the radiator freezing when high speeds are obtained as in diving. e device most generally used is a Venetian-blind type of shutter, which can be closed to prevent air having access to the radiator. It is controlled by the pilot, who is also provided with a ator thermometer, to indicate the circulating water temperature.

THE 'Auto' Fuel Waste Recorder.

(CO_2 RECORDER.)

This Instrument, for the Automatic Analysis of Boiler Flue Gases, is an absolute necessity for ensuring the economical use of Fuel and Cheap Steam Production.

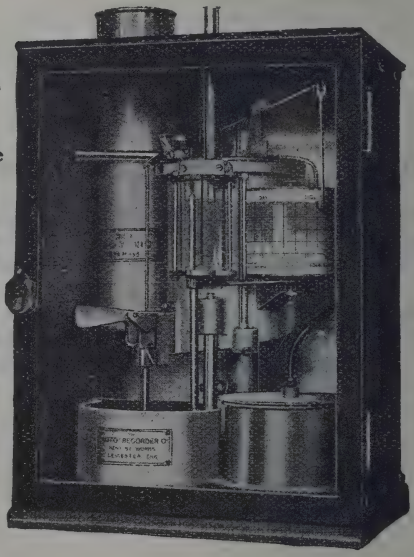
A Check for the Employer.

A help to the Fireman.

Simple and Reliable.

Entirely Automatic.

Worked by a trickle of Water.



Special Type for Marine Use.

Size 15 in. × 12½ in. × 21 in.

Weight 120 lb.

All Metal Case.

Requires less than Five minutes' attention daily.
Guaranteed accurate within half per cent.
Large numbers in use and giving satisfaction.

Repeat orders over 60%.

Patentees and Sole Manufacturers:

THE 'AUTO' RECORDER CO.

Kent Street Works, LEICESTER, ENGLAND.

Telegrams: 'LIFTING.' Telephone No. **575.**

Codes: A B C, 4th and 5th Editions.

COMBUSTION.

The heat yielded by burning any fuel is produced by the combination of the carbon, drogen, and sulphur present in it with the oxygen of the atmosphere. A little heat may be her liberated or absorbed by the decomposition of the compounds present in the fuel into their ments. When a fuel is burned in a furnace, or in an internal combustion engine, under rect conditions, the carbon burns to form carbon dioxide (CO_2), the hydrogen to form ter (H_2O), and the sulphur, which is not usually present in large quantities, to form sulphur xide (SO_2). If insufficient air be present the carbon is incompletely burned, and forms, to ne extent, carbon monoxide (CO), a considerable amount of heat being lost by this reaction cing place. The weight of air theoretically required for complete combustion may be ertained by the formula:

$$\text{Air required in lbs.} = 0{\cdot}116\,[C + 3\,(H - \tfrac{1}{8}\,O)],$$

ere C, H, and O are the percentages of carbon, hydrogen, and oxygen respectively present in e fuel.

Both the theoretical quantity of air required, and the percentage of carbon dioxide theoretically rect in the flue gas, are dependent upon the ultimate composition of the fuel. In practice the required is generally greater or less than by the formula.

Calorific Value of Coal.

If it is impossible to determine the calorific value of coal in a calorimeter it can be roughly imated from the ultimate composition by the formula:—

Net calorific value = [8,137 C + 29,100 (H − ⅛O) + 2,500 S − 600 H_2O] ÷ 100, where H, and O are the percentages of carbon, hydrogen, and oxygen respectively present, d H_2O the percentage of hygroscopic water present.

When the ultimate analysis is not known and it is desired to obtain a rough estimate of the lorific power from the proximate analysis, this can be obtained by the formula:

$$\text{Calorific value} = 1{\cdot}8(82C + aV)\ \text{B.Th.U.}$$

which C = per cent. fixed carbon, V = per cent. volatile matter, and a is a constant computed om the following: $a_1 = 100V/(C + V)$.

a_1	5	10	15	20	25	30	35	38	40
a	145	130	117	109	103	98	94	85	80

Ash and Moisture Content.

The question of ash content is a serious one, as its removal from boilers involves labour and pense. The clinker to be removed from a steam plant is greater in quantity than the weight ash content obtained by calculation from the results obtained in the laboratory.

High moisture content not only shows that water is being bought for coal. It must remembered that this moisture has to be driven off in the form of steam, and in this way tak up heat from the combustion zone, and is liable to cause smoking, with consequent reduction efficiency.

Combustion Computation.

The total heat per pound of water vapour as found in air and in flue gases may be comput within one B.Th.U., by the formula $H = 1{,}057 + 0{\cdot}46t$, where t is the Fahrenheit temperatu This formula frees the computer from all need for tables so far as computing moisture los concerned, while at the same time ensures a degree of accuracy sufficient for all practical purpos

Internal Combustion Engines' Exhaust Gases.

The exhaust gases from internal combustion engines are subject to the same considerat as flue gases. They, however, cannot be regulated so as to produce a definite CO_2 percent as to obtain this result it would be necessary to throttle down the incoming air, thus loa the engine by increasing the difference in pressure between exhaust and inlet, in which ca

Theoretical Composition of Exhaust Gas with Varying Amounts of Exc Air when Fuel has the Composition: Carbon 88 %, Hydrogen 12 %.

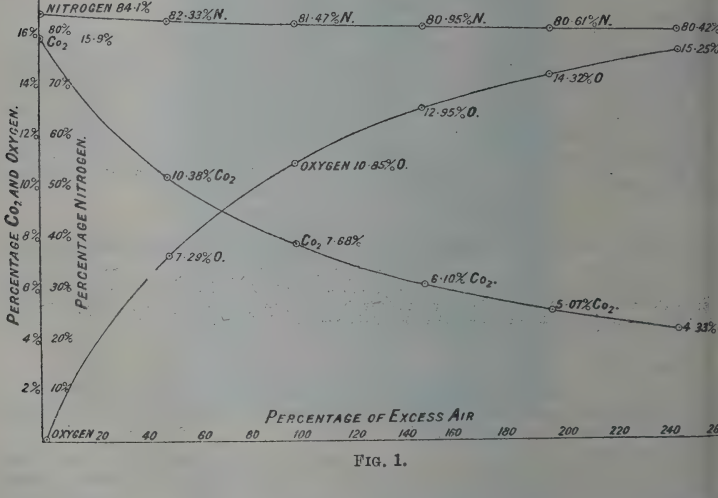

Fig. 1.

loss of efficiency would occur. The graphs in fig. 1 show the composition of the exhaust g of an engine burning heavy petroleum (about 88 per cent. C and 12 per cent. H) with va quantities of excess air. Diesel oil engines running at full load generally take about 100 cent. excess air: semi-Diesel engines a somewhat greater percentage excess air.

Composition of Flue Gases.

With an average steam coal the theoretical quantity of air for combustion would yield a gas containing some 18·5 per cent. of carbon dioxide, but if only the calculated quantity o be admitted to the furnace there is danger of loss of heat by the formation of some ca monoxide, and if the supply of air be any less than the calculated quantity, a very serious lo certain to take place for this reason. On the other hand, a slight excess of air over calculated amount does not result in great loss of heat. It is therefore desirable to allow a s excess of air. The best working is obtained by endeavouring to maintain a proportion of a 14 per cent. of carbon dioxide in the flue gas.

Most methods for the estimation of carbon dioxide are based on the absorption of this gas by potassium hydroxide (caustic potash) solution, the process consisting in measuring a volume of flue gas at a definite temperature, and then absorbing the CO_2 by means of a 35 per cent. solution of caustic potash, after which the volume of gas is again measured, the reduction in volume indicating the volume of CO_2 originally present. Many simple forms of chemical apparatus are available for this purpose.

It is frequently desirable in gas analysis to estimate carbon monoxide and oxygen as well as carbon dioxide. Similar apparatus with other absorbent solutions for the respective gases may be used. In the common form of Orsat apparatus, pipettes containing absorption solutions of caustic potash (for CO_2), acid cuprous chloride (for carbon monoxide), and alkaline pyrogallol (for oxygen) are used. The apparatus also contains a measuring burette and levelling bottle, and is generally built up in a wooden case to make the complete set easily portable.

In some cases it is necessary to estimate methane or other hydrocarbons in gas, in which case means are provided for exploding the gas with oxygen, after which the newly-formed CO_2 may be estimated, and the content of hydrocarbon gases calculated therefrom. Special forms of apparatus, made solely for the object of estimating methane and carbon monoxide, are available.

CO_2 OR CARBON DIOXIDE.

For the control of combustion, beyond occasional tests of carbon monoxide, the only product which requires frequent estimation is carbon dioxide. The process of distillation which goes on in a boiler furnace, resulting in the separation of the gases and fixed constituents in the fuel, requires widely different and constantly varying conditions in the matter of air supply for the attainment of perfect combustion. Efficient combustion (i.e. economical combustion) is secured by burning the correct proportion of fuel and air under the varying conditions of coal and atmosphere. The point, therefore, to aim at is to generate the required steam by burning as much air as possible and as little fuel as necessary. The burnt air given off passes up the flue in the form of carbon dioxide (CO_2), therefore the object to achieve is to secure as large an amount of CO_2 (say from 10 per cent. to 14 per cent.) as is possible. The relation of coal consumption to CO_2 in the flue gases has been worked out, and the result is given in standard treatises on fuel. These results are as follows:

Temp. of Exit Gases.		Percentage of CO_2 in Exit Gases.											
		4%	5%	6%	7%	8%	9%	10%	11%	12%	13%	14%	15%
F.°	C.°	Total Percentage of Fuel wasted.											
400	204	32·4	26·2	21·8	18·9	16·4	14·9	13·4	12·3	11·4	10·6	9·8	9·2
500	260	40·5	32·7	27·3	23·6	20·8	18·6	16·8	15·4	14·2	13·2	12·3	11·6
600	316	48·6	39·3	32·8	28·3	24·9	22·3	20·2	18·5	17·1	15·9	14·8	13·9
700	371	56·7	45·8	38·2	33·1	29·1	26·0	23·5	21·6	19·9	18·5	17·2	16·2
800	427	64·8	52 4	43·7	37·8	33·2	29·7	26·9	24·7	22·8	21·2	19·7	18·5

The above figures necessarily include the unavoidable loss present in every boiler plant, and the performance of any plant must be judged by comparing the total losses given in the respective columns. The figures in the columns below the 'Percentage of CO_2 in Exit Gases,' represent the wastage of coal with that percentage of CO_2. For example, take the third column and the second line. Temperature of Exit Gases °F. 500—percentage of CO_2, 6 per cent. The wastage of coal is 27·3 per cent. Following the line on to the tenth column, it is shown that with 13 per cent. of CO_2 the coal wastage is 13·2 per cent.

PRECAUTIONS IN TAKING TEST SAMPLES OF FLUE GAS.

It is the practice of many engineers when obtaining accumulative test samples of flue gases to collect these samples over water. Owing to the solubility of the component gases, especially carbon dioxide, in water and the variations of these solubilities with the temperature and pressure, this liquid should not be used to collect the sample if accurate results are desired. If water be used, it will absorb carbon dioxide, for example, until it becomes saturated with this gas with respect to that gas mixture. This results in a loss of some of the carbon dioxide that was in the gas. Then if a gas cleaner in carbon dioxide is collected over the same water, the water will give

up carbon dioxide and increase the carbon dioxide content of the gas. If, instead of water, saturated solution of sodium chloride is used, these errors will be greatly reduced, as the gas much less soluble in this solution.

The common practice of collecting flue gas from the outlet of a boiler by the use of comm iron pipe for the sampling tube is objectionable if the temperature of the gas being sampled sufficiently high to raise the temperature of the sampling tube to 750° F. When the temperatu of the iron reaches 750° F. it starts to react with the carbon dioxide in the gas, forming iron oxi and reducing the carbon dioxide to carbon monoxide. Thus a sample of gas drawn through a iron pipe when at or above this temperature would have its composition completely change appearing to contain high carbon monoxide and low carbon dioxide. For sampling at the high temperatures the tube should be made of silica or clay, or be fitted with a water jacket that it may be cooled. (*Power.*)

CO_2 Recorders.

The majority of CO_2 recorders depend upon the absorption of CO_2 by caustic potash solutio a definite quantity of flue gas being intermittently measured out, and then the CO_2 absorbe and a record made of the diminution of volume, the chart being adjusted to read in volum percentages of CO_2 present in the flue gas.

The 'Auto' CO_2 Recorder.

In fig. 2 is shown, in diagrammatic form, the construction of the instrument known as t 'Auto' CO_2 Recorder, which has been designed and constructed by the *Auto Recorder Compan* and is now in successful operation in connection with a large number of boiler installations this country and on the Continent. The action of the apparatus is as follows:

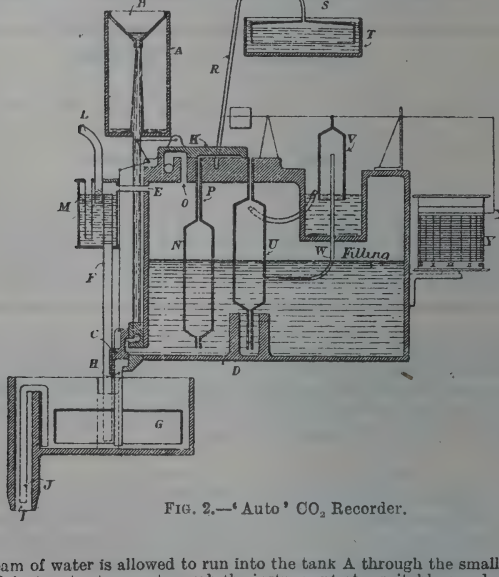

Fig. 2.—'Auto' CO_2 Recorder.

A small stream of water is allowed to run into the tank A through the small funnel B, whi only allows sufficient water to pass to work the instrument at a suitable speed. The water ru from the tank A through the valve C into the chamber D. When the chamber D is filled up to t pipe E, the water overflows down the pipe F and under the float G, which it raises, thereby movi

he valve C upwards and shutting off the water supply from the tank A into the chamber D. 'his motion of the valve C opens a communication from the chamber D through the pipe H, the 'ater rising over the float G until it flows down the pipe I, and the chamber D is empty; the ipe J then acts as a syphon and drains the water from under the float G, which is then allowed) fall again, and the chamber D to be once more filled. By this means the chamber D is lternately filled and emptied, and, as the float is connected by a system of levers to the dis- ·ibuting slide valve K, the water flowing through is the prime mover of the instrument.

The operation of gas analysis is very simple. The pipe L is connected to the supply of gas to e analysed and, as the end of the pipe dips slightly into the water seal in M, no gas can be drawn ack. When the water in the chamber D is running out, there is a slight vacuum in this chamber hich draws the gas through the pipes L and E, and, as the first measuring vessel N is in ommunication with the chamber D through the passages O and P and the slide valve K (this alve having moved over to the right by the rising of the float G), it is entirely filled with flue gas. Much more gas is drawn in than is analysed, in order that the sample may be as fresh as possible. 'hen the water reverses and begins again to run into D (the valve K having moved over to the *ft*, by the sinking of the float G), the gas enclosed in the vessel N is sent through the pipes P and , and under the dome S, which stands immersed in a solution of caustic potash contained in the essel T. This dome is of large area, and the gas is in a thin layer between the wet dome and the)p of the solution, so that the absorption of the CO_2 is rapid. After the water has risen and :pelled all the gas from the vessel N into the absorber, and has again begun to run out, the alve K having moved over to the *right*, the water, as it descends in the second measuring vessel , draws in from the absorber S the gas which has not been absorbed. As the measurer U is of ie same capacity as the measurer N, it follows that, if there is not sufficient gas received from ie absorber S to fill it, it will, after emptying the absorber, draw the remainder from under the ell V through the pipe W, and cause the bell to descend; the greater the amount of CO_2 absorbed ie lower the bell V will be pulled down. As the bell is suspended from a balanced lever, which as a pen X attached to it, the pen marks the chart Y, which is placed round a clockwork drum, ie lines made by the pen being of varying lengths, according to the amount of CO_2 which was the quantity of gas in the first measurer N.

It has been found that one of the greatest troubles with recorders of this kind is to keep the pes from the flue to the instrument clean; in the 'Auto' Recorder this is effected by a special ter.

THE 'W.R.' PATENT CO_2 INDICATOR.

(*W.R. Patents, Ltd., London and Leeds.*)

The W.R. CO_2 or Combustion Indicator is an apparatus which continually, automatically, id accurately indicates the percentage of CO_2 which is passing through the flues at any hour the day and night. With this Indicator installed on the boiler plant the percentage of CO_2 otained can be seen at once, and the necessary steps taken to increase this amount and thus ve fuel.

Fig. 3 shows a new type recently introduced and placed on the market. It can be used in l cases of combustion where any class of fuel is used, and where CO_2 is a product of this mbustion. The arrangement adopted differs materially from other CO_2 indicators.

The method employed in the 'W.R.' Patent CO_2 Recorder depends on the difference of essure generated on the two sides of a porous pot, one side of which is exposed to flue gas hilst the other contains soda lime granules contained in a paper cylinder which absorbs the coming CO_2.

An aspirator, S, worked by the natural draught which it increases, is fixed at a point near the chimney base as possible, and continually aspirates gases from the flue it is desired keep under observation. The path of gases is shown by the arrows. They are first drawn rough a filter F, and pass from thence into a chamber containing a porous pot, inside which a dry reagent, R. The flow of gas is shown by continuous bubbling through water in vessel A pipe connects the chamber with a vessel containing water into which dips one end of iother pipe, G, the other end of which is taken into the inside of the porous pot. Some of e gases penetrate into the interior of this pot, and are absorbed by the reagent, with the sult that a partial vacuum is formed, and the water is forced up the pipe G. The latter is ovided with a scale so graduated that the percentage of CO_2 in the flue gases can be read.

The W.R. Indicator is prompt in its action, having a lag of three minutes only. Its deviation om absolute accuracy has been found to be only 0·1 per cent. It is well constructed; has no echanically moving parts; is fireproof and foolproof, and can be worked by any boy of

average intelligence. With each Indicator the manufacturers furnish a blue print showing the method of fitting to each particular boiler, also special detailed instructions for installing the apparatus, which operation can be completed in from four to six hours by any works' engineer or fitter. In cases where a recording graph is desired, one of a specially approved form can be supplied by W.R. Patents, Ltd. The cartridges last 24 hours of continuous working.

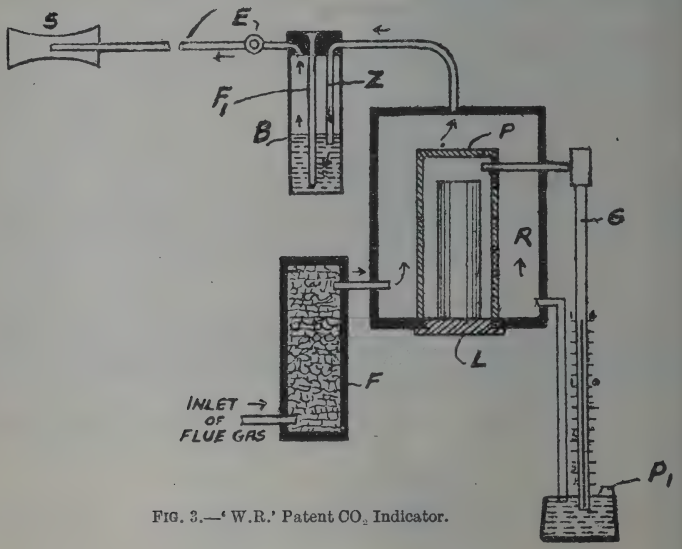

FIG. 3.—'W.R.' Patent CO_2 Indicator.

'Galvanised Iron Pipe' should never be used for connecting a CO_2 machine, that draws a continuous sample, to the sampling point at the boiler. The sulphur dioxide in the flue gas attacks the zinc coating on the pipe, forming zinc sulphate. This soon plugs the pipe and prevents the flue gas sample from being drawn through it.

Thermal Efficiency.

Petrol engines give maximum efficiency with an excess of air, and maximum power with insufficient air.

The following table gives the thermal full load efficiency obtainable when converting the heat of fuels into work by various types of engines:—

Type of Engine.	Thermal Efficiency.
	Per cent.
Reciprocating steam engine and boiler	12
Steam turbine and boiler	18
Petrol engine	22
Gas engine with producer	24
Gas engine with suction producer	26
Petrol engine (aircraft)	27
Semi-Diesel oil engine	34
Alcohol engine	36
Diesel oil engine	36

THERMAL EFFICIENCY CURVE.

Curve A (fig. 4) represents the best thermal efficiency that can be expected from gas-engine lants; B, a moderate efficiency from the same plant; C, a poor efficiency from gas plant, but robably the very best that can be expected from a large gas-fired turbo-generator plant; D may e considered a good thermal efficiency for the latter.

These efficiencies can only be expected in power plants working at a high load factor.

(*A. Hugh Seabrook.*)

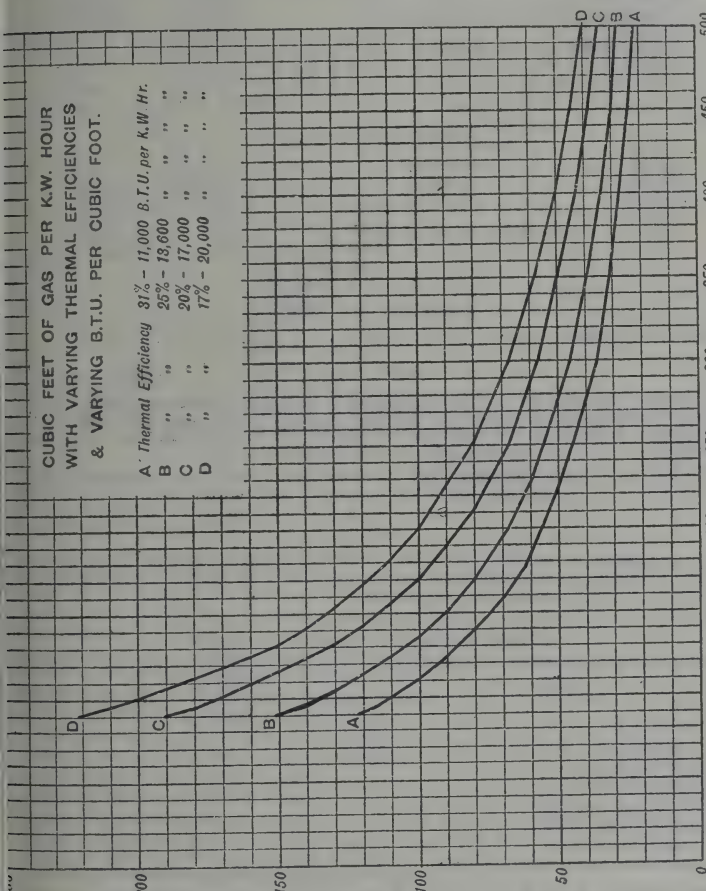

FIG. 4.—Thermal Efficiency Curve.

TEMPERATURES OF SPONTANEOUS IGNITION.

The thermal efficiency of internal-combustion engines is dependent upon the compression pressure employed in the engines. The compression pressure permissible in engines on constant volume cycle is dependent upon the temperature of spontaneous ignition of the fuel employed.

The following are recent figures for the spontaneous ignition temperatures of fuels :—

SPONTANEOUS IGNITION TEMPERATURES (IN OXYGEN).

Liquids.	Sp. Gr.	S.I.T.	
Pratt's perfection spirit No. I.	0·710	272 C.°	522 F.°
" " No. II.	0·724	270	518
Paraffin oil	0·782	253	487
Gas oil (petroleum)	—	254	489
Various crude petroleums and residua	—	254 to 275	489 to 527
Shale oil	—	253	487
Commercial 100 per cent. benzol	0·875	566	1,051
Creosote oil	1·010	415	779
Coke-oven tar oil	1·046	478	892

(*Moore*, '*J.S.C.I.*', Feb. 15, 1917.)

Gaseous Fuels (in Air).		
Hydrogen	758 C.°	1,396 F.°
Carbon monoxide	910	1,670
Ethylene	895 to 905	1,643 to 1,661
Coal gas	850	1,562
Petrol gas	900	1,652
Methane (No ignition below 1,000)	1,000	1,832

(*McDavid*, '*J.C.S.*,' *Nov.* 1917, p. 1003.)

SOLID FUELS.

The most important naturally occurring solid fuels are :—

Coal ; Lignite ; Peat ; Wood.

These may be burned in the raw state, or may be subjected to destructive distillation. In the latter case solid, liquid, and gaseous products are evolved. The more important solid fuel which may be prepared by this treatment are coke (of two kinds, metallurgical and gas-work coke), lignite coke (of little value), peat charcoal, and wood charcoal.

Powdered coal is sometimes made into briquettes by the addition of a small percentage o coal-tar pitch or other binding material, and pressing in moulds.

COAL.

The composition of coal from various fields varies considerably according to the condition to which the coal has been subjected during its formation. Its variation in composition can be seen from the following table of coal analyses :—

ULTIMATE COMPOSITION OF COAL (*Brame*).*

Type of Coal.	Carbon.	Hydrogen.	Oxygen and Nitrogen.	Fixed Carbon.	Volatile Matter.
Lignites and brown coals	69·5	5·5	25·0	52·0	48·0
Splint coal (Fife)	82·0	5·0	12·8	61·0	39·0
Gas coal (Durham)	85·0	5·5	8·2	66·0	34·0
Coking coal	87·3	5·05	6·9	73·5	26·5
Smokeless steam (Welsh)	91·3	4·05	3·9	85·5	14·5
Anthracite (Scotch)	91·1	3·5	4·65	88·5	11·5
Anthracite (Welsh)	91·0	3·9	4·28	93·0	7·0

Coal possesses a sp. gr. of from 1·2 to 1·5 (water = 1) mainly depending on its composition It also varies considerably in hardness and texture. The combustible portion of coal usually consists of from 73 to 93 per cent. carbon, 3 to 6 per cent. hydrogen, 2 to 20 per cent. oxygen 1 to 2·5 per cent. nitrogen, and 0·5 to 5 per cent. sulphur. When completely burned coals yield from 1 to 15 per cent. ash. The moisture content varies within very wide limits. The heat value of coal is generally from 12,000 to 16,000 B.Th.U. gross. A comparison of the properties of coal with those of other solid fuels may be seen in the following table :—

* '**Fuels: Solid, Liquid, and Gaseous,**' p. 32.

CALORIFIC PROPERTIES OF VARIOUS FUELS.

Analysis of Coal.

The chemical tests usually made upon coal are to ascertain the calorific value, coke value, ash content, moisture content, and ultimate composition. The volatile matter per cent. is obtained by deducting the coke value of the dry coal from 100. The 'fixed carbon' is obtained by deducting the ash content from the coke value.

The Commercial Selection of Coals.

(*Contributed by Chas. F. Wade, A.M.I.Mech.E., A.M.I.E.E.*)

The commercial value of a coal for any specific purpose and for direct combustion purposes will be dependent upon the following factors:—

(i) The lower or net calorific value.
(ii) The amount of volatile matter and nature of coke.
(iii) The amount and nature of the ash content.
(iv) Its physical suitability for the particular conditions under which it is to be burned.
(v) The price per ton, delivered on site.
(vi) Local cost of labour for handling, firing, and removal of ashes.

The net calorific value (i) calls for both a test for calorific value and also either an ultimate analysis or calculation in order to arrive at the hydrogen content of the fuel. The latter calculation or estimate is made from the percentage of volatile matter in the coal as disclosed by proximate analysis.

The net commercial calorific value will vary with the conditions obtaining in individual installations, and will depend upon the final temperature of the gases leaving the boilers or furnaces, together with the total hydrogen in the fuel as fired.

The total hydrogen will be the sum of the hydrogen combined in the fuel and that forming one-ninth of the moisture. Lower commercial calorific value for any specific plant will be

$$\text{HCV} - \left\{ 9\text{H} \left([212 - t] + 970{\cdot}4 + 0{\cdot}47\ [\text{T} - 212] \right) \right\},$$

where,

HCV = higher or calorimeter value of fuel in B.Th.U. per lb. as fired;

t = temperature of the fuel in °F., as fired;

T = final temperature of waste gases.

H = hydrogen fraction of the fuel as fired;

In the absence of direct ultimate analysis of the coal, the percentage of hydrogen in the fuel may be closely estimated by the following formula (Diederichs'):—

$$\text{H} = \text{V} \left(\frac{7{\cdot}35}{\text{V} + 10} \right) - 0{\cdot}013,$$

where,

H = percentage of hydrogen in the combustible; V = percentage of volatile matter in the combustible.

Combustible = coal, less sum of moisture and ash.

(ii) The amount of volatile matter and nature of the coke are found simultaneously in the proximate analysis. This test will give the correct classification of the coal as to its qualifying characteristics for special uses. The ratio of volatile matter to fixed carbon is of the greatest importance in deciding the suitability or otherwise of a coal for use on any particular plant; all other things being equal, the fuel with the lowest volatile content which can be efficiently consumed in the specific furnace conditions will be the most economical in use. This can only be definitely determined by the careful working test of a sample delivery of the fuel, and careful note made of the percentage of CO_2 in the waste gases, together with the final temperature of the gases and the percentage of combustible on the ash heap. The following general classification of coals will be of assistance in selecting suitable fuels for given purposes from the commercial viewpoint of economy in use.

Class of Coal.	Per Cent. Volatile Matter in Combustible.	Economical Application.
Short flame non-caking, semi-bituminous, or Welsh steam coals	12–20	Steam raising with strong draught.
Short flame caking coals	20–25	As above and coke manufacture.
Medium flame, moderately caking coals	25–32	Steam raising, domestic grates.
Long flame caking coals	32–40	Gas manufacture.
Long flame non-caking North Country coals	over 40	Furnaces, gas producers.

Burning a coal in a furnace which has insufficient draught for complete combustion will result in excessive waste of unburned carbon as coke in the ashes. Burning a coal of an unnecessarily high volatile content will produce an unnecessarily high loss in the waste gases, due to the hydrogen content, smoke will be difficult to avoid, and hydrogen loss will not be shown on any commercial form of flue gas analysis apparatus.

The amount of ash and moisture will not affect the classification given above.

(iii) The amount of the ash in the coal will not only reduce its commercial value by the reduction in actual calorific value, but also by its physical effect will reduce the value at a greater rate than that of the percentage of ash. For ordinary conditions of firing and draught, without steam jets, the rate of fall in practical value with the ash content will gradually increase until at 40 per cent. ash the fuel will be unburnable and valueless. This is for average ash.

The nature of the ash is chiefly affected by the percentage of iron in its composition, the fluxing effect of ferric oxide in the ferruginous ash coals causing the formation of liquid slag at comparatively low temperatures, which closes up the fire-bar spaces, assists in the fusion of firebars, and entraps appreciable quantities of unburned combustible. Ferruginous ash is distinguished by its red colour, the percentage of iron being roughly indicated by the depth of the coloration of the ash in the crucible after proximate analysis for ash.

(iv) The physical suitability of the coal for particular conditions depends upon the construction of the firegrates, type of mechanical stoker, and the amount of draught available. Under practically every condition of use mixed coals as regards size should be avoided. For hand-fired boilers and furnaces screened cobbles or nuts should always be selected. Large steam coal is

o be avoided; if fired as received, in lumps, efficient combustion is impossible, while breaking down results in uneven fires and waste due to the formation of a quantity of slack in the process. Fine slacks are unsuited for hand-firing on plain grates, but can be burned very efficiently on special forced-draught grates fitted with steam jets and closely spaced firebars. High ash coals may be more efficiently burned on these grates than with plain natural or induced draught.

(v) The price per ton of coal, delivered, together with the cost of labour in handling and incidental work, is the last test of the value of the coal to be applied after all the technical deductions already referred to have been made, and is to be utilised to arrive at the net number of B.Th.U.'s per unit of cost under practical conditions of work.

Wherever possible, the following procedure should be adopted in selecting the most economically suitable coals for contract purposes:—

A sample delivery should be ordered of sufficient size to allow of observation under practical working conditions for a long enough period to ascertain the maximum hourly evaporation under forced and economical conditions of work, probable ash-heap loss, chimney loss, etc. This cannot be carried out without the proper equipment of testing instruments. This working observation will allow of a close estimate of labour and power costs. A low-grade slack of about 10,000 B.Th.U. per lb. will probably call for a power and labour cost quite double that involved in the use of good quality washed nuts of 14,000 B.Th.U. per lb. This shows the uselessness of evaluation on the calorific value alone. Standing losses on the plant, such as conduction and convection, etc., vary directly as the number of boilers, etc., used.

Final evaluation should be made as follows:—

Gross or higher calorific value of the coal, air-dried, then deduct the following:—

Hydrogen loss under practical conditions of waste gas temperature;

Heat loss in waste gases due to excess air as per CO_2 and temperature readings;

Loss due to unburned carbon in ash-heap per lb. of fuel used.

The final figure thus obtained gives the practical working value of the fuel in B.Th.U. per lb.

To the price of the coal must be added the following costs:—

Cost of attendance for firing per ton of coal used;

" power, such as stoker, fan, conveyor, economiser drive, etc., per ton of coal used;

" ash removal per ton of coal used.

From the data thus obtained the ultimate cost of, say, 100,000 B.Th.U. is obtainable for the actual conditions existing with the particular plant upon which the coal is to be used.

The system which has been used with success is to reduce the value of each coal to a figure of merit consisting of its comparative value with pure carbon as a standard, the latter being taken as '100.' The average final temperature of the gases is ascertained in the usual manner. The chimney loss for pure carbon burned perfectly without excess air is then calculated for the conditions of waste gas temperature obtaining on the plant. Taking the calorific value of pure carbon as 14,544 B.Th.U. per lb., the '100' figure of merit for this plant will be 14,544 minus the gas loss per lb. of carbon. This represents theoretical perfection with the plant. The actual results obtained for the coal under examination are expressed as a percentage of the pure carbon theoretical figure, and this is taken as the relative figure of merit for the fuel.

(*C. F. Wade.*)

Economic Effects of Impurities in Coal.

Each per cent. of sulphur reduces the boiler capacity by about 1·5 per cent. In experiments made in America with a chain grate stoker, using Illinois coal mixed with various percentages of ash, the efficiency dropped gradually as the ash increased up to 35 per cent., after which the efficiency dropped to zero rapidly with a fuel containing 40 per cent. of ash.

Loss of Thermal Value of Coal by Storage.

An average of 741 tests, in America, of a particular coal showed, after three years in the open air, a reduction of from 35 to 28·3 per cent. of volatile combustible matter, indicating a thermal value loss of 20 per cent.

Coal in storage should be inspected regularly. If the temperature reaches 150° F. the pile should be carefully watched, and if the temperature rises to 175° or 180° F. the coal should be removed as promptly as possible. The coal should be thoroughly cooled before being replaced in storage.

Temperature of Decomposition of Coal.

The temperatures at which coals begin to decompose are of considerable importance, both for technical purposes and as an aid to the study of the constitution of coal. There is little published information of a precise nature on this point, and it is frequently assumed that coal may be heated to 250° C., for purposes such as drying, without causing any modification in the coal substance. A general investigation of the behaviour of coal on heating is now being carried out at H.M. Fuel Research Station, and a report recently issued by H.M. Stationery Office deals with the results of experiments to determine the temperatures at which products of decomposition of various types of coal are first given off when the coal is heated. It is shown that when bituminous coals are heated, oil fumes may appear at temperatures as low as 215° C. The investigations are continuing and further reports will be issued in due course.

Utilisation of Anthracite Wastes.

A series of tests made in America, consisting of 30, 50, and 70 per cent. run-of-mine coking coal mixed with anthracite culm, showed that the pulverised bituminous coal alone produced better results, except the mixture of 30 per cent. culm with 70 per cent. bituminous, which was equal to that of the bituminous coal alone.

Stowage Space of Coal.

The stowage space occupied by coal is 40 to 42 cubic feet for one ton of Welsh steam coal, 45 cubic feet for one ton of North country coal, and 45 to 50 cubic feet per ton of Scotch coal.

EVAPORATIVE POWER OF FUELS.

The heat required to evaporate one pound of water at boiling point is 967 B.Th.U.

To raise water from 100° F. to boiling point and evaporate into steam at 212° F. 1,078 B.Th.U. per pound of water are required.

By dividing the calorific power (in B.Th.U.) of a fuel by 1,078 we obtain the *theoretical* quantity of water which it will raise from a feed-water temperature of 100° F. and evaporate at 212° F.

In practice a good boiler develops a thermal efficiency of about 70 per cent., and the actual evaporation obtained is therefore about 70 per cent. of the theoretical figure.

Evaporative Power of Coal.

Coal.	Calorific value. B.Th.U.	Evaporative power from 100° F. (37·7° C.) to Saturated Steam at 212° F. (100° C.).	
		Theory.	Practice. (70 % efficiency.)
Welsh anthracite . .	15,000 to 15,500	13·9–14·4 lbs.	9·7–10·1 lbs.
Scotch anthracite . .	14,500 to 15,000	13·45–13·9 ,,	9·4–9·7 ,,
Welsh navigation coal .	14,000 to 15,000	13·00–13·9 ,,	9·1–9·7 ,,
Average British steam coal	12,000 to 13,500	11·1–12·5 ,,	7·8–8·75 ,,

For every 10° superheat, 0·0055 is to be added to the above factors.

Coke.

Coke is produced by the destructive distillation of bituminous coal either in coke ovens or n gasworks.

Coke-oven coke is produced by slowly heating the coal to a high temperature, about 1,000° C., by which means a hard product, almost entirely free from volatile matter, is obtained. This coke is employed in blast-furnaces, and commands a slightly higher price than the product of the gas-works. It possesses a calorific power slightly lower than that of pure carbon (14,540 B.Th.U.).

The process employed in coke ovens, namely, the gradual heating of the coal to a very high temperature, results in the production of a very hard, unfriable coke, which will withstand the high crushing stresses necessary for metallurgical operations, especially blast-furnace work. It contains all the ash, and nearly half the sulphur, present in the original coal.

Gasworks coke is a product from the horizontal, inclined, or vertical retorts used in the manufacture of coal gas. In all such plants the heat is applied more rapidly than in coke ovens, and the resulting coke is softer and more friable than coke-oven coke. The process is, of course, primarily designed to give a high yield of gas, and the coke is a by-product.

Gas coke of average quality has a calorific power of about 12,500 B.Th.U. per lb., as sold, including moisture. Coke breeze, or coke dust, is about 10,000 B.Th.U. per lb.

Experiments made with quite dry coke and a sample artificially watered up to 16 per cent. of its weight show that a given quantity in a given time furnished 228 B.Th.U. wet and 365 B.Th.U. dry, approximately 39 per cent. advantage in favour of dry coke. The proportion of moisture in coke may vary from 2 per cent. to 20 per cent., and in the condition indicated in the experiment the heat in the grate or boiler was partly used to dry out the water, which escaped as moisture into the flues, carrying heat with it and thereby reducing efficiency.

Low-Temperature Distillation of Coal.

This consists in the gradual heating of bituminous coal to a comparatively low maximum temperature (500 to 600° C.). The retorting vessels employed are designed in such a way as to ensure the rapid removal of the volatile products. By such a process a low yield of very rich gas is obtained, and a high yield of thin tar. The tar is richer in low boiling-point fractions than the tars produced by the gasworks or coke-oven plants. The residual coke contains approximately 10 per cent. of volatile matter, and may be marketed for use in domestic fires, for which purpose it is claimed to be easily ignitable, and at the same time to give off the major portion of its heat as radiant heat, and to burn without generating smoke. Until recently the process has not met with success, largely on account of mechanical difficulties in the operation of the retorts; these difficulties, however, appear to be now overcome by 'Low-temperature Carbonisation, Ltd.,' in their production of 'Coalite.'

COALITE.

The following results were obtained in a test by the Government Fuel Research Board *:

The coal used in the test was a good average Yorkshire coal, and one which has been frequently tested in every way at the Fuel Research Station.

The yield of products per ton of coal carbonised was as follows:

'Coalite'	13·92 cwts.
Gas	5,620 cubic feet or, 39·6 therms, after stripping of motor spirit. (See †.)
'Coalite' crude oil	18·62 gallons.
Ammonia liquor	26·00 gallons.
Crude motor spirit from scrubbing the gas	1·78 gallons.
Equivalent ammonium sulphate	13·55 lbs.

The 'Coalite' produced was of a very suitable size (1 to 3-inch pieces), containing only 4·6 per cent. of breeze, and was quite suitable to withstand the rough handling natural to rail or road transport. Analysis of this fuel showed a slightly lower percentage of volatile matter than usual, but when burnt in a household grate it readily ignited and gave a good hot fire.

The yield of crude oil was high, showing 68 per cent. of that obtained in the standard assay apparatus developed by the Fuel Research Board, and upon examination proved to be a normal low-temperature coal oil.

The yield of gas was greater than that anticipated from this particular coal, and averaged $\left(\frac{39{\cdot}6 \times 100{,}000}{5{,}620}\right)$† = 705 B.Th.U. per cubic foot after being stripped of its crude motor spirit.

The motor spirit obtained by scrubbing the gas was 1·78 gallons per ton, but as the crude oil also contained 1·09 gallons, the total yield of this product amounted to 2·87 gallons per ton: a most satisfactory result.

The ammonia was also higher than expected, and, when converted into ammonium sulphate, yielded 13·55 lbs.

* Report published by H.M. Stationery Office, Kingsway London, W.C., price 9*d*.

YIELD FROM ONE TON OF AVERAGE COAL (say 25-30 per cent. volatile matter).

	Low-temperature Carbonisation.	High-temperature Carbonisation.	
		Gasworks.	Coke Ovens.
Temperature of carbonisation	1,000° F.	About 1,800° F.	About 1,800° F.
Gas	6,000-6,500 cubic feet of rich gas, 700–750 B.Th.U. per cubic foot.	12,000 cubic feet of medium quality (town's) gas, 550 B.Th.U. per cubic foot.	11,500 cubic feet of poor quality coke-oven gas, 450 B.Th.U. per cubic foot.
Liquid	20 gallons coalite oil (fractionated to, say, 3 galls. motor spirit, 8-9 galls. Diesel or fuel oil, and 8-9 galls. lubricating oil).	10 gallons coal tar. (Fractionated to about half-gallon motor spirit, carbolic acid, a large amount of naphthalene, fuel oil, &c.)	8 gallons coal tar.
Sulphate of ammonia (from the ammonia)	15 lbs.	25 lbs.	28 lbs.
Residue in retort	14 cwt. of smokeless fuel coalite containing about 9-10 per cent. volatile matter.	13¼ cwt. of soft coke, containing about 1 per cent. volatile matter.	14-14½ cwt. of hard coke, containing less than ½ per cent. volatile matter.

(*David Brownlie, A.I.Mech.E.*)

From one ton (American, 2,000 lbs.) of bituminous coal, the Colorado Fuel and Iron Company of Denver, U.S.A., obtains in actual practice the following products, viz.:

Coke	1,400 lbs.	Pure benzol	1¼ gals.
Coke breeze	60 lbs.	Toluol	½ gal.
Gas	7,500 cu. ft.	Zylol	2/10 gal.
Ammonium sulphate	25 lbs.	Pitch	5 lbs.
Tar	10 gals.	Naphthalene	¼ lb.
Light oil	3½ gals.	Creosote	1 qt.
Motor benzol	2½ gals.	Paint	1 qt.

[Annual capacity of ovens, 540,000 tons (American) coke.]

Coke as a Boiler Fuel.

(*Contributed by E. W. L. Nicol, M.I.Mar.E., A.M.I.E.E.*)

With a view to cheapening the cost of steam raising by improving steam-boiler efficiency and to eliminate the emission of visible smoke, gas coke is now largely used as fuel in lieu of crude coal. In hand-fired boilers, coke exclusively is used under ordinary natural draught conditions. With a draught of 0·25 in. W.G. over the fire, the average rate of combustion is 12 lbs. to 14 lbs. of suitably graded coke per sq. ft. of grate area per hour. Some form of impelled draught is necessary if this rate is insufficient. The forced draught apparatus usually employed is some form of steam-jet blower applied to the enclosed ashpit of the boiler, and used to maintain 'balanced' draught over the fire (fig. 5). The steam consumption of the jets should not exceed 3 per cent. of the total steam generated when burning graded coke at a rate of 20 lbs. per grate-foot-hour. For hand-fired boilers the minimum allowance of grate area should be 1 sq. ft. per 22 to 25 lbs. of coke consumed per hour. In practice it is found that this rate can be exceeded only at the expense of efficiency.

Unlike coal, the combustion of coke is practically completed on the grate, a supply of secondary air over the fire being unnecessary. This tends to localise the heating effect to the boiler furnace area. The introduction of a circulator, *b*, tends to neutralise this effect and set up active circulation of the water in the boiler. The operation of cleaning fires, and the losses incidental thereto, due to inrush of cold air and consequent loss of steam pressure, are minimised by the use of the Gallagher Crompton baffle bridge *a*, also shown in the figure. During the cleaning operation the live fuel is heaped up on the baffle bridge.

In mechanically-stoked boilers fitted with both forced and induced draught, average rates of combustion exceeding 40 lbs. of graded coke per grate-foot-hour are maintained. Types of

mechanical stokers specially adapted for use with coke or coke breeze include the 'Underfeed travelling grate' and the 'Babcock balanced draught chain grate.' Existing chain grate

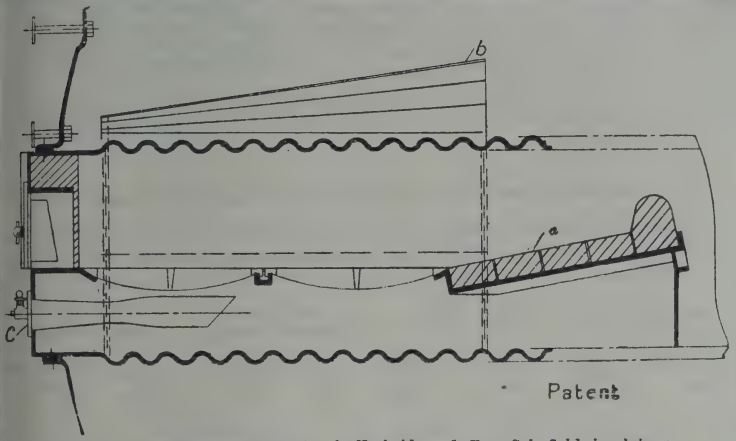

FIG. 5.—*a*, Gallagher Crompton baffle bridge: *b*, Ross Schofield circulator; *c*, Steam Jet forced draught.

mechanical stokers have largely been adapted to use admixtures of coke or breeze up to 75 per cent. at full normal rates under ordinary natural draught conditions, by means of the patent 'Sandwich' system (fig. 6), which is designed to feed, from a double hopper, well-defined layers

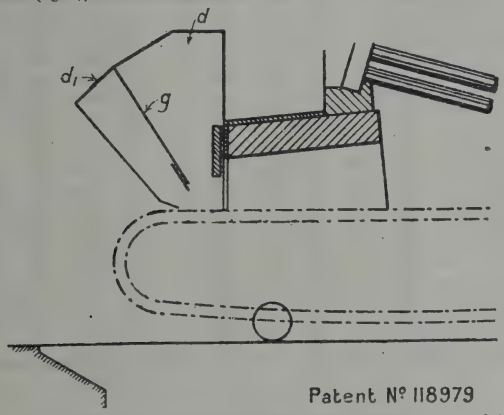

FIG. 6.—Sandwich System as applied to Chain-grate Stoker. d_1, coal hopper; *d*, coke hopper; *g*, separating diaphragm.

of coal slack and suitably graded coke of any desired thickness, the coal being uppermost. Using this system at the L.C.C. Greenwich Power Station, the General Manager gives the following data relating to the year 1919–1920:—

Tons of fuel burnt	176,400	Average percentage of ash	10·0
Average price for coal	41*s.* 11·3*d.*	calorific value of breeze	9,000 B.Th.U.
,, calorific value	10,780 B.Th.U.	,, percentage of ash	18 to 20
,, percentage of ash	14·59	Coke and breeze consumed	25,000 tons
,, calorific value of coke	11,500 B.Th.U.		

With coal at 42*s.* per ton, and coke breeze at 22*s.* 6*d.* per ton, the fuel cost per 1,000 gallons evaporated was 19*s.* 6*d.* with equal quantities of each fuel, as against 23*s.* 2*d.* with Scotch nuts alone, a saving of about 16 per cent. The official report says. 'Apart from the saving in money, low grade classes of fuel can be dealt with on the Sandwich system at a much higher efficiency than would be the case if burnt separately. The results have been extremely satisfactory and a saving of about £8,000 a year can be effected.' Average evaporation obtained with 50 per cent. mixture of coal and breeze, 7·25 lbs.; with coal and coke 9 lbs. from and at 212° Fahr. Gas coke is also used extensively as fuel for road transport vehicles of both the under-type ('Scotinel,' 'Leyland,' and 'Atkinson') and the over-type wagon ('Foden' and 'Garrett,' etc.). The following table shows the fuel cost of evaporation from and at 212° Fahr. with common solid fuels at varying prices:—

APPROXIMATE FUEL COST OF EVAPORATION FROM AND AT 212° FAHR.

Anthracite.

(*Contributed by A. Leonard Summers, Author of 'The Anthracite Industry,' &c.*)

The bulk of the anthracite produced in Great Britain is mined in the western portion of the South Wales coalfield, the best qualities in Carmarthenshire and Glamorganshire. It consists virtually of carbon—as much as 94 per cent. in the better qualities—with only a small proportion of the constituents of bitumen. It is jet-black, with a metallic lustre, very hard, slow burning, absolutely smokeless, gives intense heat, and burns with a bright red glow. These qualities fit it for many purposes. It is used largely for smelting; in the burning of lime and brick; for the generation of steam; and in the United States and on the Continent of Europe extensively for domestic heating and cooking. For malting and horticultural purposes, owing to its purity and

reedom from arsenic, etc., it is in immense demand; while in Norway, Sweden, and Italy, Welsh nthracite is used for making carbide of calcium.

The American coalfield (Pennsylvania) produces the largest amount of anthracite—about 00 million tons per annum—the Welsh output being only about 5,000,000 tons a year at present, hough capable of a much greater yield, the major part of the field being still untouched.

One ton of anthracite used in a pressure or suction-gas plant will give power equal to 10 tons f the best steam coal used under boilers. Some typical figures for a suction-gas plant using nthracite were produced by a test carried out at the Metropolitan Reservoirs, Chingford, under he direction of their chief engineer. A guarantee had been given that the consumption would not xceed 1·1 lb. of anthracite per actual b.h.p. hour, and in the report it was stated that the average uel consumption for the four main pumps was 0·913 lb. per b.h.p. hour, whilst the small pump ave the figure of 0·8 lb. of anthracite. The general average for the whole of the pumps was ·904 lb. of anthracite per actual b.h.p. hour, and the guarantee lift of the pumps was exceeded by lmost 20 per cent. The producer tests showed that 1 lb. of anthracite yields 82·1 cu. ft. of as at standard temperature and pressure, the net calorific value being 146·3 B.Th.U. per cu. ft., iving a yield of 12,011 B.Th.U. per lb. of anthracite. The calorific value of the anthracite upplied was 14,600 B.Th.U. The fuel used under the boilers which supplied steam for the roducer was taken into account.

A ton of Welsh anthracite will produce from 170,000 to 220,000 cu. ft. of gas for power urposes. The following is a typical analysis of good Welsh anthracite:

Carbon	92·73 per cent.
Hydrogen	3·37 ,,
Oxygen and nitrogen	2·69 ,,
Sulphur	0·45 ,,
Ash	0·76 ,,
	100·00 ,,

In furnace installations where crude gas can be used bituminous fuels are generally used, as he gas is supplied direct to the furnace along with the tar and soot. In small furnaces, where mall burners are used, or where necessary to convey gas a long distance, it is generally not possible o use crude gas, and anthracite is more convenient than bituminous coal. The average consumption in a pressure gas-producer is about 13 lbs. of anthracite per 1,000 cu. ft. of gas, and at normal prices this would work out between 2*d.* and 3*d.* per 1,000 cu. ft. of gas, and the overall consumption for producer and engine should be about 1 lb. of anthracite per b.h.p. hour.

The principal anthracite collieries are equipped with electrical and other machinery, the preparation of the coal being very elaborate—breaking, screening, washing, etc. A revolving breaker deals with the large coal; this coal travels to the various 'screens' for sizing. These sizing screens are placed one above another at an angle and worked on a shaking principle. Thus he coal is kept steadily on the move to obviate congestion. The large collieries break and screen heir product into at least eleven different sizes. The screens are perforated with round holes, through or over which the coal passes in sizes from 2½ ins. by 4 ins. (the largest cobbles) to ⅛ in. by ¼ in. 'grains'). Similar moving belts, but not perforated, convey the screened coal to the pickers, who remove by hand whatever shale it may contain. Impurities are picked from the cobbles nd large coal prior to the coal going to the breaker. These picking belts also load the coal into he railway trucks, but only convey the larger sizes, viz. machine-made cobbles and machine-made French' nuts. Sizes below the French nut cannot be conveniently picked and sorted by hand, nd are therefore transferred to a washer. The 'washery' belts work with the same shaking novement, carrying the small coals, such as stove nuts, peas, beans, pea-nuts, etc., through tanks f water to remove the small particles of stone. To ensure the maintenance of a maximum tandard of quality, a coal examiner usually twice daily takes and tests samples of coal from the screens and washery, and the percentage of waste material detected rarely exceeds 1 per cent.

What is known in the trade as 'rubbly culm' is the rough small coal which passes between ongitudinal bars 1¼ in. apart. It is used principally for lime-burning and steam-raising.

The 'duff,' or very fine, small anthracite, is used in the manufacture of patent fuel and cement making.

In regard to ordinary boiler furnace utilisation of anthracite not much advance has been made, due to the narrow conception of boiler-house practice, coupled with the question of availability. When anthracite is used for this purpose it must not be disturbed, and should be stoked with a

thin bed, very evenly, and if this minimum attention is given an evaporation of from 8–10 lbs. water per hour can be easily maintained. Tests made in London in which anthracite peas we used showed an evaporation of 12·2 lbs. of water per lb. of coal in one test, and 11·3 lbs. in anothe Sometimes the draught or other conditions render the use of anthracite alone impossible, but i blending with other fuels gives very satisfactory results. Where mechanical stoking is used larger proportion of anthracite—say 2 to 1—can be used, as distinct from equal quantities whe hand-firing is adopted.

An important aspect of anthracite has been the recent utilisation of the large accumulations duff and washery refuse. Hitherto, anthracite dust could not be satisfactorily burnt on standa furnaces, and considering that this fuel has a calorific value of 12,000 to 13,000, with over 80 p cent. fixed carbon, and about 10 to 12 per cent. of ash, it was obvious that valuable material w lying dormant in the dumps. Therefore a new furnace was introduced, with air spaces su divided into a large number of small holes, and other modifications. The following results of tes at a Welsh colliery show the great increase made in evaporation :

Test No.	Class of Fuel.	Evaporation in Lbs. Steam per Hour.	Remarks.
1	Duff, good quality	3,500	Jet pressure 60 lbs.
2	'Grains'	4,400	,, ,, 30 ,,
3	Duff	3 125	,, ,, 45 ,,
4	Duff	3,000	,, ,, 25–30 ,,
5	'Grains'	5,750	,, ,, 30 ,,
6	Duff	4,250	,, ,, 40–50 ,,
7	Duff	4,875	,, ,, 55–85 ,,

The first four tests were carried out on the old type, and tests 5, 6, and 7 on the newly design bar-furnace.

Burnt under proper conditions, there is no better coal for steam-raising than Welsh anthracit At one works using English coal it was necessary to employ two Lancashire boilers 30 ft. l 7 ft. 6 in., but after a patent furnace was fitted and anthracite coal introduced, *one* of the boilers was sufficient to do the work previously done by the two boilers.

Below are the standard sizes of Welsh anthracite :—

Cobbles	$2\frac{1}{2}'' \times 4''$	'Beans'	$\frac{1}{2}'' \times \frac{3}{4}''$
'French' Nuts	$1\frac{3}{4}'' \times 2\frac{1}{2}''$	'Peas'	$\frac{1}{4}'' \times \frac{5}{8}''$
Stove nuts	$1'' \times 1\frac{3}{4}''$	'Grains'	$\frac{1}{8}'' \times \frac{1}{4}''$
'Pea-nuts'	$\frac{1}{2}'' \times 1\frac{1}{4}''$		

Lignite.

The composition of lignite, and its properties, lie between those of wood and coal.

Lignite occurs in most European countries and is abundantly found in the Colonies, but doe not occur in quantities in the British Isles. Lignites vary widely in composition, but generall between the following limits : carbon 55 to 80 per cent., hydrogen 5 to 7 per cent., oxygen 10 t 35 per cent. (in the dry state). The calorific value is from 9,000 to 13,000 B.Th.U. on dry sampl The high ash and water contents of lignite frequently make it unsuitable for direct combustio but good grades may be used for steam raising. Lignite is frequently subjected to destructiv distillation, whereby valuable liquid products are obtained. It may also be used for the manu facture of fuel briquettes, or be utilised in gas producers.

Peat.

Large deposits of peat occur within the British Isles, but little use has been made of the hitherto, the high water content (80 to 96 per cent. when in bog, and 30 to 60 per cent. after a drying) being a great drawback to their utilisation. Peat is suitable for use in gas producer and is sometimes carbonised, when peat charcoal is the main fuel product.

Anderson and Dillner (*Jour. Soc. Chem. Ind.*, 1902, 459) give the following calorific powers for peat (in the dry state) :—

Average from bog	8,100 to 11,000* B.Th.U.
Reed grass peat	7,450 to 9,820 ,,
Mud peat	7,825 to 8,200 ,,

Wood.

When freshly cut, wood contains up to 50 per cent. of water, but this can be reduced to about 20 per cent. by air drying. The composition of dry wood is about 49·5 per cent. carbon, 6 per cent. hydrogen, 44 per cent. oxygen, and ·5 per cent. ash, and the heat value is generally a little below 9,000 B.Th.U. It only finds use in countries where large forests exist and where coal is not readily obtainable.

Wood Charcoal.

Wood charcoal consists mainly of carbon and possesses a calorific value of 11,000 to 13,500 B.Th.U. (Brame). Its use as a fuel is very limited.

Briquette Fuel.

(*Contributed by Arthur Grounds, B.Sc., A.I.C., Assoc. M.I.Min.E., Consulting Chemist.*)

Briquettes can be used on hand-fired boilers, without the necessity of installing special stokers to deal with the fuel. The composition of the fuel can be varied from an anthracitic fuel, suitable for consumption in domestic grates, and giving a high degree of radiant heat, to a briquette of higher volatile matter, suitable for industrial boiler firing, and giving the long flame necessary for the heating of Lancashire, Cornish, and water-tube boilers. The shape, size, and weight of the briquettes must be suitable for the purpose for which they are to be used, and for the nature and duration of the transport and storage to which they will be subjected. Their degree of cohesion should be at least equal to that of good coal, and the loss by attrition and crumbling during ordinary handling and transport should not exceed 5 per cent. by weight. Their mean specific gravity should not be below 1·24, whilst the ash content of the dry fuel should not exceed 12 per cent., and is preferably below 10 per cent. They should not contain over 5 per cent. of moisture, nor should they absorb water, whilst they should not be affected in physical character by immersion in water over a long period. Their calorific value should be at least equal to that of good coal.

Artificial fuel is made in many sizes and shapes, from the 'boulet' of 30–40 grms. weight (1–1½ ozs.) to the large block of 28 lbs. weight. The latter block is chiefly made for export to the West Indies and Egypt, and to other tropical and sub-tropical countries, as a weight of 28 lbs. corresponds roughly to that which a native labourer or coolie can carry. Between these two sizes of fuel there are the normal ovoid, about the size of a hen's egg, weighing 70–100 grms., and the larger ovoid of 200–250 grms., which has lately been developed. These ovoids are chiefly used for domestic fuel, and are largely anthracitic, whilst for steam raising the block form is most popular, the common size being the 10-lb. block, measuring 10 ins. by 5 ins. by 4 ins. Ovoid fuel has lately been made in the 'boulet' size for use in suction gas producers, and for use with automatic stokers, in place of screened nuts. The blocks are made in various shapes, either as bricks with rounded corners, quadratic flattened cube shape, or grooved in order to facilitate their breaking up in the stokehold. They may be marked with the makers' name, or with some distinguishing mark, or may be quite plain.

Domestic ovoids may be made from anthracite and a binder alone, although this has the disadvantage that, as pitch is the binder generally used, when the fuel is placed on the fire, the pitch burns off very easily at first, and then the anthracite, being a non-caking coal, falls to powder in the fire, and the result is a dull, black-looking mass. To avoid this, these ovoids are generally made from a mixture of about 80 per cent. of anthracite duff, with 10 per cent. of a good coking coal and 10 per cent. of pitch.

When placed on the fire, the pitch at first burns off and the heat of combustion leads to the carbonisation of the bituminous coking coal, which cakes and acts as an agglutinant, binding the non-caking anthracite together, and this burns very slowly and gives out a large amount of radiant heat per unit weight. This is the cheapest form of artificial fuel, as anthracite duff is the cheapest form of raw material and forms 80 per cent. of the total weight of the fuel. The binder generally used for the process is coke-oven or gas-works pitch, the grade used being known in the trade as 'medium-soft coal-tar pitch, suitable for the manufacture of briquettes.' Blast-furnace pitch is used to a certain extent, but it is inferior to coke-oven or gas-works pitch in binding power, and contains a much higher percentage of ash, and, on carbonisation, it gives

* Exceptionally high.

a swollen, instead of a sintered coke. The ash in a good pitch should not exceed 0·5 per cent whilst that in blast-furnace pitch varies from 5 per cent. to 25 per cent., or even more, according to the dust-catching arrangements at the blast-furnace from which it has been obtained. The volatile organic matter of the pitch is determined by heating 1 grm. of the pitch in a platinum or porcelain crucible over a bunsen flame for seven minutes, the flame being 18 cms. high, and the crucible being held on a triangle of fine wire, about 7 cms. above the mouth of the burner. The crucible is provided with a lid, and is weighed after heating for seven minutes, with subsequent cooling, the loss in weight giving the volatile matter. The ash can be determined by igniting the coke obtained as above until all the combustible matter has been burnt off. The residual coke from the volatile matter estimation should be in the form of a flat button. If the button is not flat, but conical in shape or puffed up, the pitch will not be suitable for the purpose. The twisting point is measured by immersing a bar of pitch, 2 ins. by $\frac{1}{4}$ in. cross section, in water at gradually increasing temperatures for a period of two minutes. The pitch is then withdrawn and a very slight pressure exerted with the fingers in the attempt to twist it round. If the pitch is still too hard, the water is heated again until it has risen in temperature another 5° C., and the pitch is again immersed for two minutes, and then tested to see if it will twist. When this is possible, the temperature of the water is taken, and this temperature is known as the 'twisting point.'

A suitable pitch for briquette manufacture should have a twisting point of 50–60° C. The melting point is determined by immersing a cube of pitch, of $\frac{3}{4}$-in. side, stuck on a No. 12 copper wire, bent horizontally, in a beaker of water. The water is gradually heated so that a rise in temperature of 5° C. or 9° F. per minute is obtained. When the cube of pitch softens and drops to the bottom of the beaker, the temperature is noted, and this is taken as the melting point. For a coke-oven or gas-works pitch of suitable quality, the melting point is usually about 85°–100° C.

The solubility in carbon disulphide is determined by weighing out 0·5 grm. of the pitch into a flask and adding 200 c.c. of carbon disulphide. The flask is heated on a water bath or an electric heater, under a reflux condenser, for an hour, and is then removed and cooled. The free carbon is filtered off through two filter papers, and is well washed with carbon disulphide, the washings being added to the filtrate. The carbon disulphide is then distilled off from the filtrate, which has been caught in a weighed flask, when the increase in weight of the flask gives the amount of matter soluble in carbon disulphide. This figure is a useful indication of the binding power of the pitch, as those pitches which give high solubility figures are generally found to be excellent binders. This figure should be in the region of 66–84 per cent. The difference between the percentage of matter soluble in carbon disulphide and 100 is the 'free carbon.'

Other tests are necessary for special purposes, but those cited are the usual tests adopted. A typical analysis of a suitable pitch would be: Volatile organic matter, 70·4 per cent.; coke, 29·6 per cent.; ash, 0·3 per cent.; fixed carbon, 29·3 per cent.; soluble in carbon disulphide, 75·5 per cent.; free carbon, 24·5 per cent. Twisting point, 56·5° C.; melting point, 97·0° C.

The amount of binder necessary varies with the coals being used, but, generally speaking, it increases with the hardness of the coals being briquetted. Thus, about 10–11 per cent. is necessary for hard anthracites, about 8·5–9 per cent. for steam coals, and 6·5–8·5 per cent. for bituminous coals, according to their volatile matter content. The hardness of the coal is roughly proportional to the volatile matter content of the coal, and the more bituminous coals, with a volatile matter content of 33–40 per cent., can be briquetted fairly easily by fine grinding (97 per cent. of the material should pass a 200-mesh screen) and pressing, taking care that the air is extracted from the fine coal before pressing. The pressure necessary for the production of briquettes made in this way is about 10 tons per sq. in. The cohesion is then about equal to that of a pitch-bound briquette. The fuel is said to stand handling well and to be weather-proof. The fuel can also be made from all coals possessing a volatile matter content of 11–12 per cent. and over, but the more bituminous coals already described are the most suitable for this purpose. Anthracite cannot be briquetted in this way. The great advantage of this process is the elimination of the binder, as the cost of pitch is a very serious item in the fuel-works balance sheet. For example, at the end of 1920, the cost of pitch had risen to £12 per ton, and assuming the pitch content of fuel to be 10 per cent., the cost of *pitch alone* in 1 ton of the fuel would be £1 4*s*. In the manufacture of the usual briquettes, with pitch as a binder, creosote and anthracene oil fractions are frequently used for the purpose of obtaining the optimum binding power of the pitch. The oil is mixed with the pitch in the pug mill in which the materials are mixed thoroughly, and the oil dissolves the pitch, which then flows more evenly over the grains of coal and coats them evenly without undue waste. By this means it is possible to cut down the pitch consumption by about 10–15 per cent., a very considerable amount when cost is taken into account.

As already mentioned, anthracitic fuel would not be suitable for steam-raising, and the coals most generally used for the manufacture of fuel intended for this purpose are blends of bituminous,

anthracite, and steam coals. The following table shows the analysis of these coals, from which it will be seen that the steam coals contain more volatile matter than anthracite, whilst the bituminous coals contain still more volatile matter than the steam coals.

Fuel.	Moisture.*	On Dry Coal.			
		Volatile Organic Matter.	Coke.	Fixed Carbon.	Ash.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Anthracite . . .	0·2– 3·5	5·0–10·0	90·0–95·0	83·0–92·0	3–7
Dry steam coals . .	1·0– 4·0	10·0–13·0	87·0–90·0	80·0–85·0	5–7
True steam coals . .	2·5– 5·0	13·0–16·5	83·5–87·0	76·5–82·0	5–7
Semi-bituminous coals .	4·0– 6·0	17·0–20·0	80·0–83·0	71·0–77·0	6–9
True bituminous coking coals . . .	4·0–10·0	20·0–28·0	72·0–80·0	60·0–74·0	6–12
Caking coals . .	4·0–10·0	28·0–40·0	60·0–72·0	48·0–66·0	6–12
Lignites, or brown coals	10·0–40·0	40·0–55·0	45·0–60·0	Varies	Varies

A good mixture for the manufacture of briquettes for steam-raising would consist of 50 per cent. steam coal, 20 per cent. bituminous coal, and 20 per cent. of anthracite duff with 10 per cent. of pitch as a binder. This would give a finished fuel of approximately the following composition :—Volatile organic matter, 21·0 per cent.; coke, 79·0 per cent.; fixed carbon, 73·0 per cent.; ash, 6·0 per cent. This is assuming that clean coals had been used in its manufacture, and such coals could be produced by washing the small coals in one or other of the washers on the market, such as the Draper, Hoyle, British Baum, Notanos, or other plant.

Briquettes can easily be prepared to specification by varying the percentages of the constituent coals used for any particular purpose. Thus, if a briquette is desired for furnace or other purposes which shall give a long flame, this can be obtained by putting in an extra large percentage of bituminous coal, whilst we have seen that for domestic fuel anthracite is introduced in order to make the fuel burn slowly and to give radiant heat, instead of throwing a large number of B.Th.U.'s up the chimney in the form of volatile constituents. Resin is sometimes used as a binder, in addition to pitch, and this substance has, roughly, twice the binding power of medium soft pitch, but briquettes made with resin alone fall and soften in the fire and are therefore unsuitable.

A large number of inorganic binders have been tried with varying degrees of success, but these are objectionable on account of the fact that they introduce still more ash into the fuel than is due to the coal alone. Such materials are Portland cement, silicate of soda, lime, clay, spent tanning materials, and sulphite cellulose liquor. Coal tar has also been used, but the resultant briquette is too weak and softens in tropical countries. Various organic materials have also been tried, such as molasses and sugar residues, jelly from Irish moss, mucilage, waste starch, etc., but the only satisfactory binder seems to be pitch.

In the manufacture of blocks, the coal is generally crushed in a disintegrator of the squirrel-cage type, whilst the pitch is broken up in a pitch-cracker, falling on to a grating provided with longitudinal slots, through which revolving arms protrude, which arms carry the pitch forward and crush it against the breaker plate. The mixture of coal and pitch is sometimes subjected to a crushing either in a second disintegrator or in a mill of the Jeffrey swing-hammer, or fixed beater type, such as the Alexander Pulvergrinder, made by Messrs. Briquette Machinery Ltd., of Leeds. The coal should not be too finely ground, as a large amount of fine coal leads to the breaking down of the binding power of the pitch. The pitch, however, should be ground to as fine a degree as possible, so as to obtain the maximum spreading effect with the least possible quantity. The coal and pitch mixture is elevated into a pug, or cooking chamber, above the press, where it is thoroughly admixed, steam being blown in at the same time. Using steam at 400° F., the steam consumption for a press turning out 17–20 tons per hour of briquettes is about 2,200 lbs. Such a press absorbs about 45–50 B.H.P., and runs at 30–40 strokes per minute. The pressure necessary for briquetting steam and bituminous coal mixtures with 9–10 per cent. pitch is about 30–35 cwt. per sq. in. Ovoid fuel is made in roll presses, the fuel mixture being

* The moisture varies according to the amount of exposure to which the coal has been subjected and to the degree of humidity of the atmosphere, but the above are given as the average of a large number of results. The ash content in general increases with increase of volatile matter content.

fed between the rolls, after cooking, at a temperature just above that of the twisting point o the pitch used, *i.e.*, about 60–70° C., with a normal pitch. The ovoids are caught on a shake screen as they emerge from the press, so that all fines are removed, and are then loaded direc into either wagons or ships, provision being made for cooling, to prevent sticking of the fue and possible fusion into a solid mass.

In some of the processes recently devised for the purpose of low-temperature carbonisatior the low-temperature coke is fed direct from the retort to a press and is briquetted without th addition of any further binder.

The Smith continuous system of carbonisation, which produces 'Carbocoal,' is a combinatio of low- and high-temperature carbonisation with briquetting. The coal, sized to pass a $\frac{3}{8}$-i mesh screen, is subjected to carbonisation at 480° C., the resulting product being a friable residu called semi-carbocoal, which contains 7–10 per cent. of volatile matter. This process takes som two to three hours for completion, but is continuous. The semi-carbocoal is reground, mixed wit pitch, and briquetted. The briquettes contain about 15 per cent. volatile matter, and thes are carbonised at 1,000–1,100° C., the residue being a hard coke containing 3–4 per cent. volatil matter. The tar yield from the primary carbonisation contains the products usually obtaine from low-temperature processes, *i.e.*, paraffin bodies predominate, whilst the tar yield from th high-temperature process gives heavy oils and pitch, with an increased yield of ammoniur sulphate. The gas yield from the first stage is 5,000–6,700 cub. ft. per ton, with a calorifi value of 650–700 B.Th.U.'s. per cub. ft. whilst from the second stage there are obtained 4,48 cub. ft. of gas of calorific value 350–400 B.Th.U.'s. per cub. ft. The average yield is therefor about 10,630 cub. ft. of gas of calorific value 584 B.Th.U.'s per cub. ft.

Other processes merely briquette the low-temperature coke whilst hot, and either recarbonis at high temperature or sell the product as a smokeless fuel for domestic purposes.

A great amount of work has been done of late in Canada by the Lignite Utilisation Boar on the briquetting of lignite. The Souris lignites are of very low grade in the raw state, bu by carbonising at 600° C. a residue is obtained which resembles charcoal and which produce an excellent briquette on binding with pitch and pressing in a roll press. The size of the lignit used is under 1/10-in. mesh, 60 per cent. of the material sizing between 1/10 and 1/20-in. mesh The binders used are coal-tar and petroleum pitches, with sulphite liquor and various wast flour residues as subsidiary bodies. The quantity of binder required, however, is much high than that which is necessary for the production of ovoids from anthracite fines, and this woul seem to be a critical factor where the cost of pitch is high. It was found that 13 per cent. c coal-tar pitch was necessary to produce a sound fuel.

The strength of fuel is generally measured in an empirical way by the 'cohesion test.' Thi is carried out by revolving 100 lbs. of the fuel in a horizontal cylindrical drum, 3 ft. long an 2 ft. 6 ins. diameter, provided with three internal ribs of angle iron 6 ins. deep, for two and a ha minutes at 28 revolutions per minute. The fuel is sawn out of the solid block into pieces 1 lb in weight, and after the test is completed the residue in the drum is screened over a sieve c $1\frac{1}{2}$-in. mesh, and the portion remaining on the sieve is weighed. This weight, in lbs., is calle the 'cohesion' value of the fuel. The revolution of the drum is supposed to represent th rolling of the ship, the attrition in the drum corresponding to the attrition in the ship due t projecting girders, baulks, etc. The cohesion value should not be less than 55 per cent., and good fuel will often average over a long period 72–82 per cent.

The chemical tests on fuel are the same as are carried out on coal, and these will be foun in any book on the evaluation of coal, such as 'Fuel,' by Coste and Andrews, or 'The Analysi of Coal and its By-Products,' by S. R. Illingworth.

Firebars.

The following proportions are for the usual cast-iron bars :—

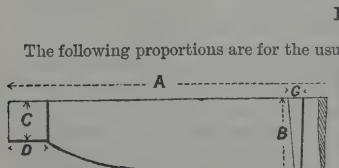

FIG. 7.

A.		B.	C.	D.	E.	F.	G.	H.
Ft.	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.
2	0	$3\frac{1}{4}$	1⅝	$1\frac{3}{4}$	$1\frac{1}{4}$	$\frac{3}{4}$	$\frac{3}{8}$	$\frac{3}{8}$
2	6	$3\frac{1}{2}$	$1\frac{3}{4}$	$1\frac{3}{4}$	$1\frac{1}{4}$	$\frac{3}{4}$	$\frac{3}{8}$	$\frac{3}{8}$
3	0	$3\frac{1}{2}$	$1\frac{3}{4}$	2	$1\frac{1}{2}$	$\frac{3}{4}$	$\frac{3}{8}$	$\frac{3}{8}$
3	6	$3\frac{3}{4}$	2	2	$1\frac{3}{4}$	$\frac{7}{8}$	$\frac{3}{8}$	$\frac{3}{8}$
4	0	$4\frac{1}{4}$	2	$2\frac{1}{4}$	$1\frac{5}{8}$	$\frac{7}{8}$	$\frac{3}{8}$	$\frac{3}{8}$
4	3	$4\frac{3}{4}$	2	$2\frac{1}{4}$	$1\frac{5}{8}$	$\frac{7}{8}$	$\frac{3}{8}$	$\frac{3}{8}$
4	6	5	$2\frac{1}{4}$	$2\frac{1}{4}$	$1\frac{5}{8}$	1	$\frac{3}{4}$	$\frac{3}{8}$
4	9	$5\frac{1}{4}$	$2\frac{1}{4}$	$2\frac{1}{2}$	$1\frac{5}{8}$	1	$\frac{7}{8}$	$\frac{3}{8}$
5	0	$5\frac{1}{4}$	$2\frac{1}{4}$	$2\frac{1}{2}$	$1\frac{3}{4}$	$1\frac{1}{8}$	$\frac{7}{8}$	$\frac{3}{8}$

Firebars require to be suited to the fuel. Clean riddled coal-nuts or cobbles may be burne on a $\frac{1}{4}$-in. bar with $\frac{1}{4}$ in. to $\frac{1}{2}$ in. spaces, but slack coal requires wider bars and narrow spaces Bars are often made with projecting fingers or corrugations in plan, thus increasing the lengt of air space considerably, though reducing it in respect of the increased width of the bar body

uch bars are made to rock for the purpose of shaking the ashes out of the fire and of breaking p clinker. Air, to supply a secondary demand behind the bridge for the combustion of the ases, is often admitted through hollow bars which heat the air and keep themselves cooler ereby, and under suitable conditions good results may be obtained.

Some firegrates are built up of short bars or links pinned together to form a side travelling and or chain ; such grates are self-cleaning and are much used in mechanical stokers, and are ood, if provided with suitable air control damper plates below. Other firegrates have a some- hat steeply inclined surface, and may be built up either of longitudinal bars or of transverse ars, in which latter case they form the so-called ' step ' grate. Such grates may have a creeping r a shaking movement of the bars in order to assist gravity to lower the burning fuel down ill to make up at the foot of the slope the vacant space left as the fuel burns away. The fuel ; mechanically fed in, above, or at the head of the sloping grate surface, and gradually descends nder the combined influence of gravity and the moving bars. A dumping device is often dded at the foot of the slope by means of which the ash and refuse may be cleared from the rnace by movement of a lever.

Grates for anthracite coal, which develops an intense heat in the fire—not sending off much as by the heat-absorbing process of distillation—are often made in the form of flat plates with number of perforated nipples or little mounds raised half an inch above the general surface. he space between the air mounds fills level with dust and preserves the iron surface from heat nd checks the adherence of clinker.

Firegrate bearers must never be rested upon the actual plates of furnace tubes of internally red boilers, but must rest on angle bracket pieces riveted to the plates by not less than two ivets each. For convenience in handling it is usual to employ two or three bars in the length f a 6-ft. grate.

Hollow bars are necessarily (or more conveniently) made in one length : this, however, makes hem cumbersome, and is one cause of their being sometimes unpopular, for they are heavy to emove and replace when cleaning ; but where conditions are favourable, hollow bars with utlets to the surface and a steam-impelled supply of air through the bars will beget economy, y enabling a cheaper grade of fuel to be employed.

Coal Combustion and Smoke.

Bituminous coal cannot be burned smokelessly except under certain proper conditions. hese are that the whole of the products of combustion must be allowed to travel over the full ength of the fire towards the bridge ; that additional air must be admitted in fine streams above he fire after each fresh charge of fuel. The fresh air thus admitted mingles with the gases from he fuel, and the mixture must be hot enough to burn at the bridge, beyond which point there ust be a clear space in which combustion may complete itself. The combustion chamber may vith advantage be wholly or partially brick-lined. The draught necessary should be not less han 30 ft. per sec. To compel air to enter over the fire, dampers are sometimes fitted to the sh pits.

The most satisfactory results in coal combustion are obtained with the thickest possible fires, ut the thickness of a fire depends on the draught and on the size of the fuel. The largest fuel vill bear the thickest fire and the strongest draught. The three factors are interdependent.

The combustion space should be at least in a good red heat so as to ensure burning all the ombustible into carbon dioxide and water, which would give smokeless operation. Although bout 14 lbs. of air is required to burn one pound of soft coal completely, only half this amount hould be admitted through the grate; the remainder should be supplied over the fuel bed. If his can be well preheated, smokeless combustion is practically assured.

Leaving the door open a short interval after feeding fresh coal, supplies an extra quantity f this secondary air when most needed. Poor draft always causes smoke and lowered efficiency. mple combustion space, involving high settings on boilers, is required with such fuels as Indiana ituminous, pulverised coal, or oil.

There are two general ways of firing bituminous coal. One is to place a thick bed of coal on he front grates. Here it will coke, and the gases given off will pass over incandescent fuel and e consumed, the coked fuel then being pushed over the remaining grate area. This is well dapted to return tubular boilers.

The second method is that of spreading the new coal evenly over the grate in small quantities t a time through alternate doors. One-half of the fuel bed is kept incandescent. A uniform size f coal, neither coarse nor fine, gives best results. High-volatile coals require a bed of four to six nches, and those with less volatile somewhat thicker beds.

Where gases rise directly upwards from a grate amongst water tubes without the admixture by travel pointed out above, smoke is inevitable.

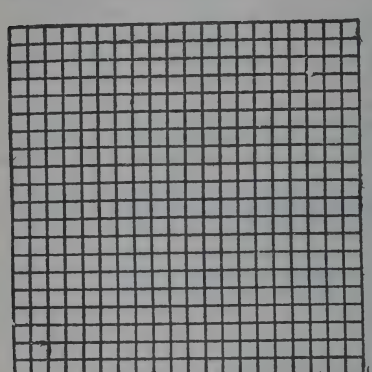
Fine dust fuel can now be burned at the rate of 40 lbs. per sq. ft. of furnace area per hour. Given furnace room, the cheapest fuel is usually the most economical. In practice the best economy is that due to the use of the cheapest fuel which can be employed to raise the steam necessary.

The foregoing, of course, is qualified by the amount of ash in the coal where the extreme of removal is great.

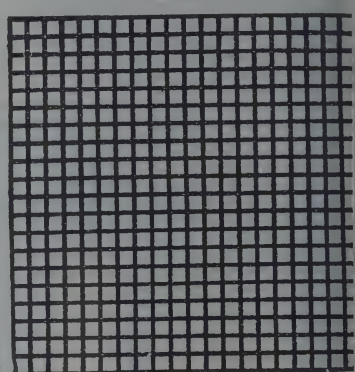
With externally fired boilers which permit of a liberal design of furnace with suitably disposed firebrick, smoke can readily be prevented. It is less easy to secure perfect combustion with

internally fired boilers, because of the difficulty of applying durable firebrick linings. But t question of smoke prevention is wholly one of air mixture and temperature. The burni gases must not too soon be brought into contact with cold plates or tubes.

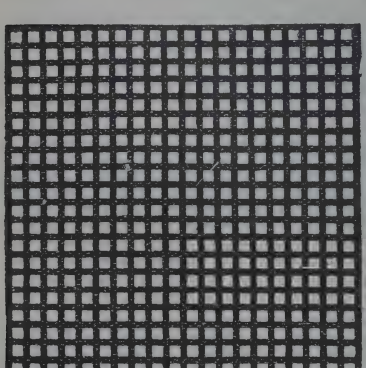
In burning bituminous coal only a part of the total heat is generated at the grate. Part of t heat of the fuel is absorbed in driving off the volatile parts of the coal in gaseous form. This he becomes latent and very materially reduces the furnace temperature. The gases pass off, contai ing a third of the total heat capacity of the coal, as well as the heat of gasification. Unless mix



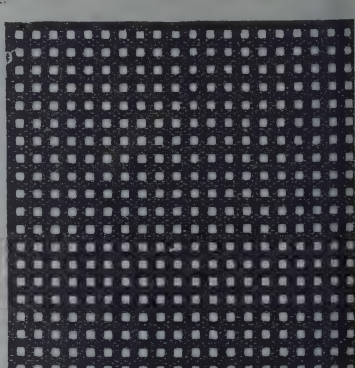
2. Light grey smoke.



3. Darker grey smoke.



4. Very dark grey smoke.



5. Black smoke.

FIG. 8.

with air and burned later, these gases may be totally lost. To burn bituminous coal not onl demands thorough air mixture, but also a sufficient temperature, and the heat of the burnin gases must not be abstracted by too early bringing them into contact with the cool surfaces the boiler. Sufficient length and clear space must be afforded for combustion to complete itsel or black smoke will be formed. The furnace arrangements of the Lancashire boiler are correct form, but the water-cooled plates are a hindrance to certain combustion in the case of hand-firing when high temperature mechanical-stoker conditions are obtained, however, it is much easi to prevent smoke with bituminous coal in a Lancashire boiler than it is in a water-tube boiler.

Water-tube boilers require a special setting to enable them to burn coal smokelessly. No furnace a be smokeless where the gases from the fire rise vertically and pass amongst cold-water tubes. uminous fuel can rarely be burned satisfactorily unless there is some extent of firebrick lining protect the gases from too early chilling. Cross water-pipes in the inner flues of the Lancare or Cornish boiler are bad, and will seriously hinder perfect combustion and produce black oke.

Colour of Smoke.

The colour of smoke is best indicated by Ringelmann's smoke charts, which are numbered from . 1, all white, to No. 6, all black. In fig. 8 intermediate sizes 2, 3, 4, 5, are shown, the lo of line to space breadth being respectively, 10 : 90 ; 23 : 77 ; 37 : 63 : and 55 : 45. Large arts drawn to these proportions and hung about 50 feet from the observer where the chimney) can be seen simultaneously, if possible, are very great aids in correctly estimating the relative okness of smoke.

The four scales of the figure are called light grey, darker grey, very dark grey, and black, extreme all white or all black being respectively no smoke or dense black.

MECHANICAL STOKERS.

Mechanical stokers are of two types, coking and sprinkling. In coking stokers the combustion the volatile hydrocarbons contained in the fuel is effected at a different portion of the grate rface from the combustion of the fixed carbon or coke. Sometimes an independent air supply provided for the combustion of each portion of the fuel. In coking stokers the fuel is ually fed on to the front of a moving grate, the volatile portion being expelled and burnt ar the front, while the fixed portion is burnt whilst being conveyed towards the back of the e by the movement of the grate surface. The incombustible portion of the fuel (ash) is opped into a chamber behind the grate. The movement of the grate surface may be reciproting, or it may be a continuous movement backwards. The 'Underfeed' class of grate also longs to the coking type. In this class the fuel is forced onwards and upwards in a central ough by a helix conveyor or ram ; it rises along the whole length of the trough, to the ex of the grate surface which is like a flattened Λ in cross-section ; the hydrocarbons are pelled and burnt near the apex, and the coke is supposed to be burnt whilst it is conveyed ften by a rocking movement of the overlapping grate-bars) to the sides of the furnace. In rinkling stokers the fuel is thrown on to the grate surface by means of a throwing shovel or uivalent device, and almost the whole of the grate surface is utilised for the combustion of th volatile and fixed portions of the fuel. The furnace bars of this type of stoker are usually ven a reciprocating movement in order to provide for the continuous and automatic removal clinker.

The relative advantages of the two types of machine stokers depend largely on the class of fuel be burnt ; but, in general, it may be said that, if properly worked, the sprinkling type will ually generate more steam from a given boiler, and with at least equal efficiency. On the other nd, with coals containing a high percentage of volatile matter, machines of the coking type can worked smokelessly with less skill on the fireman's part than is needed by sprinkling machines.

The Babcock and Wilcox Patent Improved Mechanical Chain Grate Stoker.

The grate of this stoker (*Babcock & Wilcox, Ltd.*), as illustrated on page 1659, consists an endless chain of short interlocking cast-iron grate bars, linked together, running on gle irons and rollers, and driven by a revolving shaft and sprocket wheels at the front d of the stoker. The necessary power to drive the revolving drum is transmitted rough a link chain and sprocket wheels from a shaft arranged either overhead or underround. The starting or stopping of the stoker, or the variation of speed, is effected rough the Babcock & Wilcox patent gear box, which can be driven at varying speeds. his box forms an oil bath in which the gear runs, and also contains an efficient clutch r putting the driving gear out of action should any unusual strain arise from an obstruction the grate. Any small repair, such as replacing a link, can be carried out with the stoker in lace under the boiler ; but in case of need the whole stoker can be brought out clear of the oiler, the frames being provided with wheels running on rails placed at the sides of the ashpit. he slack of the chain can be taken up from the front end of the stoker, thus avoiding the ecessity for obtaining access to the back end for tightening the grate. The grate bars or links re of a special interlocking pattern, which allow the smallest coals to be used, and, while proiding for an ample supply of air for the combustion of the fuel, prevent the influx of cold air t the back of the grate. The coal is fed over the whole width of the grate, and the depth of the re is regulated by the adjustment of the vertically lifting fire-door.

The feed of the coal is slow, and the gas evolved from the fresh fuel as it drops on to the rate readily perfects its combustion by passing over the incandescent fuel further on. The epth of the fire being regulated by a vertically lifting fire-door, the stoker can be adjusted in

a moment to suit the class of fuel to be consumed and varying demands for steam, both by depth of the fire and the speed of the grate. Where the special requirements of the work ma it desirable, the stoker can be fitted with an arrangement of vanes for cutting off the air supp to a portion of the grate during periods of light load, thus enabling the general efficiency to kept up under all conditions of work.

Babcock & Wilcox also manufacture forced draught chain grate stokers of both the compa mental and the boxed-in type, for efficiently burning low-grade and other difficult fuels. Wh average quality coal is used forced draught is not necessary, and by simply opening the two fr ashpit doors—an operation occupying only a few minutes—the stoker can be used as an ordin natural draught plant.

Bennis Stokers.

(Ed. Bennis & Co. Ltd., Little Hulton, Bolton.)

The Bennis Sprinkler Stoker.

This apparatus, fig. 9, affords a perfectly regular output of steam under the most try conditions; its flexibility permits a rapid response to urgent demands for increased stea Minimum labour costs, low fuel bills, and smokelessness are a few of the leading advanta

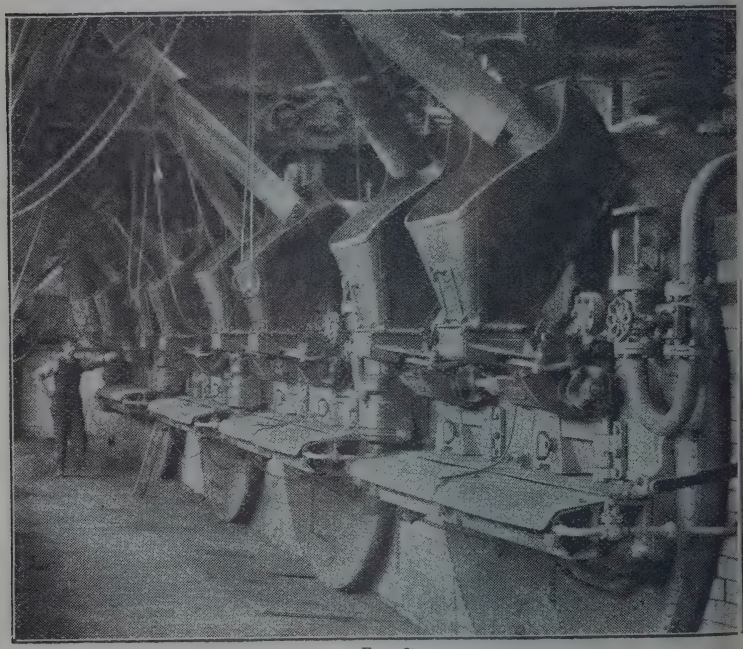


Fig. 9.

that accrue where the sprinkler stoker is in operation. The fuel fed into the hopper of t stoker—preferably mechanically fed—is led to the front of the pusher plate where it is even pushed over a ledge formed by the base of the feeding-box. The weight of fuel pushed regulated, the fuel being deposited on to a flat plate called the shovel box, and then project into the fire at intervals by an angular shovel actuated by patent pneumatic gear and effectual scattered over different portions of the grate where and as the fire requires it.

The pneumatic gear actuating the shovel, which includes an air cushion to obviate t possibility of shock or jar on the boiler front, is noiseless in operation.

An integral portion of the sprinkler stoker is the self-cleaning compressed air furnace, whi prevents clinkering, and ensures perfectly clean fire-bars.

THE BENNIS SELF-CLEANING COMPRESSED AIR FURNACE ARRANGED FOR HAND-FIRING IN COLLIERIES.

This furnace, fig. 10, thus arranged burns any class of fuel, large or small, and burns with special advantage poor quality and refuse fuels, pond settlings, coal pickings, large lumps or small, coke dust, shale, or material which contains a large percentage of ash or clinker. With such refuse it is stated to be able to generate steam as quickly as furnaces fitted with stationary bars burning a higher grade coal. The furnace consists of a strong cast-iron front lined with fire-brick, and fitted with a door of ample size for hand-firing.

THE BENNIS PATENT CHAIN GRATE STOKER.

This arrangement, fig. 11, is applicable to any water-tube boiler or to return-tube boilers—where the fire is under the boiler shell and the flame returns through the tubes—to brewers' coppers and similar furnaces. One of the principal advantages claimed for this particular chain grate is that a larger grate area can be obtained under the boiler than with those of other makes. The Bennis chain grate with the patent halved link was the first chain grate capable of satisfactorily burning fine slack coals. There are many improvements connected with this grate, in addition to the central improvement which gives to the grate its distinction.

The Bennis patent link can be easily fitted to chain grates of other makes, and many successful replacements have been carried out, with the result that considerable economies have been effected by using cheaper coal.

THE BENNIS COKING STOKER.

This stoker, fig. 12, is an improvement on the ordinary type of coker, as it ignites the fuel and cokes it at a more rapid rate than is possible with other types. It is claimed that the immediate result is a higher evaporative boiler duty and greater economical efficiency. It consists of a machine supplied with hoppers into which the fuel is fed. Beneath the hoppers are duplicate feed-boxes with reciprocating feeder rams which feed the coal into the furnace intermittently. A sight hole situated between the feed-boxes makes it easily possible to ascertain the state of the fire at any moment. The feeder rams are worked by means of levers. The rate of the coal feed is easily adjustable. Large air-cooled fire doors are provided beneath the feeder-boxes, their object being to pass cool air into the protection plates fitted immediately round the stoker front on the fireside, thereby preventing damage to the stoker front and also to the boiler.

The Illinois Patent Chain Grate Stokers.

(Vickers Boiler Co., Ltd.)

The Illinois patent Chain Grate Stokers, for forced draught, natural draught, and induced draught, are made under licence by Vickers Boiler Co., Ltd., who hold the sole manufacturing and selling rights in all countries outside the United States.

Broadly, the stoker is of two standard types, viz.:

Type 'A' for natural or induced draught, fitted with air control dampers, and

Type 'G' for forced draught fitted with cast-iron air compartments, hopper bottoms, and device for the discharge of riddlings.

These stokers are of heavy and substantial construction, the frames are of heavy section, well braced and ribbed. The side frames, which, owing to their position inside the casing, are subjected to high temperatures, are independent of the head frames which are outside the setting.

Adjustable ledge plates are arranged at the top of the stoker side frames to prevent leakage of air between these and the chain, and also to prevent the riddling of fine coal. These ledge plates are so set that the distance between them gradually increases towards the rear of the stoker to permit of expansion of the grate and prevent the possibility of the chain binding between the frames.

Drive.

The grates are driven from the front by uniformly spaced driving sprockets which engage on loose rollers on the chain rods, and not on the links or rods, thus minimising frictional loss and reducing the power required, as also the maintenance. The arrangement also ensures a uniform distribution of the driving power over the whole width of the grate.

Idler drums are used on the rear shaft.

The advantages of driving the grate from the front are :

(*a*) The links are in compression, and consequently their strength is greatly increased over that of cast iron in tension.

(*b*) The spaces between the top links are kept closed, and therefore the riddling of fine coal is prevented.

(*c*) The driving sprockets are accessible through inspection doors in the head frame.

(*Continued on p.* 2104.)

BENNIS STOKERS.

FIG. 10.—BACK VIEW OF THE BENNIS COMPRESSED AIR FURNACE.

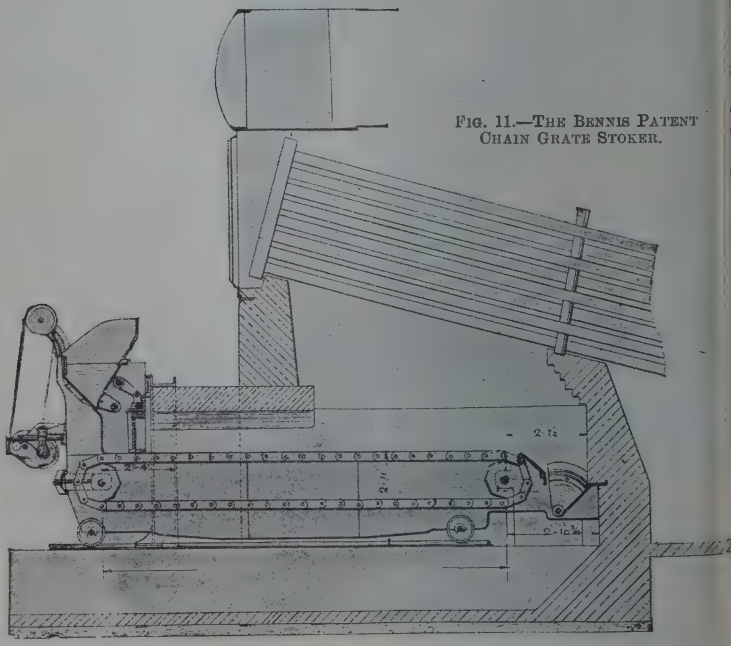

FIG. 11.—THE BENNIS PATENT CHAIN GRATE STOKER.

THE BENNIS HIGH TEMPERATURE SMOKELESS AND GRITLESS COKING STOKER.

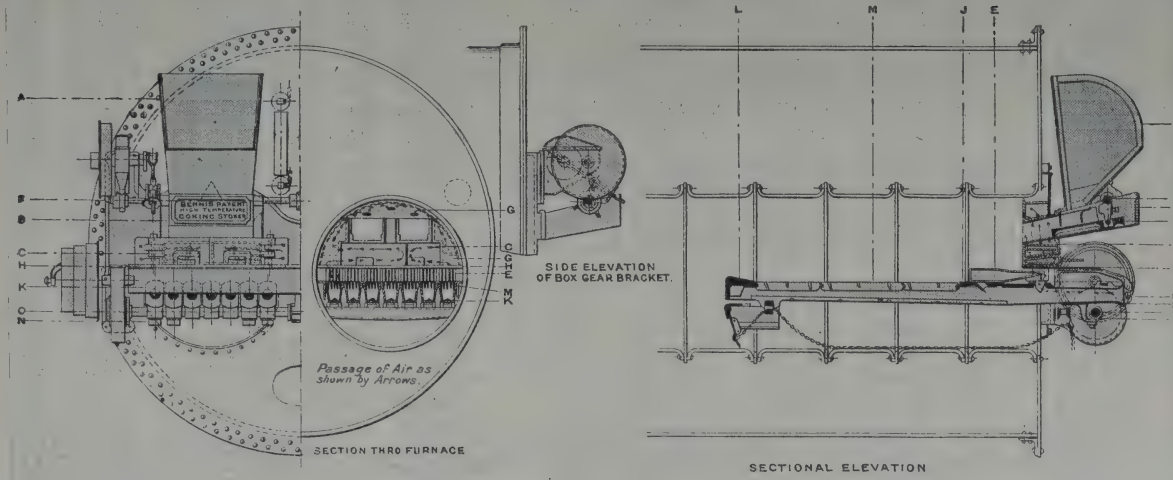

FIG. 12.

The Illinois Patent Chain Grate Stoker—*cont.*

The Grate.

The grate is composed of a number of links connected by means of twisted chain rods; tl use of these rods prevents the accumulation of dust, rust, and ashes between the rods and link with a consequent reduction in power consumption and maintenance cost.

The grate tension can be adjusted at any time while the stoker is in operation.

Special repair links are made and supplied for expeditious maintenance under runnir conditions.

Grate Support.

Chain skids are used instead of the roller construction.

The stokers are made up to 24 ft. in width in a single stoker, which necessitates the use suspended arches.

Illinois Stokers are in use in this country at the present time up to a width of 18 ft. 6 ins., ar stokers up to a width of 24 ft. are in hand.

The forced-draught stoker 'G' is of the compartment type.

The air is delivered from the main air supply duct to a wind box in the side wall extendir the full length of the grate.

Stokers of medium width are supplied with air on the one side only; the wider stokers a provided with a wind box on each side.

The whole length of the active grate surface is divided into a number of compartments. Eac compartment has its own opening into the wind box controlled by a circular plate damper. The dampers can be locked in any desired position by means of an operating lever and lock plac outside the wind box.

When the stoker has a wind box on both sides, dampers are provided on each wind box. Tl compartments are constructed of cast iron with hopper bottom and riddling discharging devic

For the burning of anthracite coal, coke breeze, lignite, or other high-moisture or low-volati fuels, mechanical ignition is provided by means of a mechanical ignition zone at the front end of tl stoker, comprising a small compartment running across the entire width of the stoker; in th compartment a suction is maintained whereby a small portion of the hot furnace gases are drav down through the incoming green coal, causing the fuel to be completely ignited for its enti depth.

The stoker throughout is of robust construction, with a view to ensuring continuity of operatio freedom from trouble, and low maintenance cost.

The Erith-Roe Stokers.

(*Erith's Engineering Co., Ltd.*)

These stokers, for water-tube boilers, figs. 13 and 14 (p. 2105), are of the inclined multiple reto underfeed type, in which the fuel is fed from the bottom of the stoker hoppers into a series of reto units, from which it gradually rises to the surface of the fuel-bed and passes down an inclined plan so that the ash and clinker finally fall into the ash hoppers in a continuous manner, witho manual labour.

A heavy fuel-bed is carried, and the *surface* of the fire is maintained in an incandescent cond tion, so that the heat radiates direct to the boiler tubes; coking arches being entirely dispens with, their cost and upkeep is eliminated.

The upkeep cost of the stoker is low, due to the metal being kept covered with the incomir fuel that has not risen into the zone of high-temperature furnace combustion.

A regulated supply of air from a fan is furnished to the air chamber below the stoker, and suitably distributed through the retort tuyeres, etc., at the requisite pressure to secure 'balanc draught' conditions. A special baffle in the air chamber (which forms the subject of an addition patent) has been found of considerable value in improving the air distribution, so that the mir mum of excess air, combined with a very high percentage of CO_2, can be maintained in regul service. Under these regulated and controlled conditions, low-grade slack and other fine coal c say, 10,000 B.Th.U.'s per lb., or less, can now be burned with a thermal efficiency nearly equal that obtainable with high-grade fuel.

The robust and simple operating mechanism of the stoker consists of a slow-moving crankshaf which is normally run at about one revolution per minute; it operates, in series, the coal-feedir rams and distributing pushers within each retort, together with the stepped slicing bars reciproca ing between each retort (which automatically slice the fires and keep them open and porous) well as the reciprocating extension grates over which the refuse passes before it finally falls in the ash hoppers at the rear.

In the Erith-Roe stoker provision is made for the immediate and *independent* adjustment the levers controlling the movement of the fuel-bed, which experience has shown to be essential f

ERITH'S Feedwater HEATERS are of the OPEN type, ensuring protection from the Oil in exhaust steam and maximum HEAT RECOVERY without any working cost.
They can be furnished with large-area Settlement and Filtration tanks, if the incoming water is dirty.

ERITH'S HEATER-SOFTENERS are furnished for BAD WATERS needing either Soda-Ash Solution and/or Lime Treatment to keep Boiler Plants FREE from damage due to SCALE.

burning the widest range of fuels to the best advantage. No alteration from the original adjustment is, however, required, unless the conditions are materially altered through the coal being changed, etc. The Erith-Roe stoker is a British invention, and is being increasingly adopted for centratation and industrial service at home and in the Colonies.

The Underfeed Stoker Co.'s Stokers.

(The Underfeed Stoker Co. Ltd.)

THE 'B' TYPE STOKER FOR LANCASHIRE BOILER.

In this stoker the fresh fuel for the maintenance of the combustion is continuously supplie from *below* the level of the fire and gradually advanced upward to the zone of combustion b the arrangement shown by fig. 15.

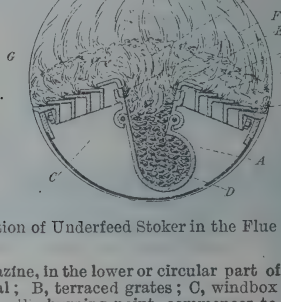

FIG. 15.—Cross-Section of Underfeed Stoker in the Flue of a Lancashire Boiler.

A is a retort or fuel magazine, in the lower or circular part of which revolves a taper-feedir worm which conveys the coal; B, terraced grates; C, windbox; and D, green coal; the latt being gradually pushed up to the burning point, commences to ignite at the point E, where meets the incoming air from the tuyeres F' and F'. Here the coal is coked, i.e. deprived of i volatile hydrocarbon gases. These being mixed with air introduced at this point through th air inlets of the fuel magazine, and escape being possible only by rising through the glowin coke above, the gases are heated to such a high temperature that they are completely consume without smoke, while the combustion of the fixed carbon of the coal is completed by the a introduced through the apertures in the sides of the terraced grates B.

The effect of this method of underfeeding is to keep a continually clear, bright surface incandescent fuel, combustion with even highly bituminous coals being complete.

THE CLASS 'A' STOKER.

In this stoker, the unit idea of construction adopted combines the impelled draugh fans and driving mechanism with the grate itself, with many resulting advantages. It will b seen from fig. 16 that the fans are mounted one on each side of the fuel hopper, with short, eas connecting air ducts leading to the air chambers of the grates. The driving motor, bolted to base plate which forms the front side of the hopper, has its armature shaft extended at each en to carry the fan wheels. This shaft runs at from 850–1,000 r.p.m., and by means of a chain the 'silent' type in conjunction with a worm and wheel, both encased in a common chamber, th speed is reduced to 9–10 r.p.m. From this mechanism a direct connection is made to the grat change-speed gear. This gear has eight different adjustments for speed, varying the travel the grate from a combustion of fuel for 8 lbs. per sq. ft. to 60 lbs. per sq. ft. of grate area.

The whole of the driving mechanism, whether high speed or low speed, runs in dust-tight, o bath chambers, and the oiling arrangements are reduced to the greatest simplicity. Some of th advantages claimed are :—The reduction of the power required to drive the complete machin comprising fans and grate, to one-third of one per cent. of the steam generated by the boiler the removal of the dust and dirt of the boiler room at the point where it is created, thus keepin a clean, well-ventilated room; the avoidance of large air-carrying ducts, and what was formerl the necessity of breaking joints with duct at such times as it was necessary to remove the stoke from the furnace.

The air pressures employed in the air chamber of the stoker vary from $\frac{1}{4}$ in. to $\frac{7}{8}$ in., dependin upon the nature of the fuel. The higher pressure is employed in such fuels as coke breeze, whic is very fine in texture and lies very closely upon the grate.

THE 'UNDERFEED' CLASS 'E' STOKER.

In this stoker, figs. 17 and 18 (*The Underfeed Stoker Co. Ltd.*), the fuel is deposited by coal-conveying machinery or hand labour, in a large hopper, and conveyed under the fire by means of a reciprocating sliding bottom which runs the full length of the trough. As the coal rises from the trough it is distributed to the sides of the furnace by means of moving bars.

The coking and burning coal is constantly carried, by the action of the moving bars, to the dumping trays along each side wall, where the resulting clinker and ash are deposited. These dumping trays are operated by levers on the outside of the furnace, enabling the ash and clinker to be automatically discharged.

The sliding bottom is actuated by a steam motor shown in fig. 17 at C, the number of strokes of which may be varied from one in three minutes to fifteen in one minute, each stroke carrying into the furnace about 6 lbs. of coal.

The movement of the piston of cylinder C is transmitted directly through the piston rod to the crosshead D, which is bolted to the sliding bottom E. This sliding bottom extends the full length of the retort. The block B has the same movement as D and E; thus the coal is fed by block B from the bottom of hopper A on to the sliding bottom E, which not only carries it to the back end of the furnace, but forces it to rise the full length of the trough. As the coal rises in the trough, or coking retort, it is flooded on to the bars F. These bars are alternately moving and fixed. The moving bars work transversely to the retort. The extent of the movement is from ¼ in. to 1 in., depending upon the size of the furnace and other conditions. On the bottom of each moving bar are cast two lugs which engage with the bulb of the longitudinal rocking bars H. These rocking bars in turn receive their movement through the agency of two spirals and nuts, which mechanism is entirely outside the furnace. The nuts are bolted to the crosshead D and therefore reciprocate with the bottom E. The reciprocation of the nuts causes the spiral to rock to and fro.

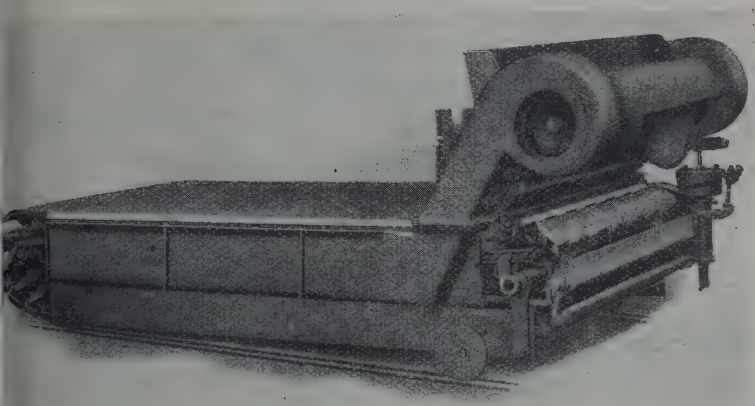

FIG. 16.

The movement of the grates, in addition to carrying the burning fuel to the sides of the furnace, also conveys the clinker down and deposits it on dump plates K, which are fastened to hinge-bar L. This hinge-bar is actuated by a lever, conveniently placed outside the furnace, to dump the accumulation of ash and clinker into the ash-pit.

One of the important features of this stoker is the distribution of the air, which enters the stoker through the aperture N, controlled by the wind gate O. This wind gate is adjusted by the crank P. The air, upon entering the wind box Q, passes upward along each side of the trough, or retort, and is discharged, partly through the holes R, into the retort. The remaining air passes through the bars F, which are made hollow. These bars have no openings in their top surfaces, and no air can find its way into the fire above until it has passed through the aperture S at the bottom end of the bar, from which aperture it is discharged into the enclosed air

hambers T. From here the air rises and passes through the small spaces between the bars into he coked fuel. The action of the air in passing through the bars keeps them cool, thus greatly rolonging their life. The heat taken off the bars in this way raises the temperature of the air n the air chambers T to from 350° F. to 400° F. The pressure of air in the chamber T varies rom zero to $\frac{3}{8}$ of an inch of water.

As the casing forming the air chambers T is sealed from the main ash-pit of the furnace here is no escape of air into the furnace when the dump plates K are dropped.

MECHANICAL DRAUGHT.

Various mechanical methods have been introduced for increasing the draught for boilers; his may be accomplished by an exhausting fan drawing the products of combustion through he flues, or by blowing air into a closed stokehold or an enclosed ashpit, and forcing the air hrough the fire with the necessary pressure, which varies according to rate of combustion esired. There is also a combination of these mechanical means, termed 'balanced draught,' in vhich air is forced under pressure into the ashpit by one fan and the gases are drawn off by n exhausting fan so arranged that there is neither pressure nor vacuum above the fire. Another nethod is the 'ejector draught' system in which the flue gases are drawn up the chimney by high speed jet of air.

The advantage of mechanical draught produced by a fan is that the first cost is less than half hat of a chimney; also the draught is independent of atmospheric conditions, can be varied nstantaneously to suit the demand for steam, permits of economisers, and allows the reduction f the temperature of the waste gases to be carried to the lowest practicable point. It increases he capacity of the boiler, and permits of a more perfect combustion with less excess of air. t allows the use of lower grade and less expensive fuel, and so produces steam more cheaply.

Any desired rate of combustion from the normal of 20 lbs., to 30 or 40 lbs. of coal per square oot of grate area, may be maintained with a mechanical draught plant. The air volume required lepends upon the style of boiler, condition of boiler setting, skilful stoking, the kind of coal used, nd other factors; in round numbers 250 to 300 cub. ft. of air will be required per lb. of coal; hese figures represent about 12 per cent. and 10 per cent. CO_2 respectively.

To drive a fan requires about $\frac{1}{2}$ to 1 per cent. of the total power generated. The full benefits f mechanical draught are only obtained where means are employed to utilise to the fullest ex- ent the heat of the flue gases (by means of superheaters or economisers) before the latter are lischarged into the chimney. The cost of installing a fan and engine is very much less than he cost of a chimney, so that mechanical draught is economical in first cost.

Fan draught enables a heated air supply to be employed, and it is said that by heating the ir supply to 180° the fire temperature will be raised an additional 360°, owing to better ombustion, etc.

The Musgrave System.

(*Musgrave & Co., Ltd., Belfast.*)

This is an induced system of mechanical draft. The action of the fan is substantially the ame as that of a chimney, the gases being drawn through the furnace and discharged up the stack; his is usually found to be a very convenient and natural method of applying mechanical draft, nvolving little or no alteration to existing boiler plant, and having a wide range of flexibility. The fact that the draft is set up by suction instead of pressure gives a more uniform flow of air hrough the fuel, thus reducing the tendency to blow holes through the fire. All leakage being nward, all danger of discharge of flame and smoke at the furnace doors is avoided. In tubular oilers better contact is obtained between the gases and tube surfaces, the tendency with forced draft being for the gases to form a contracted vein at the front end of the tubes, resulting in a onsequent loss of heat transmission.

With the induced system the fullest possible use can be made of economisers, either in the orm of feed-water or air heaters. There being no necessity to maintain a high gas temperature n the chimney to create draft, as is the case when natural draft is depended on, the whole of the vailable heat in the gases may theoretically be utilized, and the maximum economy obtained. In actual practice, however, the temperature to which the gases may efficiently be reduced is bout 300° F.; to reduce the gas temperature below this figure, the increased cost of economisers or air heaters involved, the additional draft required, and the corrosion due to the condensation of acids from the gases on the cooling surfaces, render further reduction impracticable.

To obtain flexibility and perfect control in a mechanical draft installation, an independent fan drive by steam engine or electric motor is preferable to a drive from a line shaft by means of belt or rope; the speed of the engine or motor can be immediately adjusted to suit the varying draft requirements, and in suitable cases an entirely automatic control can be utilised. The steam consumption of the engine will not exceed $1\frac{1}{2}$ or 2 per cent. as a maximum of the total steam generated, while the steam jet type of blower absorbs from 5 to 10 per cent. of this total.

The great loss of heat where chimney draft alone is depended upon puts it out of consideration altogether in modern plants.

To obtain maximum economy the design of the fan must be correctly proportioned to the required duty, so that the air supply necessary for efficient combustion may be obtained with the minimum expenditure of power under all conditions. All flues should be as short and direct as possible, avoiding all unnecessary bends, changes of section, and obstructive dampers.

Musgrave's induced draft fans are constructed both of the multiblade and straight-bladed types, depending upon the duty. The former with their higher rotational speed are more suitable for use with direct-coupled motor or turbine drive, the latter for engine drive.

Where large quantities of dust are entrained in the waste gases, the straight-bladed wheel is better, owing to its freedom from all possibility of clogging.

The casing may be either of the full or three-quarter housing type: in the latter case, the lower portion of the periphery is formed in brickwork or concrete. The shaft carrying the wheel is usually overhung, being adequately supported in two ring oiling bearings of ample size. For normal gas temperatures the bearing adjoining the fan housing is provided with a water-cooling jacket. For particularly high temperatures both bearings are jacketed, and occasionally a forced lubrication system adopted. Reliability is assured by the provision of ample bearing surfaces in engine and fan bearings, and sound scientific and mechanical design throughout.

The Sturtevant Systems.

Figs. 19 to 21 show the various systems installed by the *Sturtevant Engineering Co. Ltd., London*, which are in use in power stations, workshops, factories, warships, passenger and freight steamers, etc.

Induced Draught (fig. 19). This is the most commonly adopted system, as it is generally applicable to an existing boiler installation, and is economical in operation. The products of combustion are drawn through the flues, economisers, etc., by an exhaust fan, and discharged to an existing stack or to a short length of steel chimney built just high enough to carry the gases above surrounding buildings. The fan is fitted with water-cooled bearings.

Forced Draught (fig. 19A) is advantageous for burning small or low-grade fuel. The fan blows air under pressure into the closed ashpit, and the gases are discharged either to existing stack or short steel chimney. For ship use the closed stokehold method is generally used.

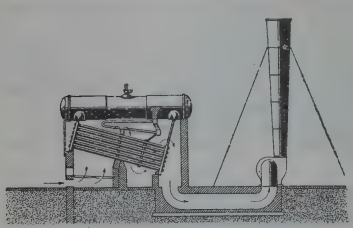

FIG. 19.

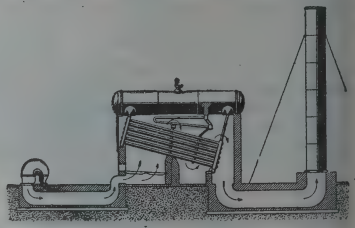

FIG. 19A.

Balanced Draught (fig. 20) is a combination of induced and forced draught. Air is forced under pressure into the closed ashpit by one fan, and the gases are drawn off by an exhausting fan so arranged that there is neither pressure nor vacuum above the fire. This is only used in special cases, owing to the cost being much higher than either fig. 18 or fig. 19.

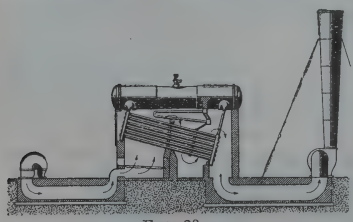

FIG. 20.

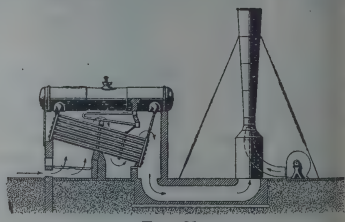

FIG. 21.

Indirect Induced Draught with Ejector (fig. 21). The combustion gases are drawn up a chimney of special design by the effect of a high speed jet of air, which if desired can be mixed with a portion of hot gases. This system is of special value in cases where the flue gases are corrosive or excessively hot, as they need not pass through the fan. This plant requires very careful designing, otherwise the efficiency is very low indeed.

The Howden Forced Draught System.

The principles on which this system of forced draught (*James Howden & Co. Ltd., Glasgow*) based are (1) the supplying under pressure of hot air for combustion in quantities suited to the ıality of coal used; and (2) the utilisation of the heat in the waste gases for the purpose of ising the temperature of the air for combustion.

Briefly stated, the following are the principal advantages of this method of combustion :—

(1) Great increase in the steaming power of the boilers. (At least 30 per cent. and probably uch more over best natural draught conditions. Probably as much as 50 per cent. could be ıtained if necessary, though quite such a high rate is not recommended for regular working.)

(2) Unequalled economy in fuel. (At least 10 per cent. and frequently 15 per cent. per lb. of ater evaporated over the best natural draught conditions and probably much more.)

(3) Reduced size and weight of boilers for a given power, giving correspondingly additional ıace available for other purposes.

(4) Complete control of combustion and steam supply under all conditions of the atmosphere. With this system of draught the volume and pressure of the air for combustion is entirely ıntrolled by the fan and the manipulation of the air valves in the furnace fronts.)

(5) Capability of burning all classes of coal and coke. Low-grade fuel can always be burned ıtisfactorily where this system of forced draught is applied. Under natural draught conditions ıis is often difficult and sometimes impossible owing to the inability of supplying the greater olume of air always required where the greater quantity of inferior fuel is used. For the reasons ıated in (4) this difficulty is surmounted, the additional quantity and pressure of air necessary ing easily obtained by running the fan a little faster.

(6) Preservation of the boilers on account of the more uniform temperature maintained in the ırnaces. Boilers fitted with the Howden system of draught are less liable to the leakage and ouble generally present under natural draught conditions; the reasons being that no cold air ver enters the furnace during the period of working, and much greater uniformity of temperature maintained than under natural draught conditions. Sudden alternations from heat to cold, and ıe consequent contraction and expansion, have an injurious effect on the internal parts of steam oilers, and such sudden fluctuations in temperature are prevented by the use of this system. Vhen the furnace doors are opened the air pressure in the ashpit immediately ceases, and only the ot air from the upper air supply valve passes into the furnace, first in a direction vertically ownwards, thereby forming a hot screen over the furnace mouth and preventing access of cold ir. Such conditions when firing or cleaning fires are also conducive to economy. The benefit of ıe system regarding fluctuations of furnace temperature is most marked and appreciated when ı is compared with the working conditions of the closed stokehold system. In the latter a con-iderable air-pressure is generally used, so that the fluctuation in temperature of furnace is both apid and violent and puts a severe strain on the boiler structure. This is quite obviated in the Howden system.

(7) Reduction of smoke.

(8) No high chimney required. For land installations a small iron funnel, sufficient to carry ff the waste gases clear of the surrounding buildings, is ample for the purpose.

(9) Coolness in boiler-room and ease of working. With this system the air casing, reservoirs, nd furnace fronts on the boiler end effectually prevent radiation into the stokehold, which is hereby kept quite cool, making the work easier than with the closed stokehold system, which is ery trying for the firemen.

(10) Great reserve power available in case of emergency.

The general arrangement of the Howden system consists of a fan (driven by a steam engine, lectric motor, or belt), which supplies the air for combustion, discharging it through a conduit nto the air-heating chambers. In these air-heating chambers the air circulates round a series of ubes. The waste gases, after leaving the boiler, and before entering the uptake, pass upward hrough these tubes in the air-heating chambers, or in the Lancashire type of boiler horizontally hrough tubes in air heaters in the side flues, thus giving up part of their heat to the air, which hen passes along passages into air-tight reservoirs or chambers surrounding the furnace fronts. From these chambers the air is passed through furnace fronts by valves into the ashpits, and over he fires through air distributing boxes in proportions exactly suited to the kind of fuel used and he rate of combustion required, thus ensuring a very perfect combustion of fuel.

In the furnace fronts the ashpit air valves are operated by one handle, and a safety locking levice is also fitted, which prevents the furnace door from being opened until the ashpit air valves ire closed. In marine type boilers, retarders are also fitted (one in each boiler tube).

Silley patent smokebox door fastenings form an important adjunct to the forced draught ıpparatus. These fastenings ensure a thoroughly air-tight smokebox and entirely obviate the rouble usually experienced with buckling, etc., in doors secured by other methods.

At the present time there are about 6,600 installations of the Howden system fitted, and the number is rapidly increasing every year. The aggregate i.h.p. of these is over 24,000,000. They comprise steamers for almost all the principal steamship companies of the world, and a consider-able number of installations on land boilers. Many warships, and the principal fast Channel steamers, are also fitted with the system.

The Howden Air Preheater.

This new type of air-preheater, manufactured by *Messrs. Howden & Co., Ltd.*, is much more efficient than the smoke-tube type. In addition to its suitability for cylindrical boilers it is also adaptable for water-tube boilers on land and sea, and other types of furnaces. By this arrangement the temperature of the waste gases is reduced by about 300° F. and this heat is returned to the furnaces when it can do useful work, thus materially increasing the efficiency of the boiler. See also p. 2384.

PULVERISED COAL.

(Contributed by L. C. Harvey, London.)

General.

Coal in pulverised form was first successfully applied to cement-burning kilns. This method of heating cement kilns has now become universal practice, the steady long flame with its resulting continuous and unvarying heat development inside the rotary kiln being ideal for this work. Moreover, the ash which has always been a source of trouble in other applications does not apply in this industry, where ash forms a useful addition to the ultimate product.

For cement burning the coal is reduced to a fineness of about 80 per cent. through a 100-mesh screen (10,000 holes to the square inch). It is essential to pulverise to a greater degree of fineness for general applications. A coarser product can be permitted when burning high volatile fuel (30 per cent. V.M. and upwards), or in the case of very large steam-raising units, as now installed in the latest super-power stations in America and elsewhere (see p. 2118), but the American standard of fineness, *i.e.* 85 per cent. through a 200-mesh screen (40,000 holes to the square inch) should be accepted for general boiler firing and for all metallurgical work.

This fine degree of coal-dust, coupled with a low pressure on the air supply, thereby decreasing the velocity of the gases passing through the furnace or boiler, and a wider adaptation of the principle of turbulent mixing of the fuel and air, resulted in the removal of the former troubles due to the formation of ash slag in chequer-work, on metal to be heated, or on boiler tubes.

Great progress continues to be made in the application of pulverised coal to metallurgical furnaces, and in a very marked degree to power-house boilers.

The extended use of pulverised fuel as a means of firing boilers and other furnaces in America continues to increase the annual tonnage of coal burned in this manner, and the estimated total consumption of pulverised coal in the United States of America is now appreciably over 30 million tons per annum.

Many important plants are now in operation in France, Belgium, Germany, and other Continental countries. Particular attention is being given to the development of pulverised fuel firing in Europe by the International Combustion Company, who have made rapid strides in the development of the 'Lopulco' system and patents, and have so equipped several power stations in Great Britain (p. 2123).

At the Tennessee Coal, Iron, and Railroad Company's works, and at the Ford Company's works in America, boilers of considerable size are installed for firing either with blast-furnace gas or with pulverised coal. The original practice of using gas and coal together has been discontinued in favour of burning one fuel or the other. It was thought at the outset that the firing of gas in conjunction with pulverised coal prevented the formation of ash clinker, but subsequent improvement in the method of firing pulverised coal has demonstrated that the best results can be obtained when using either one or the other fuel alone, excepting only when pulverised coal must be introduced at times of shortage of blast-furnace gas.

The old fallacy so frequently advanced in connection with pulverised coal firing is the 'ash nuisance' from boiler-house chimneys. Tests carried out at Milwaukee show that as little as 15 per cent., and as much as 85 per cent., of the ash in coal passes out at the chimney top under certain conditions. These conditions are controllable, and whatever may be the amount permitted to escape into the atmosphere, this dust is unlikely to become a nuisance, for it is in such fine particles that the dust rises into space, and careful tests have failed to discover any trace of ash deposit within city boundaries.

There are now some hundreds of large plants in continuous operation within city boundaries. In not one instance, to the writer's knowledge, has any complaint been forthcoming. The reverse is usually the experience—smokeless and dustless conditions in the vicinity of pulverised fuel-fired boilers, furnaces, and kilns.

Pulverised coal-fired boilers are now guaranteed to give a continuous evaporation of 13 lbs. (from and at 212° F.) of water per sq. ft. of heating surface, at a boiler and furnace efficiency of 81 to 83 per cent. and a peak load evaporation approaching 20 lbs. per sq. ft., with water-tube furnace linings in series with the boiler elements.

It is expected that the design of water-tube boilers for pulverised coal-firing will undergo considerable change. Water-tube protective linings for combustion chambers, the Murray Fin

ubes, have demonstrated new principles of steam generation. The 'Wood' boiler wherein the ain steam generation is effected in a tube-lined combustion chamber has given the first con- rmation of the exceptionally high steaming rates, due to radiant transmission of heat, which will e obtainable from these new types of boilers.

Some further progress has been made in the firing of locomotives with pulverised fuel in hile, where the 'Fuller' equipments are in use for the burning of the local lignite. The tended use of pulverised lignite as a locomotive fuel is also under consideration in Austria.

Difficulties with the deposit of ash across the tubes at the firebox end are still sufficiently rious to prevent any considerable advance in the application of pulverised fuel for locomotives nder present known systems. The pre-gasification of pulverised fuel is a new method which ay remove these defects.

The use of pulverised fuel for this purpose remains practically dormant, but the statistics elative thereto are retained pending the revival of this application. The great development of nall, high-speed pulveriser units and the turbulent mixing types of burners will undoubtedly fluence renewed attention to locomotive firing in various countries.

For the firing of marine boilers there is every reason to expect that pulverised coal will enter to competition with oil fuel. Extensive investigations carried out at the League Island Navy ard, U.S.A., with various types of pulveriser mills and burners, have clearly shown that marine oilers can be successfully fired in this manner. The self-contained unit mill is preferred for use n board ship. The development of low-temperature distillation will be of great influence. he residual fuel is ideal for marine use—soft, friable, readily pulverised, of reasonable volatile and sh content, free from spontaneous combustion tendencies, and therefore safe for storage in ships' unkers. Previously pulverised semi-coke, such as the product of the 'McEwen Runge' process). 2124), offers special advantages. Oil or coal burners, the Peabody, the Buell, etc., are equally ultable for either fuel.

Mill House Plant for Central System.

Fig. 22 shows an outline arrangement of a typical coal-pulverising plant with screen separator ill and rotary coal-fired dryer.

The coal delivered by rail wagon is crushed to $\frac{3}{4}$-in. cube and passed up the No. 1 elevator o the crushed coal storage bin.

From this bin the crushed coal is fed by gravity into the rotary dryer, wherein the moisture ontent of the coal is reduced to 1 per cent. This is a necessity for bulk pulverisation, storage, and or conveying the fuel through pipes.

Rotary coal dryers are fitted with furnaces, either hand fired, stoker fired, or arranged for urning powdered coal. The hot gases from the furnace should not pass through the dryer in irect contact with the coal until these gases have been considerably cooled. Some dryers are so lesigned that the hot gases do not pass over the coal before they have travelled the full length f the dryer through a central tube, when they are diverted into the outer portion of the dryer nd pass back to the furnace end in direct contact with the coal. For high volatile coal this type s essential.

The average coal consumption in the dryer is about 20 to 30 lbs. of coal per ton for a reduction f 10 per cent. in the moisture content. When coal is very wet it then becomes necessary to ass the coal twice through the dryer. The final temperature of the coal leaving the dryer should ot be above 250° F.

From the dryer the coal passes up No. 2 elevator to the dried coal bin, passing over a magnetic eparator pulley in order to remove any pieces of iron from the coal, and is fed by gravity into the ulveriser.

With the static dryer, which has no moving parts, a portion of the waste gases from the boilers, enerally about 10 per cent., is forced through the coal, with the result that the coal is thoroughly ried without any loss of the volatile constituents or fine dust.

The stationary type of dryer has been generally adopted for power-house installations. Initial troubles, regarding the flow of coal from the dryer and uneven or over-heating, have been eliminated.

Raw coal can be delivered to the bunker above the dryer, from whence it falls by gravity through the dryer to the pulveriser mill. Thus, the rotary dryer motor, the No. 2 elevator, and, if necessary, the dry coal bunker, shown in fig. 22, are dispensed with, and only in special cases are rotary coal-fired dryers necessary.

The application of this dryer does away with a considerable portion of conveying machinery, for handling both the raw coal and the dry coal at the same time, eliminating expensive plant and fuel used to dry coal. As much as 2 to 3 per cent. of the coal purchased is sometimes employed in drying fuel in revolving dryers, with the static dryer this coal is replaced by waste gases from the boilers. On the Continent the revolving disc, grid, or shelf type of dryer heated by super-heated steam is favoured.

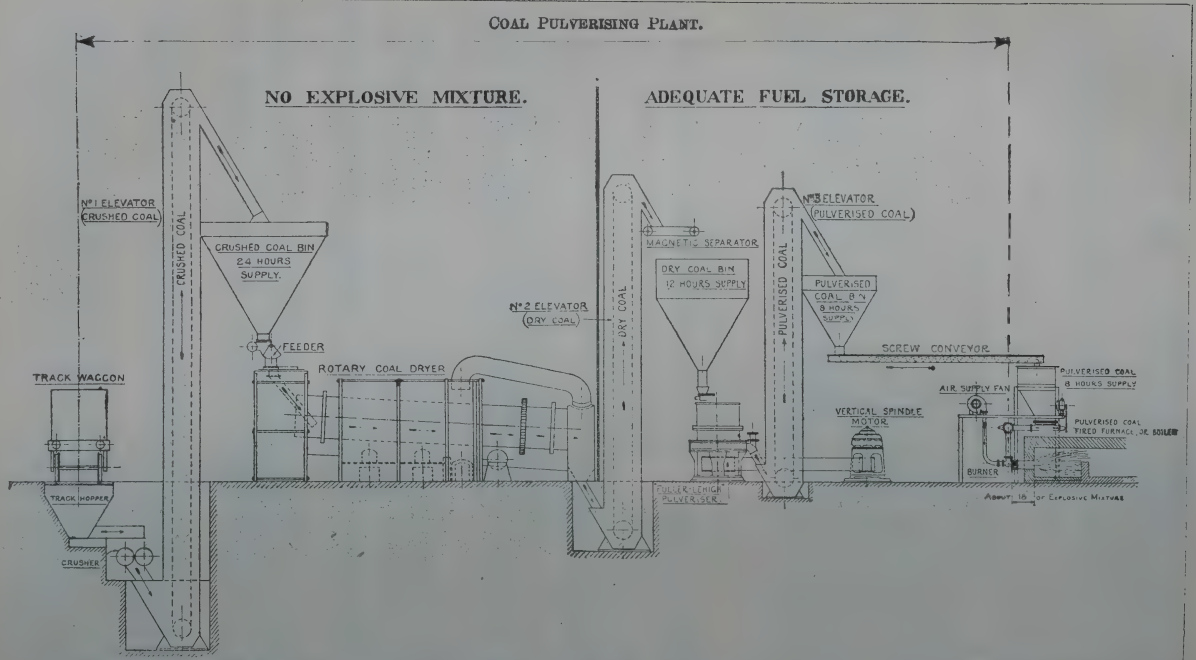

FIG. 22.—General View of 'Central' Pulverised Coal Plant, showing flow of coal from the Track Wagon to the furnaces, and indicating the positions of the Coal Crusher, Elevators, Coal Dryer, Pulveriser Mill, Magnetic Separator, Screw Conveyor, Furnace or Boiler Bin, and Screw Feeder. In place of the Screw Conveyor either the Fuller-Kinyon Pump (p. 2116) or the air-pressure system is now generally adopted for long-distance transmission.

Screen separator mills, such as the 'Fuller,' made by the Fuller Lehigh Company, have been used very extensively in the cement industry for pulverising the coal and for grinding the cement clinker. In this type of mill the fine particles of coal are thrown tangentially through the mill screen; the fine product is then raised by means of No. 3 elevator to the powdered coal bin, or it is delivered direct into the screw conveyor or into a Fuller-Kinyon type of pump, for transport to the bins at the furnaces.

In the air-separator type of mill the fine coal-dust is exhausted through a fan and deposited by means of the upward air current into the cyclone collector, whence it is delivered into the powdered coal storage bin, or direct on to the screw conveyor or pump.

The power required for operating a screen separator mill with its pulverised fuel (No. 3) elevator is somewhat less than the power required for operating a screen separator mill and exhaust fan. The wear and tear on the latter may be excessive when abrasive hard coal is pulverised, but the vacuum extraction of the coal-dust from the mill tends towards a cleaner mill-house.

Against the screen separator mill may be placed the occasional damage to the screen by a stray piece of iron. Any perforation of the screen due to this cause permits coarse coal to escape with the pulverised product.

Both types are in general use, and at the present time the advocates of one are as numerous as the advocates of the other.

Hardinge ball mills in conjunction with Hummer screen separation are also in use for pulverised coal production.

Transportation of Pulverised Coal.

The original method of transporting coal-dust was by means of weathertight screw conveyors. This method, fig. 22, p. 2114, although used to some extent for small and compact installations, has given place to air pressure and pump transmission systems for larger plants or greater distance delivery.

The Quigley Furnace Specialities Co.* introduced an excellent system of transporting the coal-dust from 'blowing tanks' situate at the mill house. The coal-dust is forced from these tanks by means of compressed air applied to the top of the coal, and the coal is forced through 3-in. or 4-in. pipes to the bins at the furnaces, and over distances up to ½ mile.

Semi-automatic solenoid controlled switch valves are placed at the branches from the main supply pipe. This method of transportation is very compact, convenient, and successful in use.

In the Bonot * 'air-transmission system,' the coal-dust is mixed at the mill house with approximately 50 per cent. of the air required for combustion. The mixture is forced through the supply pipes at a velocity of about a mile a minute, and ordinary branch pipes are taken to the furnaces. No furnace bins are therefore needed with this system. Care must be exercised in arranging this system to suit existing conditions, so that danger of accidental explosion taking place in conveyor mains may be realised and necessary precautions taken.

The Fuller-Kinyon * system of pumping powdered coal through supply pipes has now been developed by the Fuller Engineering Company, whereby a small quantity of air delivered by a pressure blower is pumped into the powdered coal to prevent 'packing,' so that the fuel can be transported long distances with a minimum of power. Ordinary pipes are used which can be laid underground or placed overhead in the same way as for water pipes. (See fig. 23, p. 2116.)

For any one of these methods of conveying pulverised fuel the product must be dry, otherwise packing troubles will occur.

Feeders.

Whenever coal-dust is held in bulk at furnace bins, feeders are attached thereto fitted with screws or worms to introduce the dust into the air-blast as it enters the furnace, or compressed air is used as a means of syphoning out the fuel.

The screw or worm of the feeder is usually operated by means of a variable speed motor.

One of the best types of variable speed feeder-mixers forms the basis of the 'Lopulco' system (p. 2121) of applying pulverised coal to boilers and other furnaces.

The Quigley * feeders have adjustable jaws to govern the supply of dust, and in this way constant-speed motors can be used.

The Simon Carves table feeders have been used with considerable success. This type consists of a horizontal circular table with pockets pierced to take the fuel supply. The rate of rotation is

* The Quigley, the Bonot, the Buell, and the Fuller patents and designs are now associated with the Babcock and Wilcox, Ltd., Companies.

THE FULLER-KINYON PULVERISED COAL PUMPING SYSTEM.

ontrolled by friction concentric disc drive, and constant speed motors can be employed. On the ame principle a single Bailey feeder can be used over a range of 1,000 lbs. to 10,000 lbs. per hour or the supply to any number of burners.

In the 'air-transmission system' no feeders at all are required at the furnaces.

Burners.

The usual type of coal-dust burner met with in general practice has been of very simple onstruction, merely consisting of an air-carrying supply pipe into which coal dust is fed by the crew feeder. These simple types of burner have given fairly good results, but later practice as established the necessity for a more intimate mixing of the air and powdered coal.

Many special burners have therefore been devised whereby a pre-mixing of coal dust and air s effected before the final stream of air for combustion is introduced.

Exceptionally good results have been recently obtained with the turbulent mixing types of urners, such as the Peabody, the Buell, the Bailey-Tenney, and the Couch burners, to effect a hort diffused flame.

In each type a well-conceived combination of air and coal passages with adjustable or deflec- ion plates or vanes renders it possible to control the direction, length, and intensity of flame.

By reason of the thorough mixture of air and coal, pulverised coal can be applied direct to he fire tubes of Lancashire and Cornish boilers without the use of external combustion cham- ers, unless high ash coal is used, when it is preferable to collect much of the ash prior to its assage through the boiler tubes. These burners also eliminate the extensive furnace alterations equired for long flame burners.

No difficulty is experienced in burning low ash coal (10–15 per cent.) without external com- ustion chambers.

By reason of wide diffusion of the air and coal-dust mixture, the areas of combustion chambers sually provided for hand or stoker firing are in most cases sufficient.

An actual example of results obtained with the 'Buell' burners, as applied to the stoker ettings of a B. & W. boiler of 3,240 sq. ft. of heating surface, without external combustion hambers, is as follows :—

	Stoker Firing.	'Buell' Burner.
Coal—B.Th.U. per lb.	12,562	10,370
,, lbs. per hour	1,792	1,175
Water evaporated from and at 212° F. per hour	13,365	10,552
,, Per lb. of coal	7·4	9·0
Efficiency of boiler and furnace	57 per cent.	83 per cent.

Another method of liberating a very greatly increased number of B.Th.U. in a small com- ustion area has been developed by the Fuller Engineering Company in their 'Well'-type Burner, hich consists of a rectangular chamber with pulverised coal burners at each angle, these pro- ucing a high degree of turbulence within the water-cooled burner chamber. (See Combustion rea, p. 2119.)

Power of Motors.

Mill House Plant (for 40 tons per 10 hours).

Preliminary crusher (not required with slack coal)	15 to 20 h.p.
Nos. 1, 2, and 3 elevators	7½ h.p. each
Dryer	10 to 15 h.p.
Pulveriser mill screen separation	60 ,, 75 h.p.
,, ,, air ,,	80 ,, 100 h.p.

(Mill capacity, 4 to 5 tons per hour.)

Fuel Transportation (say 5 tons per hour, 300 ft. and 40 ft. lift).

*By screw conveyor	15 h.p. (motor).
†By air pressure	75 ,, (compressor).
*By air mixture	60 ,, (fan mixer).
*By screw pump	20 ,, (screw pump and compressor).

* Continuous operation. † Intermittent operation.

(For an approximation of power used, see note below, 'Progress in America.')

Coal-dust Feeders.

Constant or variable speed motors . . . . . 1 to 3 h.p.

($\frac{1}{2}$ h.p. motors are sometimes used, but are generally unsuitable under mill conditions.)

Air Fans.

No accurate figure can be given for the power required for air fans, as this will depend upon the size of burner used. The total quantity of air per pound of coal allowed is usually 180 cub. ft., 120 cub. ft. being supplied at a pressure of 3 or 4 ozs. per square inch; the remainder is induced at the burner.

Pre-Gasification of Coal.

Much of the success obtained in the various applications of pulverised coal has been due to the fine and uniform pulverisation of the coal, and the provision of combustion chambers of considerable cubic area.

Until the advent of the turbulent mixing type of burner, the latter requirement precluded the development of pulverised coal-firing for such purposes as marine boilers, Lancashire boilers, locomotives, and the smaller range of trial furnaces.

A greater measure of success is still to be obtained by subjecting pulverised coal to temperatures in the neighbourhood of 1,000° C. at high velocity, and with an air supply sufficient only to maintain this refractory surface temperature, gas can be generated and delivered direct to furnaces or boiler firing chambers with little loss of the sensible heat.

Developments are now in train for the practical application of pulverised coal in this manner, and when success has been established it will extend the use of pulverised coal for general application, and it will be the means of very greatly reducing the combustion chamber sizes now essential for the burning of pulverised coal in the direct way. Moreover, it will doubtless be possible to utilise such generators or pre-gasifiers with either liquid fuel or pulverised coal.

Progress in America.

The amount of pulverised coal used in the U.S.A. up to 1912, chiefly in the cement industry, was approximately six million tons per annum. In the copper, steel, and iron industries for locomotives and boiler work, and including the cement industry, the annual usage of coal in powdered form is now upwards of 30 million tons, following the adoption of pulverised coal-firing at the 200,000 kw. super-power station at Milwaukee. Many other new American power stations have been equipped for pulverised coal firing, one of the latest stations being the 600,000 kw. station of the Union Electric Supply Co., at 54th Street, New York.

Many of the most recent super-power stations in America and elsewhere are now operating with or have been arranged for pulverised coal firing, and, among others, the following stations have been equipped with boilers of very considerable size:—

	Approximate Heating Surface of each Boiler. Sq. Ft.
Milwaukee Electric Railway & Light Co., U.S.A.	32,200
Allegheny Steam Heating Co., Pittsburg, U.S.A.	30,800
Ford Company, River Rouge, Detroit, U.S.A.	28,480
Detroit Edison Co. (Marysville), Detroit, U.S.A.	29,800
Detroit Edison Co. (Trenton Tunnel), Detroit (Projector), U.S.A.	28,720
Cleveland Electric Illuminating Co., Cleveland, U.S.A.	30,600
Providence Electric Railway Co., Boston, U.S.A.	12,600
Berlin Electricity Works, Rummelsburg, Germany	17,200
Duquesne Light Co., Brunots Island, U.S.A.	26,500
Western Pennsylvania Power Co., Springdale, U.S.A.	15,300
Metropolitan Edison Co., Middletown, U.S.A.	14,680
Union Electric Light & Power Co., Cahokia, U.S.A.	18,010
Union d'Électricité, Gennevilliers, France	20,200
Union d'Électricité, Vitry, France	16,670
Nippon Electric Co., Tokio, Japan	10,080
Hams Hall, Birmingham, England	20,000

At the Cleveland Electric Illuminating Company's plant, the coal, which is of high volatile ntent (33 per cent.), is pulverised to a fineness of 60 per cent. through a 200 mesh, and 85 per nt. through a 100 mesh screen. Operating power has been determined at 14·5 kw. for production, kw. for screw conveyors, and 4 kw. per ton for feeders and air blowers. Ratio of furnace lume to effective heating surface of boiler is 0·85, or 0·95 to total heating surface, furnace lume being 29,150 cubic ft.

The rating of each boiler is 3,060 h.p., and each boiler operates at 225 per cent. rating on ntinuous load, and at 300 per cent. rating at peak load.

A specia lfeature of this installation, as at other American power plants, is the automatic ntrol of the fuel and air required for combustion, in direct relation to the load on the boiler, means of the system perfected by the Bailey Meter Company of Cleveland.

Combustion Area.

The ratio of combustion area to boiler-heating surface at the Cleveland plant is referred to ove. The ratio at the Cahokia power station is somewhat less, being 0·635 of the effective ating surface of the boiler.

American practice has established satisfactory results for boiler firing, when burning between 6 and 2·0 lbs. of coal (calorific value, 12,500 B.Th.U. per lb.) per hour per cu. ft. of combus- n area. At normal steaming this means that in each cu. ft. of combustion area there can liberated about 18,000 B.Th.U. per hour, and at maximum load about 25,000 B.Th.U.

In Germany, at a special pulverised coal research station, a definite figure for metallurgical gh temperature work has been fixed at 33,500 B.Th.U. per hour per cu. ft. of total combustion ea. The special Well-type burner recently adopted by the Fuller Engineering Company, ferred to under 'Burners' (p. 2117), makes it possible to liberate a much higher number of .Th.U. per cubic foot of combustion area per hour, and it is claimed that this type of burner, ith pulverised coal, has been burned at the rate of upwards of 100,000 B.Th.U. per cu. ft. per our.

On the above bases of B.Th.U. per cu. ft. of combustion area, calculations can be made for oiler and metallurgical work, for any quality of coal: the higher the ash content, the lower ill be the B.Th.U. value per lb., and consequently the larger the combustion area necessary. he greatest obstacle to the general use of pulverised coal for industrial purposes has been the er-increasing cubic areas of combustion chambers to such a pitch that prices are quoted for the tter which are half the total cost of boilers.

The development of the turbulent mixing types of burners has clearly shown that combustion ambers can be greatly curtailed when using burners giving wide flaring or diffusion effects. ee 'Burners,' p. 2117.)

Self-contained Pulveriser Units.

Great attention has been given to the perfecting of these small unit mills, which can be placed ongside the boilers or furnaces to be heated. So much progress has been made in design, duction of power consumption, maintenance costs, etc., that their installation at French and erman iron and steel works and at American power houses has been generally accepted. Whereas power consumption was anything up to 30 kw. per ton of coal, these units now operate s 12 to 15 kw. for similar fuel as burned at the furnace, including air supply. These units are so pulverising fuel containing up to 15 per cent. of moisture, but this moist fuel must necessarily e supplied direct to the furnace burners, and not stored in bunkers.

The figures given in the table on p. 2131 represent the capital outlay required for complete ill-house plants of various capacities. The initial cost of same, with transportation system, rnace bins, motors, feeders, etc., necessitates an expenditure which, in many cases, will or an only be contemplated when actual results have proved that the collective advantages nd economies thereby introduced render such an investment wholly attractive.

For smaller fuel requirements and for testing pulverised-coal firing upon individual boilers r furnaces, a self-contained pulveriser unit can be conveniently installed. There are now many fficient machines of this type available, and built upon entirely novel principles is the 'Atritor' nit, which embodies the use of eddy currents of air within the grinding zone for the dual purpose f rapid agitation and deflocculation of coal particles and the exposure of maximum surface or driving off moisture. In this unit, therefore, is combined the operation of drying and ulverising.

The French 'Rex' machine is also novel in its provision of carborundum grinding element and also in its fuel and air regulation and totalising adjustments. The power consumption wi this unit is also exceptionally low; 6 to 10 kw. per ton of bituminous coal.

Coal containing comparatively high percentages of moisture—20 per cent. or so—can pulverised in several of the well-known types of units, and through the medium of hot air, up 500° C.; the resultant fuel powder will be practically bone dry. Coal containing 5 per cent. 10 per cent. of moisture can be dried and pulverised with air at atmospheric temperature, t resultant degree of fineness depending upon the humidity in the atmosphere at the time grinding.

By the installation of self-contained units the value of pulverised-coal firing for any specif purpose can be ascertained, so that the question of capital outlay upon a complete mill-hou plant and attendant equipment can be based upon the results ascertained in this manner.

The makers of the well-known Bettington sectional water-tube boilers and self-containe pulveriser units have generally improved the construction of both these, so much so that t boiler should find an extended use, and the pulveriser, which is particularly silent and efficien a useful and general application.

Self-contained pulveriser units have been widely adopted on the Continent, many electr light stations now being fitted with this class of equipment, and some details of the Clark Chapman Turbo Pulveriser unit are given below. This unit is very similar to the Fren 'Resolutor' unit in general use for boilers and metallurgical furnaces on the Continent. T German B. & W. unit and the Bema Mill are also extensively installed.

The Clarke, Chapman Turbo Pulveriser.

(Clarke, Chapman & Co., Ltd., Gateshead-on-Tyne.)

This pulveriser is a self-contained unit, complete with beaters, primary and secondary a fans being mounted on or shaft and driven by belt electric motor as desire If fitted with motor, th whole is mounted on bed plate, making a very nea and efficient plant.

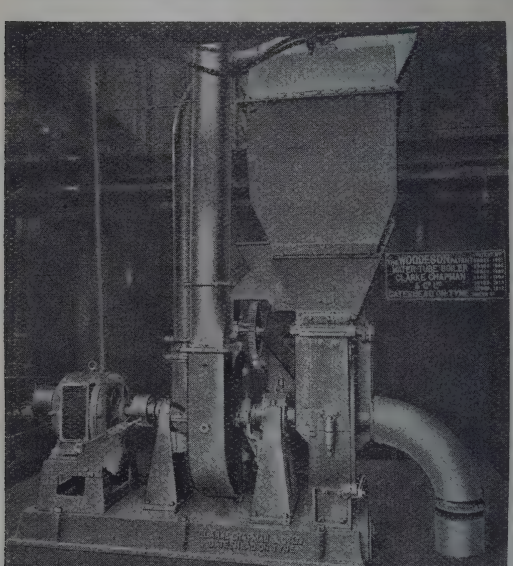

FIG. 24.—The Clarke, Chapman Turbo Pulveriser, dealing with 2¼ tons of coal per hour, firing 'Woodeson Patent Water-Tube Boiler.'

The coal in this machin is pulverised entirely b impact and is fitted with simple means of controllin the fineness of the pul verised product. This ad justment, apart from th coal feed, is the only on on the machine, and th operation of the plant i most simple.

In many pulveriser extraordinary precaution have to be taken to exclud tramp iron, but in the cas of the Clarke, Chapma Pulveriser it is recom mended that a grid havin 1½ in. mesh be fitted ove the hopper, and then an tramp iron which can pas will do no harm whateve to the machine.

A special chamber i provided for its reception and this may be cleaned ou periodically. This machin is being regulary made i standard sizes up to 8 ton per hour.

The Lopulco System.

(International Combustion, Ltd.)

A typical arrangement of a boiler fitted with Lopulco plant is shown in fig. 25 (p. 2122).

In such a system the raw coal—in pieces of a size that will pass through a 1½-in. diameter ring is passed through a dryer to bring the total moisture below 6 per cent., and is then fed to a Raymond pulveriser which has 4 to 6 pendulum rollers running inside the grinding ring.

The coal is fed to the grinding chamber by means of a feeder, where it is picked up by rotating ploughs which throw it between the rollers and the grinding ring, and as soon as it is reduced to the required fineness it is separated from the coarser particles by a current of air which is drawn through the pulveriser by an exhauster fan. This air carries the fine particles to a cyclone collector situated at the top of the boiler-house, and as fast as the particles are swirled out, the carrying air returns to the pulveriser to bring up a fresh supply.

The degree of fineness is adjusted to suit the amount of volatiles contained in the fuel; for example, bituminous coals having a high percentage of volatiles do not require to be ground so fine as semi-anthracite coal which has low volatiles.

A suitable condition of fineness for good bituminous is such that 90 per cent. will pass through a 100-mesh sieve—that is to say, a wire mesh having 10,000 holes to the square inch—and also that no particles are left on a 40-mesh sieve.

The pulverised fuel is stored in bins which are large enough for several hours supply to each boiler, and is fed as required from the bins by means of groups of feeders which are driven by variable-speed electric motors.

A certain amount of primary or carrying air is introduced with the coal at the feeders in order to supply the Lopulco burners with a heavy homogeneous mixture.

There is a burner to each feeder, the number depending on the size of the boilers (see tabular data (page 2123), which give particulars of some installations carried out by *International Combustion, Ltd.*).

Each burner has a fishtail nozzle which gives a flat stream of fuel and primary air, and this shape is adopted because it provides for greater exposure of the coal particles than would be possible with a round nozzle of sufficient diameter to carry the same amount of fuel and air.

Outside the nozzle there are passages through which air is induced in such quantity as to ensure the rapid ignition of the mixture, and also for the purpose of cooling the nozzle, this amount being regulated by two adjustable dampers.

The flames are projected downwards into the combustion chamber with enough velocity to give a U-shaped flame, the hottest zone being thus in the middle of the combustion chamber.

As the flame reaches the lower part of the combustion chamber, it loses its downward velocity and doubles back on itself, and the resultant hot gases are drawn upwards through the boiler tubes. In its downward travel the flame encounters horizontal currents of secondary air which are induced through ports in the front wall, and as this air is drawn at right angles to the flame, it mingles intimately with all the incandescent particles, thus giving perfect combustion, so that at all loads it is possible to give a high percentage of CO_2 in the product of combustion.

The amount of secondary air is induced through doors which are controlled by a single hand wheel, and the opening of each door is so adjusted that the correct amount of air for completing combustion enters the furnace in correct proportion.

The furnace is entirely steel cased and insulated with special insulating tiles and built of first quality firebricks, etc., in such manner as to provide freedom for the brickwork to expand and contract without buckling or binding.

The combustion chamber walls may be air-cooled or water-cooled, or a combination of air and water cooling may be adopted. With the former the walls are made hollow, and the secondary air circulated in them before it enters the combustion chamber. In this way the air required for combustion is advantageously pre-heated, while the brickwork is maintained at a reasonably low temperature. With water-cooling the tubes may be located in front of the brickwork or embedded in the brickwork. As an alternative, the Murray Water-Cooled Wall may be employed. This consists of a number of 4-in. diam. tubes, fitted with a pair of diametrically opposed fins welded on, grouped together, and connected to headers at each end. The Murray Wall has the great advantage that where fitted in a combustion chamber, no refractory brickwork is in contact with the hot gases.

Across the bottom of the combustion chamber there is a screen of water tubes which forms part of the boiler, these tubes being of seamless steel expanded into forged steel headers. The particles of ash which drop from the flames pass between the tubes and are thus chilled below melting point, so that they fall into the ash hopper and are easily removed as fine dry particles.

The following figures give the power required for a Lopulco equipment to deal with 6 tons of pulverised fuel per hour.

Motor for fan of the dryer	12 kw.
Motor for Raymond pulveriser	40 ,,
Motor for fan of pulveriser	33 ,,
Two motors for six feeders	5 ,,
Motor for fan for fuel	17 ,,

This works out at 17·8 kw. per ton of coal pulverised per hour, which, at a halfpenny per unit, is 9*d.* per ton; *i.e.* about one per cent. of the total steam production is required to work the pulverising plant.

The McEwen-Runge System.

(Coal Oil Extraction, Ltd.)

This process in the main involves the pulverisation of the fuel to be carbonised, and the elevation of this fuel to the top of an internally heated tower. The powdered fuel is caused to fall down this tower in the form of a cloud, meeting in its downward passage an upward current of hot inert gases. The large surfaces presented by the powdered fuel ensure a rapid interchange of heat, so that, in the very short time occupied in the passage of the fuel from the top to the bottom of the tower, carbonisation is effected. The carbonisation is progressive in that the fuel is gradually raised to the maximum temperature and the direction of travel of the fuel is contra to that of the gaseous distillation products.

The process is continuous, and consists merely in feeding to the top of the towers a regular supply of pulverised fuel and withdrawing from the bottom a finely subdivided semi-coke, which can be at once delivered to the burners of a furnace.

The McEwen-Runge process may be operated in a variety of ways to produce either a very rich gas, or it may be varied to yield a lower grade gas to suit local conditions and according to the local demand for this product.

It may be operated as a single-stage process or a two-stage process, but the following description is for the two-stage process, which has a higher thermal efficiency and is better suited to a wider range of fuels:—

In the two-stage process the treatment in the first stage serves to eliminate all free and cellular moisture, all CO_2, and gases of no heating value. In the second stage a higher temperature is employed and carbonisation is effected. The heat required for the first stage is extracted from the carbonised semi-coke by a heat exchanger, thus the sensible heat in the semi-coke leaving the retort is transferred to the coal in the first stage of the treatment, thereby securing a very high thermal efficiency.

An important feature in the McEwen-Runge process is that there are no moving parts in any part of the installation which is under heat, the coal dust being subjected to heat whilst in suspension, and in both (1) the preheating stage, and (2) the secondary or carbonising stage, the coal dust falls down against an uprising current of heated gas which may be composed of either (*a*) air alone, or (*b*) a part of the products of combustion, or (*c*) of both.

In the case of the preheating stage, a current of air, the heat for which is derived from the hot semi-coke dust, suffices (the air, of course, not being in direct contact with the hot dust, otherwise complete combustion of the latter would result). The two stages are carried out in steel towers lined with refractory material. These, which are superimposed, are about 30 ft. high and 6 ft internal diameter. The temperature of the gas or air current in the first stage is, at the point of entry, about 700° F., and 500° F. on leaving the retort, say an average of 600° F. The products of combustion or gases resulting from this moderate temperature treatment are neither large in quantity nor of particular value, consisting chiefly of carbonic acid gas, and they are dissipated into the atmosphere.

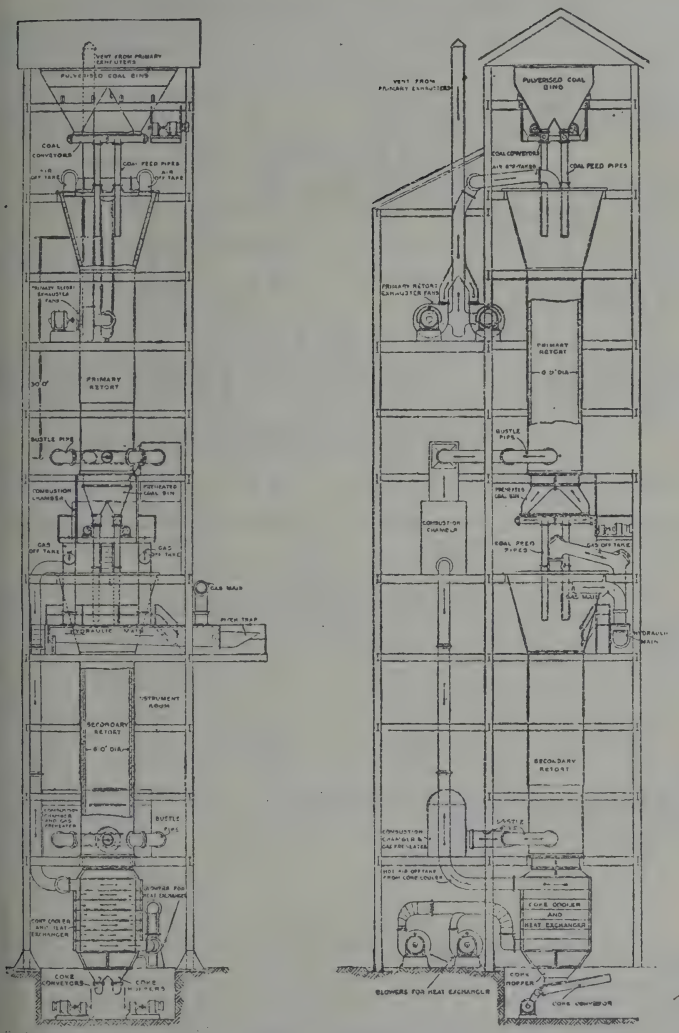
If the products of combustion are utilised for heating the carbonising current, that is, in the second stage, one-third of the gas manufactured is used for this purpose. In this stage the temperature of the incoming gas is about 1,500° F., *i.e.* at the bottom of the retort, and on leaving about 600° F., or an average temperature of 1,050° F.

The treatment of the dust in each stage occupies about 35 seconds. After treatment in the first stage the dust passes into a receiving hopper and is thence conveyed to the second or lower tower—the whole process taking only 6 minutes—and the throughput per unit per diem is 210 tons.

Fig. 26 shows the general arrangement of the towers with the two-stage process. The towers are superimposed. The coal from the pulveriser is elevated to a receiving hopper above the tower of the first stage. From this receiving hopper it is fed by means of automatic feeders, the speed of which can be regulated, through four distributing pipes which project about 8 ft. into the top of the tower, which latter has an enlarged area at the top, so that separation of dust from the issuing gases may be effected in a zone where the velocity, already low, is reduced and out of contact with the incoming fuel. Rising against the falling cloud of powdered fuel is a stream of a mixture of hot air and products of combustion; the hot air is, as previously stated, derived from the heat exchanger at the bottom of the second tower, the heat being extracted from the hot semi-coke. In the event of the heat units in this air being insufficient for the purpose of preheating the coal to the desired degree, the heat supply is supplemented by products of combustion which are caused to mix in a suitable mixing chamber with the hot air.

The preheated coal dust, still in the form of a finely subdivided powder, but showing some slight change in physical condition, when examined under the microscope, as compared with the original coal, is passed from the bottom of the tower, by means of automatic feeders similar to those already described, to the carbonising tower. In its passage down the carbonising tower the fuel meets an uprising current of hot gas, which may be (*a*) preheated permanent gas, (*b*) products of combustion introduced into the tower, (*c*) products of combustion generated within the tower by the admission of a suitable quantity of hot air.

From the bottom of the carbonising tower the finely subdivided semi-coke passes through the heat exchanger already referred to, and thence to conveyor arranged for the disposal of the fuel as circumstances may require.



General Arrangement.
McEwen-Runge Two-stage Coal Treatment. Capacity 200 Tons per Day.

FIG. 26.

Pulverised Coal for Locomotives.

The advantage for pulverised coal, lignite, etc., as a locomotive fuel are—

30 to 40 per cent. fuel economy as against hand-firing, running mileage and cylinder pow of engines increased, cost of firing tools and repairs to fire grating eliminated, no cinders sparks from the smoke stack, reduction of fire-box strains, firing conditions with pulverise coal firing analogous to oil-firing with similar fuel-bunkering facilities. Any local fuel with reason can be used.

The following fuels have been and can be used:

	A	B	C	D
Chicago and North-Western Railway.				
	Per Cent.	Per Cent.	Per Cent.	
Illinois bituminous	3·18–15·36	10·00	34·47	10,720–12,400
Kentucky bituminous	1·9 – 2·8	8·00	36·54	13,964

The Delaware and Hudson Railway				
Pennsylvania anthracite culm	0·5	12·22	8·30	12,000 (averag
,, bituminous	0·5	9·0	33·0	13,750

A. Range of moisture. B. Ash. C. Volatile matter.
D. Calorific value. B.Th.U. per lb. (dry).

On the Lehigh Valley Railway a locomotive has been run on a mixture of 55 per cent. r anthracite silt and 45 per cent. bituminous coal. Full steam pressure is maintained easily all times, and the anthracite silt contains 38·42 per cent. of ash, and has a B.Th.U. value 9,675, while the soft coal which is mixed with this has an ash content of 11·6 per cent. and B.Th.U. value of 12,650. Analyses of these coals are as follows:—

Anthracite Silt.	Per Cent.	Soft Coal.	Per Cent.
Moisture	2·26	Moisture	1·90
Volatile	10·39	Volatile	36·59
F.C.	49·30	F.C.	49·89
Ash	38·42	Ash	11·60

The raw coal and lignite to be burned on locomotives in Italy has the following analys figures representing the limits in each case are given:—

	Per Cent.		Per Cent.
Moisture	12·52 to 26·80	Volatile	31·5 to 60·94
Ash	11·6 to 32·60	Carbon	35·26 to 68·50

B.Th.U. values from 3,640 to 10,440

Locomotive Equipment.

A brief specification of the locomotive equipments supplied by the Fuller Engineering Co pany of America is given below:—

Special cast-iron coal hopper base to receive duplex feed screws. Vertical marine-ty steam engine for operating same, with intermediate connections, including gears, g shafts, shafting, etc.

Steam turbine driven fan for conveying the coal dust from the feeder to the tender.

Flexible steam connections between engine and tender, as well as flexible connecti for transporting the pulverised coal between engine and tender.

Burner, with necessary dampers and connections for operating same.

3,000° F. pyrometer for indicating fire-box temperatures. Electric revolution coun for indicating speed of engine driving coal-feed screws. Revolution counters for each p of feed screws, gauges, and valves for operating this equipment.

Mechanism for operating the slag pan or slag pans, as well as mechanism for operating the air dampers in the sides of the combustion chamber beneath the fire-box.

The equipment is started and coal supply commenced with a steam pressure of from 0 to pounds.

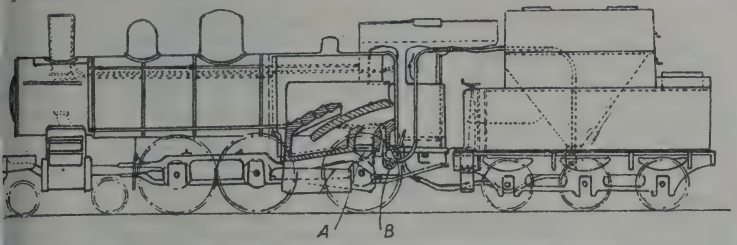

FIG. 26A.—Pulverised Peat Fired Locomotive on Swedish Railways.
A. Hand-fired Coal Grate. *B*. Peat and Air Mixture Inlet.

An article by *Bureau Engineer*, Carl Flodin (Centraltryckeriet, publishers, Stockholm, 916), includes full data regarding tests made with peat-fired eight-coupled freight locomotives: tractive power, 9,000 kg.; weight, 51,000 kg.; tender, 36,000 kg.; water capacity of nder, 14,000 kg.; pulverised peat, 4,000 kg.

It was found on these tests, for equal boiler duty, that 1 kg. of coal was equal to 1·4 kg. pulverised peat, the coal used having a calorific value of 7,240 cals. and the peat as used 400 cals., or approximately 13,000 and 7,900 B.Th U. per lb.

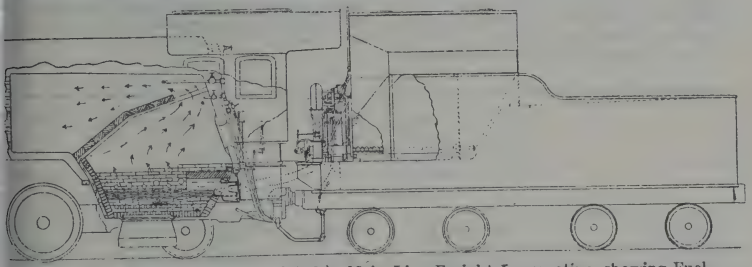

FIG. 27.—Fuller Equipment as fitted to Main Line Freight Locomotive, showing Fuel Hopper, Control Equipment, Burner, and Combustion Chamber.

The arrangement of the firebox setting, fig. 26A, allowed for a small grate on which coal was burnt nder the incoming mixture of powdered peat and air. On this small hand-fired grate 3 to 4 kgs. f coal were consumed per 100 kg. of peat; the analysis of peat and coal was as follows:—

	Powdered Peat. Per Cent.	Coal. Per Cent.
Carbon	47·0	75·5
Hydrogen	4·5	4·4
Oxygen	29·5	8·6
Sulphur	0·5	1·5
Nitrogen	1·1	1·2
Ash	3·2	6·2
Moisture	14·2	4·6
	100·0	100·0

Analogous tests made with coal-fired and powdered peat-fired locomotives gave the following verall boiler efficiencies and firebox temperature of gases:—

	Efficiency. Per Cent.	Temperature.
Hand coal-fired	65	1,510° F.
Pulverised peat-fired	73	1,670° F.

Recorded and corrected figures for parallel trips with coal and peat-fired locomotives are given, the following being the more important:—

Parallel Test Run.	Trip Number.	Weight of Loco., Tender and Wagons.	Wagons.	Average Speed, Km. per Hr.	Consumption of Fuel Kg. per 1,000 Kg. Inclusive Loco. and Tender.	Smoke-box Temp.	Kg. Steam per Kg. Fuel.
		Ton per 1000 Kg.	Ton per 1000 Kg.			° F.	
Service.							
A. Freight	1. Pulverised peat	787	700	29·2	37·5	255	4·47
	2. Coal . .	782	700	27·5	25·6	290	6·83
B. Freight	3. Coal . .	782	700	28·7	27·7	312	6·62
	4. Pulverised peat	787	700	27·0	40·7	294	4·56
C. Passenger	5. Pulverised peat	387	300	42·3	56·9	289	4·52
	6. Coal . .	382	300	41·7	39·0	268	7·0

Many grades of coal (in South Africa, for instance) are considered unsuitable for use on locomotives.

That it is quite possible to eliminate a large quantity, if not the whole, of imported coal or coal transported long distances by rail, is now being realised in various parts. Brazil has already supplanted imported railway coal to some extent by fuel which hitherto has been considered useless, and continuous extensions in this direction are to be made. The coal used in Brazil is of lower quality than the South African fuels, as the following comparative analyses of Brazilian and South African coals show:—

	Brazilian Coal, as used 'dry' in pulverised form for locomotive fuel.		South African Coal, Undried.		
			Durban.	Kroonstad.	Dundee.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Moisture . . .	7·90	1·73	1·60	8·29	0·84
Volatile . . .	28·04	9·50	27·10	31·27	25·30
Fixed carbon . . .	34·73	61·50	60·05	45·32	68·94
Ash	29·33	28·27	11·25	15·12	5·76
Sulphur	3·16	9·10	1·51	1·43	1·53
B.T.U. per lb. . . .	8,820	10,177	12,950	11,020	14,722
Evap. power . . .	9·20	10·40	13·40	11·40	15·23

The Brazilian coal analysis represents the fuel in pulverised form after treatment in a rotary dryer. The fuel is of friable nature, and the ash of such form that when subjected to heat flows round the lumps of fuel on a hand-fired grate, rendering it impossible to burn the coal. Kroonstad coal contains about the highest degree of moisture recorded—8·29 per cent.—whereas most South African coal contains but 1 or 2 per cent. of water, and for which drying plant would not be required. This is an important consideration.

Refractory Linings for Combustion Chambers.

The construction and composition of the linings of combustion chambers for pulverised coal fired furnaces are questions of considerable importance.

Although the experience gained of recent years has rendered it possible so to design combustion chambers that the refractory linings are not subjected to the severe destructive action from the flame and ash slag as heretofore, it is still highly desirable under all conditions to have

a lining that will not only withstand high temperatures, but will at the same time resist the corrosive chemical action of the ash under these conditions.

In the case of high temperature metallurgical furnaces the factor of corrosion is one that must be carefully considered in view of the presence of metallic oxides introduced through the furnace charge.

Most coal ash consists chiefly of alumina, silica, and iron oxide, together with very much smaller quantities of five or six metallic oxides.

Metallic oxides are of primary importance, in view of the fact that many of them have a marked fluxing action on almost any refractory material. Thus, a fuel ash that contains much iron oxide has in itself a destructive action on furnace linings, irrespective of any of its other constituents.

Apart from this, some fuel ash contains a predominating amount of basic material, whilst in other cases there may be an excess of acid material. When a furnace is to be fired generally or entirely with a fuel containing a basic ash it is highly desirable to provide a basic lining, for by so doing much of the trouble and expense for renewal and repair of furnace linings will be avoided.

Preliminary analysis and investigation in connection with the composition of the coal ash and furnace linings will often save expense and prevent lining troubles during the subsequent operation of the plant.

The more common and cheaper grades of refractory bricks usually contain a more or less equal amount of silica and alumina, and the slight excess of one or the other should be taken advantage of. Combustion chambers of suitable design and having the requisite combustion area will then run satisfactorily with linings of ordinary firebricks.

If, however, there are exceptional conditions to contend with, such as high temperatures, confined combustion space, chemically active ash, etc., it is necessary to make use of the best grades of refractory materials.

In many cases carborundum (silicon carbide) can be used as a facing material for linings with good results. Carborundum, however, although generally chemically inert, will not resist the action of iron oxide or ash containing much potassium or sodium compounds.

In some few cases pure silica bricks can be used when the fuel ash composition is suitable and high temperatures have to be withstood, but special provision must be made for expansion of the bricks.

Pure alumina, magnesite, or bauxite are all high-grade refractories that may be used to resist high temperatures when ash or slag is of a basic nature.

Advantages of Pulverised Coal.

The chief advantages of using coal in pulverised form are:—

Utilisation of low grade coals, peats (coals with 30 per cent. and 40 per cent. ash); lignites, anthracite slush and pit washings can be used.

Control of flame temperatures with uniform heat regulation and greatly reduced requirement of attendant labour—in fact, labour required is equivalent to oil-firing practice.

Increased efficiencies of furnaces due to direct firing of the fuel in minute particles, causing instantaneous and complete combustion, without smoke production.

Some approximate savings in fuel consumptions that have been realised in practice are as follows—

Boilers—80 per cent. efficiency, and savings of 15 to 50 per cent. over hand firing.

Open-Hearth Steel Furnaces—a saving of 300 lbs. per short ton of steel as against producer gas for small plants.

Puddling Furnaces—a saving of 1,500 lbs. per short ton of iron over hand firing, and from 300 to 500 lbs. over mechanical stokers.

Reheating Furnaces—20 to 40 per cent. saving over hand firing.

Heavy Forge Furnaces—25 per cent. saving over hand firing.

Light Forge Furnaces—20 to 40 per cent. saving over hand firing.

Annealing Furnaces—30 per cent. saving over hand firing.

Tinning and Galvanising—20 to 30 per cent. saving over hand firing.

Sheet and Pair Furnaces—30 to 40 per cent. saving over hand firing.

Copper Smelting Furnaces—40 per cent. saving over hand firing

Locomotives—30 to 50 per cent. saving over hand firing.

Cupolas—30 to 50 per cent. saving in coke and hotter iron.

Crucible (Brass Melting) Furnaces—The use of coal in place of metallurgical coke or oil.

The output from many of these furnaces has been greatly increased by reason of coal-dust firing, what are known as 'stickers' in the tin-plate trade having been reduced 60 per cent. whilst the quantity of tin and zinc used has been reduced considerably owing, in a great measure to the improved surface of the metal, and also to the more even heating of the kettles.

Reduced oxidisation of steel and iron heated in powdered coal-fired furnaces and increased life of annealing boxes have accounted for an annual saving of many thousand pounds in some works.

Very important economies have been made in firing malleable iron melting and annealing furnaces with pulverised coal, so much so that The Grindle Fuel Equipment Co. of America have specialised exclusively on this work.

1,000	48	6–57	1–57	4–14	1–14	6	144	3	384	6·9

In a properly designed plant, and with due attention to ordinary common-sense regulations there is *no fear of explosion* from the coal-dust, and, as has been already stated, the old trouble with the ash slag have been overcome

There are certainly many instances where the use of fuels in powdered form would show a handsome return for capital invested, and the following table will enable an estimate to be made as to economy that can be expected.

APPROXIMATE COST OF COMPLETE MILL HOUSE, PLANTS AND OPERATION EXPENSES.

If static dryers are installed the cost of plant can be reduced by 5 per cent. up to 350 tons, and by 7½ per cent. thereafter, and the cost for coal for rotary dryers is then omitted.

Daily Output in Tons.	Labour. Cost per Ton.	Power. Cost per Ton.*	Dryer Fuel, Cost per Ton. 2 per cent. of coal dried.	Repairs, Cost per Ton.	Without Stand-by Plant.				With Stand-by Plant.			
					Cost of Mill House Plant, including Building.	Interest per Ton at 6 per Cent.	Depreciation per Ton at 10 per Cent.	Total Preparation. Cost per Ton.	Cost of Mill House Plant, including Building.	Interest per Ton at 6 per Cent.	Depreciation per Ton at 10 per Cent.	Total Preparation. Cost per Ton.

Cost of plant exclusive of foundations and erection.

* Can be reduced to ⅓rd for power-station plants.

The table of costs is based on the following assumptions :—

Labour at £4 per man per 44-hour week.

Power at 1½*d.* per kilowatt-hour (a high cost even for local supply), and an average allowance of 20 kw.-hours per ton of coal pulverised and delivered to the exit of mill house, including power for all operations. Dryers to be fired with pulverised coal, which is taken as 40*s.* per ton at the dryer burners ; an average allowance of 2 per cent. of the coal dried is made for dryer fuel, assuming the moisture content of coal to be reduced from 15 per cent. to 1 per cent.

Yearly output is based on 300 working days.

Vertical or Horizontal Flame Projection.

Pulverised coal can be applied to boiler furnaces through horizontal or vertical burners. As a general rule the burning of bituminous coal and lignite is best effected by means of horizontal burners, and when fuel of less than 20 per cent. volatile matter is to be burned the vertical burners are recommended.

Illustrations of four standard types of water-tube boilers as equipped with horizontal and vertical burners are shown in fig. 28. Horizontal burners are generally used for high volatile fuel and vertical burners for low volatile fuel.

REFUSE DESTRUCTORS.

Calorific Value of Refuse.

The calorific value of refuse is about $\frac{1}{5}$ to $\frac{1}{7}$ that of an equal weight of good dry coal.

Average composition and calorific value of London ashbin refuse, containing the average percentage of water :—

Component parts of Refuse.	Amount in 100 lbs. of Refuse.	Calorific Value.
	Lbs.	B.Th.U.
Coal	·35	3,260
Coke	·15	1,200
Bones and offal	·37	1,970
Breeze and cinder	25·55	102,000
Rags	·40	1,330
Paper, straw, fibrous material, and vegetable refuse	13·15	33,100
Ash	47·00	Nil
Dust and dirt	9·75	,,
Bottles	·48	,,
Metals, including tins	·68	,,
Crockery	1·72	,,
Glass	·37	,,
	99·97	142,860

The above is the average of 1,000 cart-loads.

About 60 per cent. of the refuse is combustible.

The character of the refuse varies a great deal. In factory districts the percentage of unburnt cinder is high, whereas in residential districts with gardens it is much lower.

When it is considered that ordinary green garden refuse when piled in a heap over a nucleus of fire will consume itself, it is obvious that refuse containing cinders will contain enough heat, if properly applied, for its perfect destruction. It is essential that combustion should take place in brick cells, and that no heat should be abstracted until combustion is complete, after which the gases may be used for steam raising. If 40 per cent. only of the refuse is combustible, its calorific value per pound will be about 5,800 B.Th.U. if it were dry. Taking it only as 1,500, this is more than would raise the temperature of the whole gaseous and solid matter to a red heat. If half the weight were water, this would absorb about 600 B.Th.U. to evaporate and about 300 to become red hot, or 900 in all. The remainder of 600 B.Th.U. would raise the gases and solids to nearly 5,000° F. Thus destruction may be perfect with only the equivalent of one-tenth its weight of dry carbon. Inodorous combustion demands high temperature, and hence must occur in brick cells, with suitable movement of the fuel, so that the gases and steam cannot escape until fully incandescent.

Extract from Official Test of 'Heenan' Refuse Destructor at Pontypridd.

U.D.C. Electricity Generating Station, Treforest.

Date of test	February 10, 1910.
Plant tested	One unit (3 cells of 25 sq. ft.) 75 sq. ft. grate area, B. & W. Water Tube Boiler of 2,010 heating surface, Green's Economiser of 96 tubes, 4 ins. in diameter.
Duration of test, 10 A.M. to 6 P.M.	8 hours.
Weight of refuse burnt	18 tons, 1 cwt. 1 qr. = 40,460 lbs.
Rate of burning per hour	$\frac{18{\cdot}0625}{8}$ = 2·257 tons per hour.
Equivalent evaporation from and at 212° F. of destructor plant without economiser	3·223 lbs.
Mean temperature in combustion chamber over 8 hours	2,437° F. (1335° C.)
Average percentage of carbon dioxide in products of combustion under boiler	14·65 per cent.
The station is working non-condensing, the consumption basis being 40 lbs. of steam. Estimated per kilowatt, the units generated on test (an equivalent of 151 units per ton of refuse)	2,724 B.Th.U.
The actual was 104 B.Th.U. The total, 1,905 B.Th.U.	

Feb. 11, 1910. (*Signed*) J. E. Teasdel.

* This does not take into account steam wasted in blowing off.

Total works costs reduced from 1·10 to ·82 per unit—1,500*l.* per annum on 100,000 units per month (four weeks).

Value of coal 13·5 shillings per ton (2,240 lbs.).

Note, in the preceding tables, that from September 1908 to the end of January 1909 the destructor had not been installed. In the corresponding months of 1909 and 1910 note the large reduction in the coal consumed, notwithstanding the increased current consumption.

At Rotterdam Messrs. *Heenan & Froude, Ltd.*, have installed a large combined destructor and generating station. The refuse collected daily suffices to drive a 1,250 kw. generator and supplies current for operating the whole of the cars of the city. This is one of the largest and best equipped stations in the world, having a destroying capacity of about 500 tons per day of 24 hours, although, at the present time, only something approximating one-half of this is available.

The following tables give particulars of the evaporation and the electrical output, as well as the refuse burnt on representative weeks during the months of September and October 1912. It will be noted that the quantity of refuse collected and delivered at the Destructor Depot is an increasing one, and it will further be noted that the calorific value of the refuse during the winter months rises appreciably.

GENERATION OF ELECTRICITY BY DESTRUCTORS IN GREAT BRITAIN.

In the Annual Report of the Electricity Commission * it is stated that the total units generated by destructors during the year ending March, 31, 1926, was 25,636,974 (from 29 stations), as against 26,241,342 (from 27 stations) in 1925.

LIQUID FUELS.

Whereas solid fuels are solely used for external combustion it is possible to employ almost all liquid fuels for either external or internal combustion. On comparing the most important liquid fuel petroleum with the most important solid fuel, coal, many remarkable advantages of the former over the latter are found to exist. The heat value of petroleum is some 50 per cent. greater than that of average coal, the stowage space being slightly less. Liquid fuels are more convenient to store (places inaccessible to coal may be employed) and are more easily transported than solid fuels. Liquid fuel is almost entirely free from ash. When used for internal combustion the thermal efficiency of liquid fuels is double that of the solid fuels used for power production. Certain liquid fuels can be employed in high speed engines, whereby a higher power per unit weight of engine is obtainable than by any other type of prime mover.

The most important liquid fuels are petroleum, shale oils, coal tars and their products, and lignite tars and products.

Petroleum.

Petroleum occurs in the earth, and is generally found in strata of conglomerate or of oil sands. It is generally accompanied by gaseous and also by solid hydrocarbons. The crude oil is usually brown or black, and the products of different fields vary greatly both in physical and chemical properties.

Petroleum consists almost entirely of carbon and hydrogen. These are present in the form of compounds known as hydrocarbons. Hydrocarbons may be divided into three main groups, known as aliphatic, aromatic and hydroaromatic hydrocarbons. These groups may be subdivided into numerous series, the members of which possess certain definite relationships between the number of carbon and hydrogen atoms present in the molecules. The physical properties of the members of these series generally progress by fairly regular steps. The carbon atoms in the aliphatic hydrocarbons are connected together in the form of chains, and the more important series of this type of hydrocarbons are :—

Paraffin Series.
General formula—C_nH_{2n+2}

Methane	CH_4
Ethane	C_2H_6
Propane	C_3H_8
Butane	C_4H_{10}
Pentane	C_5H_{12}

Olefine Series.
General formula—C_nH_{2n}

Ethylene	C_2H_4
Propylene	C_3H_6
Butylene	C_4H_8
Pentylene	C_5H_{10}

* Generation of Electricity in Great Britain, year ending March 31st, 1926. H.M. Stationery Office, Adastral House, Kingsway, London, W.C. 2. Price 1*s.* 6*d.* net.

The carbon atoms of the aromatic compounds are connected together in the form of rings a typical compound being :—

Benzene, formula C_6H_6 . . . 
The hydroaromatic compounds also contain carbon rings, but are richer in hydrogen than th aromatic hydrocarbons. A typical hydroaromatic compound is hexamethylene, C_6H_{12}.

Petroleum oils contain members of all these series, but the proportion varies according to th locality from which the oil has been obtained. Pennsylvanian oils consist mainly of aliphati hydrocarbons, Russian oil mainly of hydroaromatic compounds. The products of the destructiv distillation of coal consist mainly of aromatic compounds. Crude petroleum from Mexico an South America generally contains quantities of a viscous sulphur-containing body known a asphaltum, which has great influence on their properties as fuels. Little petroleum is consume in the crude state, it being usual to separate it into fractions boiling over various ranges b means of repeated distillations. Many petroleum fractions are also treated with sulphuric aci and with caustic soda in order to remove certain undesirable constituents.

The principal fuels obtained from petroleum are :—

Benzine	boiling from 70°–150° C., 155°–302° F.	Specific gravity ·700–·760
Kerosene, illuminating, or paraffin oil . . .	boiling from 150°–300° C., 302°–572° F.	„ „ about ·800
Gas oils, solar oils, etc. .	boiling from 250° C., 482° F. upwards.	„ „ „ ·850
Petroleum residuum, 'fuel oil,' boiling point varies greatly		„ „ ·880–·950

The world's production of petroleum in 1926 was 1,095,934,000 barrels, and the United State production was 770,874,000 barrels, or 70 per cent. of the total. The import of motor spirit o petrol into the U.K. in 1926 was 562 million gallons.

Benzine.

Benzine is the petroleum fraction from which motor spirits are prepared. Motor spirits are generally called petrol in this country. Petrol contains about 14 per cent. hydrogen and 86 per cent. carbon. Heavy fuel oils contain about 12 per cent. hydrogen and 88 per cent. carbon.

Kerosene.

Illuminating oil or kerosene, generally known in this country as 'Paraffin Oil,' possesses a specific gravity in the neighbourhood of ·800. It is slightly lower in calorific value than petrol, but on account of its higher specific gravity it yields more heat per unit volume of fuel. The ultimate composition of kerosene is approximately carbon 87 per cent. and hydrogen 13 per cent. Apart from illuminating purposes, kerosene finds frequent use as a fuel for vaporising engines. A large number of heavy distillates of petroleum are prepared for various technical purposes. Of these gas oil is probably the most important. Gas oil is prepared with a view to its use in the preparation of carburetted water gas or oil gas, and is also used as fuel for semi-Diesel and Diesel engines. It is a brown clear liquid of specific gravity about ·850, and has a net calorific value of about 18,000 B.Th.U. The distillates, whether prepared from asphaltic or non-asphaltic petroleum oils, are generally very similar in quality, though the proportion of each distillate yielded by the different crude oils may vary considerably. The residuum which is run off the still at the end of distillation, and is frequently marketed as 'fuel oils,' varies very greatly in properties according to the nature of the crude oil from which it originates. The non-asphaltic petroleum residuum which is sold as fuel oil is generally dark brown or black, almost opaque, quite mobile, and has a specific gravity of ·870 to ·920. It is largely used as a fuel for semi-Diesel and Diesel engines, also for boiler firing in the Navy. The residua prepared from asphaltic oils are usually black opaque liquids possessing high viscosities and specific gravities from ·920 to ·980, the viscosities and specific gravities being dependent on the asphaltum content.

Examples of analyses of the more important petroleum fuel products are given in he table on page 2142.

Shale Oil.

Shale exists in many parts of the British Empire, the shale oil industry being most fully eveloped in Scotland. The shale is mined in a similar manner to coal, and is then subjected o destructive distillation, the principal products of value being ammonia and crude shale oil. he crude oil is subjected to distillation, whereby a series of products similar to the petroleum istillates is obtained. The shale oils are richer in unsaturated bodies than petroleum. In fuel roperties they very closely resemble the petroleum products.

Petrol.

Petrol, known in France as 'Essence' and in America as 'Gasoline,' is a mixture of liquid ydrocarbons principally composed of the chemical 'paraffins,' Hexane C_6H_{14}, Heptane C_7H_{16}, ctane C_8H_{18}, and Nonane C_9H_{20}: these have boiling points 155°F., 208° F., 248° F., and 302° F. spectively. It is obtained by distillation from crude petroleum and, as now used, varies in . gr. at 60° F. from about 0·70 to 0·76, the average being about 0·725. The consumption Great Britain rose from about nineteen million gallons in 1905 to upwards of two hundred illion gallons in 1919. Petrol, being a mixture of hydrocarbons, has no fixed boiling point, d its density increases during evaporation; it was largely from this cause that surface car- rettors proved unsatisfactory, selective evaporation occurring and a heavy non-volatile sidduum being finally left; with the jet-carburettors now almost universally employed no lective action is possible.

As petrol is very expansible, tanks and closed vessels should never be quite filled with the uid, so as to avoid risk of rupture following a rise in temperature. Coefficient of expansion, 00063 per ° F. (0·001138 per ° C.).

The composition of commercial petrol averages about 85½ per cent. carbon and 14½ per cent. drogen, and the net calorific value per lb. varies but little from 18,600 B.Th.U.

Heavy petrol gives quite satisfactory results with modern carburettors; motor omnibuses ploy 0·760 spirit very largely on account of its lower cost.

It was formerly assumed that the suitability of a motor spirit could be determined from its ecific gravity, but in recent years the use of benzol in admixture with petroleum spirits has come common, and such a mixture is a very satisfactory fuel, in spite of its having a higher ecific gravity.

On the other hand, if the air supply exceed about 15 lbs. per lb. of petrol, there is an air excess l no CO appears in the exhaust; instead one gets free oxygen. The practical range is from out 11 air to 1 petrol, to 17 air to 1 petrol; recently the Royal Automobile Club has adopted the standard for carburettors such a mixture as would give an exhaust containing about er cent. of free oxygen; this prevents the presence of CO, and gives nearly the highest thermal ciency and also nearly the maximum power. Maximum thermal efficiency usually occurs h a somewhat greater excess of air, and maximum power with a slight defect of air, due in s latter case to the higher mean pressure obtained by reason of the considerable expansion the products of combustion with 'rich' mixtures. One lb. of petrol, occupying 4 cub. ft., uires for its complete combustion roundly 15 lbs. of air occupying 196 cub. ft. at 60° F.: the lbs. of mixture thus occupies a volume of 200 cub. ft. at 60° F., and contains 2 per cent. by ume of petrol vapour—that is, assuming that the petrol is gasified, and not atomised.

Theoretical Efficiency of Petrol Engines.

The theoretical efficiency, E, of an engine operating on the constant volume cycle is—

where, $$E = 1 - \left(\frac{1}{R}\right)^{n-1}$$

R = expansion ratio.

If no heat is lost, then $n = 1{\cdot}45$, but in practice heat is lost during compression, with a result t the exponential n is reduced to the value of 1·35. Ricardo states that when heat leakage, tional losses, and losses due to friction of gases have been allowed for, then $n = 1{\cdot}25$, so that maximum efficiency obtainable in practice may be considered to be

$$E = 1 - \left(\frac{1}{R}\right)^{0{\cdot}25}$$

CRACKING PROCESS.

A very large proportion of the world's production of motor spirit is now obtained by cracking from heavier oils. The original Burton process has been largely replaced by the modern liquid phase cracking plants of Dubbs and Cross. In these the oil is heated while travelling rapidly through tubes arranged in a furnace, and thence passes to a reaction chamber, where the cracking mainly takes place. In the Dubbs plant a pressure of 300 lbs. per sq. in. is maintained, while the Cross plant employs a higher pressure of 800 lbs. per sq. in.

The specific gravities and distilling temperatures of petrols are liable to be varied from time to time as the market conditions warrant. The increased demand for motor spirit during recent years has been to a large extent met by including both higher and lower boiling distillates in the motor spirit fraction. By subjecting the crude oil to high temperatures in the absence of air, frequently accompanied by high pressures, a decomposition of the more complex hydrocarbons is brought about. This action, which is technically known as 'cracking,' results in large yields of motor spirit. The motor spirit prepared in this way is rich in unsaturated compounds, possesses a characteristic odour, and is higher in specific gravity than the direct distilled petrol which comes over between the same temperatures.

Some of the petrol at present being imported into this country is naturally rich in benzene and toluene, and this is particularly the case with the Borneo spirit imported by the Shell group and it has been found, both experimentally and in practice, that owing to the higher spontaneous ignition temperatures of benzene and toluene, mixtures containing these hydrocarbons do not so readily cause preignition or detonation in petrol engines. In view of this, petrol which does not naturally contain benzene has occasionally been mixed with benzene in order to decrease the liability to preignition.

Analyses of Pratt's No. 1 and Shell No. 1 spirit by Mr. Harold Moore, on behalf of *The Motor*,* gave the following results:—

Pratt's No. 1 Motor Spirit:—Specific gravity, 0·729 at 15° C. (59° F.).

ENGLER DISTILLATION TEST: Initial boiling point, 33° C. (91·4° F.).

Temperature	C.°	55	60	70	80	90	100	110	120
„	F.°	131	140	158	176	194	212	230	248
Drop per cent.		—	1·0	3·5	11·5	21·5	31·0	45·0	57·5
Temperature	C.°	130	130	140	150	160	170	180	190
„	F.°	266	266	284	302	320	338	356	374
Drop per cent.		67·5	67·5	77·0	83·0	87·5	91·5	93·0	94·5

Initial boiling point is the temperature at which the first drop falls from the bulb of the thermometer when the latter is placed ¼ in. below the outlet tube of flask.

Drop temperature is taken when the first drop leaves the end of the condenser.

Acid Coloration.—Acid has brick-red colour, and petrol separates out slowly.

Aromatic hydrocarbon content = 10·2 per cent. by weight.

* *The Motor*, September 7, 1921.

Shell No. 1 Motor Spirit: Specific gravity, 0·754 at 15° C.

ENGLER DISTILLATION TEST: Initial boiling point, 34° C.							
Temperature	C.°	57	70	80	90	100	110
,,	F.°						
Drop per cent.	.	—	1·5	6·0	12·5	24·0	39·0
Temperature	C.°	120	130	140	150	160	170
,,	F.°						
Drop per cent.	.	53·5	67·0	78·0	86·5	92·0	95·0

Acid Coloration.—Acid only slightly discoloured, light brown, and petrol separates out almost immediately.

Aromatic hydrocarbon content = 21 per cent. by weight.

DETONATION.

High efficiency in petrol engines is best attained by employing very high compression ratios, but in practice it is found that a high compression ratio is accompanied by 'pinking' or 'knocking' when running at slow speeds with heavy loads when ordinary motor spirit is used. For such spirits the limiting compression ratio is about 4·5 to 1. Benzol is very much less prone to give this phenomenon of knocking, or detonation, and it permits of the use of a considerably higher compression ratio. The use of alcohol as a fuel permits of a compression ratio of as much as 7 to 1. Certain organic compounds have been found by Midgley & Boyd to be much more efficient than benzol in preventing detonation; for example, tetraethyl lead is 625 times as powerful as benzene. Fuel containing a minute proportion of this anti-detonating agent has been extensively used in the U.S., and is known commercially as 'ethyl gas.'

Benzol.

Benzol had come into prominence before the war as an alternative home-produced fuel for the engines of motor vehicles, partly in consequence of the high price of petrol. Since the withdrawal of the restrictions on the use of benzol its use has become more general than before, though the motoring public do not yet fully appreciate its value as a fuel. Benzol is the commercial name for a mixture of hydrocarbons prepared by the distillation of coal tar, and also obtained by stripping the gas which is produced as a by-product from coke ovens. Commercial benzol consists almost entirely of a mixture of the hydrocarbon benzene (C_6H_6: not to be confused with the petroleum fraction 'benzine') and the hydrocarbon toluene (C_7H_8). The usual commercial grades are '90 per cent. benzol,' which on distillation yields 90 per cent. of distillate at 100° C., and consists of approximately 70 per cent. benzene and 30 per cent. toluene, together with traces of the xylenes (C_8H_{10}, and '100 per cent. benzol,' which on distillation yields 100 per cent. of distillate at 100° C., and contains a higher proportion of the hydrocarbon bezene than 90 per cent. benzol.

There is little to choose between these two bodies as motor fuels, and provided they have been satisfactorily refined they are both preferable to pure benzene, as the mixtures do not so readily solidify in cold weather. Pure benzene solidifies at a temperature of + 6° C. (43° F.), and boils at 80·4° C. It possesses a specific gravity of ·88 at 15° C., and a gross heat value of about 18,090 B.Th.U.

Both commercial benzol and pure benzene possess very high temperatures of spontaneous ignition, and they will withstand compressions of about 200 lbs. per square inch in internal combustion engines without being affected by preignition. This property, together with the high specific gravity, accounts for the increased mileage per gallon obtained when using benzol as fuel instead of petrol. Benzol gives about 16 per cent. greater mileage than petrol, and also gives greater power to the engine. When changing over from petrol to benzol it is advantageous slightly to reduce the size of jet, though it is not absolutely necessary to make any modification. The colour of benzol for motor use should be perfectly clear and white, as yellowish colour indicates unsatisfactory refining. Certain bodies (mainly phenols, unsaturated hydrocarbons and sulphur containing compounds) are present in benzol when it is first prepared by distillation. These compounds are removed by treatment with caustic soda solution and afterwards with concentrated sulphuric acid. If these bodies are not removed there is a liability for the benzol to form resinous substances after prolonged standing, and also to form gummy deposits in the engine. Petrol undergoes a similar refining process during its preparation, but it is rare to meet with badly refined petrol nowadays, as the quality necessary for the motor spirit market is well understood by the petroleum firms. Petrol and benzol are perfectly soluble in each other, and can be used with satisfaction in the form of mixtures.

British Standard Specification for Benzol for Motor Fuel.*

Report No. 135, 1921 (*Abstract*).

(1) The term 'Benzole' shall denote a liquid consisting essentially of a mixture of benzen and not more than 30 per cent. by volume of toluene and xylenes.

(2) The material shall be a clear 'water white' liquid, free from undissolved water an other visible impurities.

(3) The specific gravity at 15·5° C. (60° F.) shall be not less than 0·870, and not mor than 0·885.

(4) When 100 cc. of the material are distilled in the Standard Distillation Apparatus, at rate of 7 cc. per minute, there shall distil at 760 mm. pressure—

Not less than	60 cc.	at or below	90° C. (194° F.).
„ „	75 cc.	„	100° C. (212° F.).
„ „	90 cc.	„	120° C. (248° F.).

The flask shall be dry at a temperature not exceeding 125° C. (257° F.). The temperatur recorded by the thermometer shall be corrected for emergent stem and barometric pressure.

(5) The amount of non-volatile residue remaining when 20 cc. of the material are evaporated and subsequently heated for two hours on a water bath at 100° C. (212° F.), shall not excee 0·01 per cent. by weight.

(6) The coloration imparted to pure sulphuric acid (90 per cent. H_2SO_4), free from nitri acid, when 90 cc. of the material are shaken with 10 cc. of the acid for five minutes at ordinar temperatures, shall be not more than a light brown.

(7) The total sulphur content shall not exceed 0·4 per cent. by weight. Freedom from aci and alkali.

(8) The material shall give no reaction for free acid or alkali when tested.

(9) The material shall give no reaction for sulphuretted hydrogen when tested.

(10) The freezing point shall not be higher than — 14° C. (7° F.).

Detailed descriptions of the methods employed in testing are given in the original publication

Alcohol.

Although the heat value of alcohol per lb. is comparatively small, yet, on account o its heaviness as a vapour, and the small volume of air required to burn it compared with benzene and petrol, it yields 89·2 B.Th.U. per cub. ft. of mixture at 60° F. and atmospheri pressure. Moreover, the products of combustion are 6½ per cent. greater in volume than tha of the unburnt mixture, with corresponding increase in the pressure developed. There is thus thermally considered, not very much to choose between alcohol and petrol; alcohol is, in fact an excellent fuel for suitably designed internal combustion engines, and is largely used in Germany where its production is encouraged by the Government; in 1904 the price of alcohol in German was only 9*d.* per gallon when purchased in large bulk.

Mr. E. Bury of the Skinningrove Iron & Steel Works, Middlesbrough, has made trials of process for the abstraction of ethylene from coke-oven gas and its recovery as alcohol, by which an average yield of 1·6 gallons per ton of coal carbonised is obtained. The application of thi process to the whole of the 14,635,000 tons of coal reduced to coke in this country in 1918 would yield 23 million gallons of alcohol. It is calculated that the recovery of alcohol from the gas works of the country on similar lines would yield 27 million gallons per annum.

Alcohol has a great affinity for water, and ordinary commercial qualities contain water i various proportions up to about 15 per cent.; in the following table estimated calorific value per lb. are given for alcohol-water mixtures containing from 0 to 50 per cent. of the latte ingredient.

* By permission of the British Engineering Standards Association.

ESTIMATED CALORIFIC VALUE OF ALCOHOL-WATER MIXTURES

0·5	0·5	6,210	5,160

Alcohol engines require larger carburettors and piping and valves than are necessary when étrol is used. As the latent heat of alcohol much exceeds that of petrol, especially when water present in any considerable proportion, it is also necessary to well jacket the carburettor with ɔt water or exhaust gas, and to heat the in-going air to about 350°F. in order to ensure com-ɛte vaporisation. The cylinder-jacket water should also be kept nearly at 212°F.; too cool cylinder results in imperfect combustion of the mixture, acetic acid, aldehyde, etc., being formed stead of CO_2 and H_2O only, with loss of efficiency and corrosion of internal parts. Starting ɔ from cold is a special difficulty with alcohol, and engines are usually started with petrol, the cohol being turned on when everything is well warmed up. Some engines are arranged so as ɔ start and *stop* on petrol; in this way any traces of water or acid from the alcohol are cleared ɪt of the cylinders and passages during the last few revolutions of the engine, and risk of corro-ɔn of parts is thus avoided. Tests on a 14 horse-power 'Locomobile' alcohol engine of 8·28 ins. ɔre and 11·8 ins. stroke made by Prof. E. Meyer in 1901 showed a brake thermal efficiency of ɨ per cent., using alcohol containing about 13 per cent. of water. The volume ratio of com-ɛession was 5·9. The cylinder-jacket water temperature was maintained at 208°F. The engine n at 280 revs. per minute and developed 13·9 b.h.p. at full load.

COMPOSITE MOTOR SPIRITS.

Various mixtures containing alcohol, etc., have been put on the market as motor spirits. 'Natalite' is said to be a mixture of 40 per cent. of ether and 60 per cent. of alcohol (prepared om molasses), with traces of ammonia and denaturants, and is extensively used in South Africa. 'Discol,' used in this country, is a mixture of alcohol, heavy petrol, and benzol, containing about) per cent. of alcohol.

Coal Tars and Coal Tar Distillates.

When bituminous coal is subjected to destructive distillation, gas, coke, tar and ammonia e obtained. The physical and chemical properties of the tars are dependent upon the type of al from which they originate, and the conditions which exist in the carbonising chamber. ie appliances in use for the carbonisation of coal are mainly gas manufacturing plants and ke manufacturing plants. A few special plants exist which do not belong to either of these tegories.

Gas manufacturing plants may be divided into three classes—horizontal retort, inclined tort, and vertical retort plants. Retorts of the first type yield tars of high specific gravity, 15 to 1·25, rich in free carbon, and viscous. Vertical retorts yield thin brown tars of low avity (about 1·05), which are comparatively low in free carbon content and rich in aliphatic drocarbons. The tars from inclined retorts are intermediate between the products of hori-ntal and vertical plants in their chemical and physical properties.

Coke-oven tars are very variable, but usually approximate to horizontal retort tars in mposition.

Tars from gas producers are generally too high in water-content to be of use as fuels.

Blast furnaces yield tars containing large quantities of ash which render them useless in the w state.

Several processes for the low temperature carbonisation of coal have been advocated, but no rge quantity of the tar, which is exceptionally suitable for fuel purposes, is available.

The majority of coal tars may be employed for boiler firing purposes. Tars from vertical torts have been found suitable for use on both two and four cycle Diesel engines, providing at certain special adjustments or fittings are employed, large quantities of such tars being

The volatile products obtained by the distillation of coal tar (mainly benzol and toluol) have been extensively used in automobile engines prior to the war. Creosote and anthracene oils are high boiling distillates of coal tars and are extensively employed for fuel purposes, both for external and internal combustion. The 'tar oil' sold for fuel is usually a mixture of both these above-mentioned fractions. Analyses of some tar oils, together with a petroleum residuum, and alcohol, are shown in the following table :—

Lignite Tars and Lignite Tar Distillates.

Lignite yields valuable liquid products by destructive distillation. The tar is of a butterke consistency and possesses a specific gravity of ·860 to ·920. Its sole use in the raw state is as uel for Diesel engines, for which purpose its richness in aliphatic hydrocarbons makes it behave milarly to petroleum. It therefore does not require either raised cylinder compressions or the se of an ignition oil.

Fuels for petrol engines and heavy oil engines can be obtained from lignite tar by distillaon. Their properties are very similar to those of the corresponding fractions obtained from etroleum.

Tar oils were used in considerable quantities on Diesel engines in this country during the war riod on account of the scarcity of petroleum. The difficulties encountered in burning tar oils e mainly due to their comparatively high spontaneous ignition temperature. The ignition of e fuel charge in a Diesel engine is dependent upon the temperature of compression, no special

ignition device being provided. With the fuel oils derived from petroleum or shale it has be found that a compression pressure of 450 to 500 lbs. is sufficient to ensure regular ignition und starting conditions and at all loads. Whereas the spontaneous ignition temperature (in atm sphere of oxygen) of petroleum and shale oils is in the neighbourhood of 270° C., this val for tar oils is generally over 400° C.* As a result of the high ignition point engines will n start, or run at low loads, on tar oil unless special means are taken for raising the temperatu of the air in the combustion space at the time of fuel injection. The more important metho adopted for this purpose are—(1) to heat the cycle air, blast air and fuel, (2) to increase t

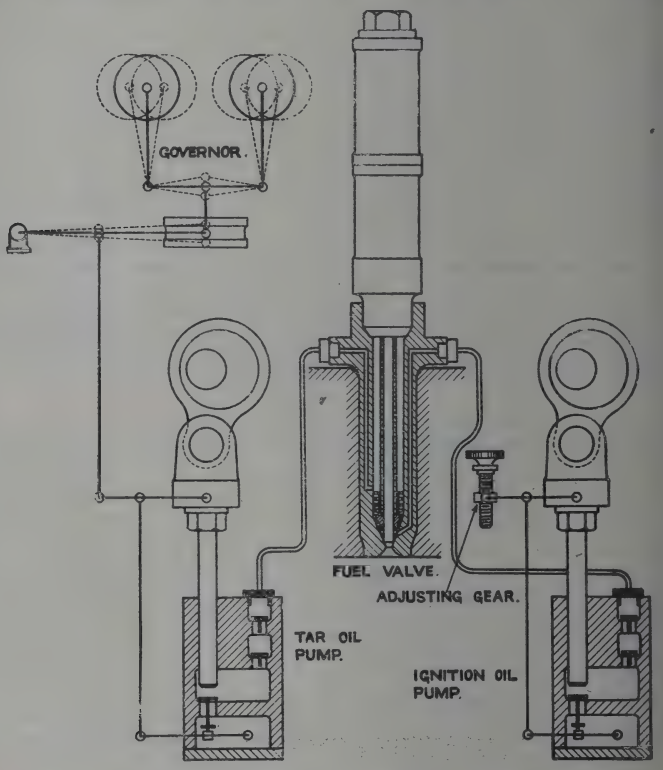

FIG. 29.—Diagrammatic Arrangement of Fuel Pumps for Tar Oil Engine.

compression ratio, (3) to employ an ignition oil, and (4) to inject a small charge of tar oil pr to the main tar oil charge.

Heating of cycle air, blast air and fuel is difficult to effect under starting conditions a has a deleterious action on the fuel valve when running. The increase of compression neces tates a specially heavy design of engine to withstand the higher stresses on liners, cylinder cov and bearings. To ensure certain starting on tar oils the compression would require to exce 600 lbs. The starting difficulty may be overcome by running the engine on a petroleum before closing down and when starting. If the engines can be always maintained at half load over, a compression pressure of about 550 lbs. per square inch will give good running.

* Moore, *Jour. Soc. Chem. Ind.*, February 15, 1917, p. 109.

The introduction of a small charge of a petroleum oil into the working cylinder prior to the ain charge of tar oil has been found the most satisfactory method of burning tar oils. The nition oil charge is pumped to the atomiser nearer the cylinder than the place where the main r oil charge enters. Thus when the fuel valve opens the ignition oil is first injected into the linder and is immediately followed by the tar oil charge. The combustion of the ignition oil ats the air in the cylinder so that the temperature exceeds the spontaneous ignition temperature the tar oil. The proportion of ignition oil is 6 to 8 per cent. of the total fuel at full load; at her loads the quantity of ignition oil remains practically constant, the proportion increasing about 50 per cent. at no load. This method has been found to yield satisfactory results at all ads, and under starting conditions, with cylinder compression pressures of 480 to 500 lbs. per uare inch. An arrangement of ignition oil gear as given in a paper by Mr. C. Day,* is shown fig. 29. Devices have been designed to give a small charge of tar oil prior to the main charge tar oil. The device is so arranged that the initial tar oil charge is not accompanied by any preciable blast air, the expansion of which would reduce the temperature of the combustion ace. Such devices are said to have given good results on the Continent, but are little used in is country.

In addition to the ignition question tar oils are particularly liable to form deposits in the omisers of Diesel engines. A résumé of some experiences of burning tar oils on Diesel engines is given by Mr. G. Porter in a paper read before the Diesel Engine Users' Association, May 24, 17. In this paper several specifications for tar oils for use in Diesel engines are given. An stract of these specifications is appended below :—

Specifications of Tar Oil Fuel for Diesel Engines.

(1) Specification of the M.A.N. Company :—

The tar oil must be a distillate of coal tar.

The oil must flow freely at 61° F., and on being cooled down to 46·5° F. and resting in a ace undisturbed by vibration no separation shall take place at this temperature within the ace of half an hour.

The following constituents shall not be present in quantities greater than the stated rcentages—

Ash	·05 per cent.
Sulphur	1·0 „

Proportions of water and coke residue not stated.

Per cent. insoluble in xylol ·2.

(2) Continental specification for tar oil quoted by Mr. C. Day in his paper on 'Tars and Tar ls as Fuel for Diesel Engines' (January 19, 1916) :—

Tar oils must not contain more than a trace of constituents insoluble in xylol.

The water content should not exceed 1 per cent.

The coke residue should not exceed 3 per cent.

At least 60 per cent. of the oil should be distilled on heating up to 300° C. (572° F.).

The net calorific value should not be less than 15,840 B.Th.U. per pound.

The open flash point must not be below 65° C. (143·6° F.).

The oil must be quite fluid at 61° F.

(3) Specification of tar oil proposed by Mr. C. Day (January 19, 1916) :—

The tar oil must be a product of the distillation of coal tar. No product that has not dergone distillation must be present.

Per cent. insoluble in xylol	Not more than	2·0
„ ash	„ „	0·08
„ water	„ „	2·5
„ coking residue	„ „	3·0

The oil must be liquid at 60° F. when maintained at that temperature for half an hour.

---

* C. Day. Paper read before the Diesel Engine Users' Association, January 19, 1916.

(4) Specification of tar oil by Mr. Batho (the Diesel Engine Users' Association, February 23 1916) :—

Specific gravity—Between 1·0 and 1·1.
Viscosity—Generally 2° Engler.
Flash point—100° F. to 130° F.
Colour—One drop on white paper should show no black residue, as is the case with tar.
Lower calorific value—Between 15,800 and 16,500 B.Th.U. per 1 lb.
Ash—Should not exceed 1 per cent. (unburnt residue of tar oil is mostly harmless).
Water—Should not exceed 1 per cent.
Sulphur—·5 to 1 per cent.

The burning of raw tars on Diesel engines has been accompanied by the same difficulties a the burning of tar oils, but an additional trouble is encountered on account of the free carbo which is always present in raw coal tars.

Furnace Firing with Liquid Fuel.

Liquid fuel possesses many advantages over coal or other solid fuels for furnace firing. Th advantages when using heavy petroleum oils may be briefly enumerated as follows :—

(1) Petroleum fuel oil possesses a gross heat value of approximately 19,200 B.Th.U., whils the gross heat value of coal averages about 14,000 B.Th.U. This fact alone shows two pound of oil to be about equivalent to three pounds of coal.

(2) In spite of its lower specific gravity, oil can be stored in less space than a correspondin weight of coal.

One ton of coal occupies about 43 cubic feet.
„ oil „ 40 „

For marine purposes oil is conveniently stored in ballast tanks and inaccessible places, whic could not be utilised for coal bunkerage.

(3) Oil rarely contains more than 0·1 per cent. of ash, a negligible quantity, while coa may contain as much as 15 per cent. ash. This ash necessitates the removal of clinker from th fires, and besides involving expense it causes a serious loss of heat.

(4) Oil can be conveyed by pipe line, a cheaper, cleaner and more rapid method than any method of coal conveying.

This is of great importance in naval work.

(5) Oil firing does not involve so much manual labour and attendance charges which accompany furnace firing with solid fuel.

(6) A boiler fired with oil will raise about 30 per cent. more steam than the same boiler coa fired.

(7) The furnace doors can be kept closed when oil firing, thereby increasing the efficiency of the boiler and lessening the wear and tear on the boiler plates caused by frequently being chilled with cold air, as is the case when burning solid fuel.

(8) Boilers can raise steam much more quickly when oil fired, thus lessening stand-by charges

(9) Boilers fitted for burning both solid and liquid fuel may be run on coal under norma conditions, while oil can be burned for peak loads, thus minimising the number of boilers i use.

1 lb. coal under favourable conditions raises 9 lbs. steam.
1 lb. oil under similar conditions raises 14½ lbs. steam.

It is essential that firing devices for liquid fuel should break the oil into an exceedingly fin state of division, so that the air can reach the oil readily and ensure speedy combustion.

The methods of breaking up the oil are :—

(1) By means of steam.
(2) By means of compressed air.
(3) By a high pressure on the oil, which is pulverised on passing through a fine jet.
(4) By means of mechanical breaking up in a pulverising chamber.

Steam Jets.

The majority of oil-burning installations used on land are operated by steam. Steam i always available at the face of the boiler, and at the same time steam burners, though not giving quite so high an efficiency as air burners, give a soft flame, which is less liable to injure the plate or tubes with which it comes into contact. For marine purposes there is a distinct disadvantage in the use of steam on the oil burners, as it causes the loss of a considerable quantity of water which has to be carried in storage tanks or else has to be specially prepared by a distillation plant whilst at sea. This drawback does not apply to land installations, where plenty of wate is usually available. Steam burners operate on a variety of principles, the majority of construc tions being somewhat in the form of an injector.

The Kermode steam jet burners, which have met with much success on land service, are designed to impart a rotary motion to the gases by passing the oil through a helical groove. The steam is passed through an annular space surrounding the oil duct, and in addition to causing atomisation, it is used to induce an air current which assists in the combustion of the fuel.

With the Holden steam jet burner, fuel steam and air are passed through annular spaces, the centre of the burner being left open to facilitate cleaning.

Another principle used for pulverising oil by a steam jet is to allow the oil to trickle from a weir over a thin slit through which the steam is passing. This system is used in the common type of burner known as the 'Mexican trough.' A modification of this principle is also used in the Ajax burner, made by Meldrums Ltd.

Compressed Air Burners

The use of compressed air for pulverising purposes allows a higher efficiency on boiler-firing installations. At the same time the saving is not so great as might be anticipated, as the steam or power used for driving the compressors is almost as great as the amount lost through steam burners. The flame has a higher temperature than that of the steam jet, and greater care must be taken to prevent it impinging on the plates. Some of the most recent types of compressed air burners will operate on air at low pressure (about 10 lbs. per square inch), and therefore do not necessitate costly air compressors, as they can be operated with complete satisfaction by low-pressure air from a rotary blower. Such burners are the 'White' burner, the 'J. Samuel White,' and one of the burners by Alldays & Onions.

The Oil Pressure System.

This is mainly used for marine purposes, and complete oil-burning installations on this principle are comparatively expensive, on account of the necessity for well-constructed and effective preheaters, filters, and the specially constructed fuel pumps.

In this type of burner the oil is forced through fine jets under a comparatively high pressure. Many burners are so constructed as to impart a rotary motion to the pulverised fuel (*e.g.* Korting burner). The pressure system, although expensive, is probably the most efficient of oil-burning appliances. The power consumed in driving the fuel pumps is almost negligible, and the combustion is excellent. The pressure system is meeting with much success in marine work at the present time. Good examples of this type of apparatus are made by the Wallsend Slipway Co., Kermode, and Korting.

Mechanical Pulverisers.

It is possible also to pulverise oil by mechanical means, such as breaking the oil up in a squirrel cage. The rich oil-fog thus produced can then be treated as a gas and burned together with secondary air in the furnace. Installations of this type, however, have not met with much success, probably on account of their high initial cost.

Atomisers.

Holden's steam atomiser is shown by fig. 30; fig. 31 shows the Guyot atomiser used in the French Navy.*

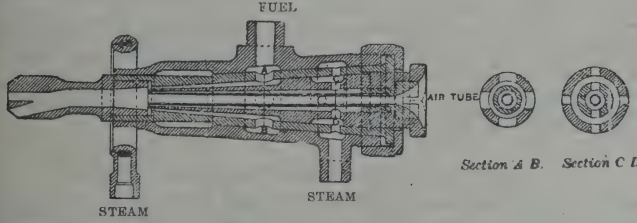

Fig. 30.

Where boilers have the mixed coal and oil system, the oil is best atomised into the front of the furnace, parallel with the grate and about 10 ins. above it.

Where liquid fuel is used alone, the draught required is very small, because the greater part of the draught is always spent in overcoming the resistance of the fuel bed on the grate.

* From 'Liquid Fuel and its Combustion,' by W. H. Booth.

Whereas the calorific capacity of liquid fuel is roundly 20,000 B.Th.U. per pound, as compare with 15,000 for best coal, the commercial value is more nearly as 2 : 1, because liquid fuel can t burned perfectly with very little excess of air, and the temperature in the furnace is higher, th boiler efficiency is better, the boiler being also cleaner, and there are no expenses for removal ashes and for flue cleaning. About 15½ pounds of air are required chemically to burn one poun of liquid fuel, or say 200 cubic feet of air. In the mixed system of coal and oil firing, a larg excess of air may be admitted through the coal fire, and will be used by the oil, which is atomise above the fire.

In locomotives the blast-pipe may be much enlarged for liquid fuel so as to soften the draugh The Macallan variable blast-cap is used on the G. E. Section of the L. & N.E. Railway for thi purpose. The flow of oil requires special regulation. Exactness is secured by such devices a a stop-cock, in which the hole through the plug is square and placed diagonally, thus admitting fine regulation.

To be successful, the burning of oil fuel must follow the lines of successful bituminous co combustion, viz., air mixture, space, and temperature; hence the need for refractory brick lining to keep off the too early chilling effect of cold plates. In steam raising, liquid fuel has a highe percentage efficiency than solid fuel, because less excess of air need be employed; furnace temper ture is higher, causing higher efficiency of heating surface, which is also cleaner. There is a larg

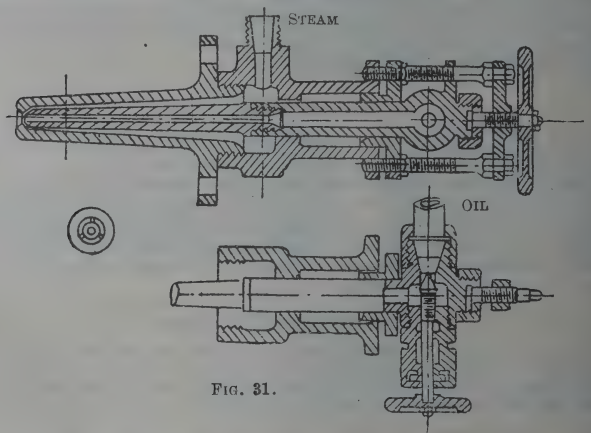

FIG. 31.

saving in labour of stoking, cleaning, ash removal, etc., but perhaps greater expense in firebrick renewals.

Liquid fuels can be burned by means of mechanical burners, without steam or air spraying, i heated to not much more than 140° F., and forced through a whirling jet nozzle at a pressure o not less than 40 lbs. per sq. in. and, with benefit, up to 150 lbs.

For general purposes ashore, high-pressure steam is a more satisfactory spraying agent than air

At sea, for forced draught conditions, the United States Navy Liquid Fuel Board consider a to be the best medium, especially as it avoids the otherwise inevitable loss of fresh water.

In the ss. 'Nebraskan,' oil heated to 175° F. was atomised by air of 1¼ lb. pressure. The oi had a pressure itself of 15 lbs., and a very fine spray resulted; the air was heated. Retarders were necessary in the 3-in. tubes of the Scotch boilers to enable the heat of the gases to be utilised by retarding the flow, or probably by mixing up the gas.

WALLSEND-HOWDEN PATENT LIQUID FUEL BURNING SYSTEM.

In this system the liquid fuel is injected into the furnaces under pressure by means of specia oil-fuel pumps, these pumps being fitted in duplicate so that one can act as a stand-by in cases of breakdown to the working pump. On its way to the burners the liquid fuel is passed through strainers and heaters in which it is thoroughly filtered and then heated to the correct temperature

The oil is forced into the furnace in the shape of a conical spray of exceeding fine particles which burst into flame at a distance of six to eight inches from the nozzle. The flame being conical, and there being no fire-bars fitted in the furnace, the whole circumference of the furnace is available for heating surface. This is a great advantage in the ordinary multitubular boiler, as the lower portion of the boiler becomes heated sooner than would be the case with coal and consequently the circulation of the water in the boiler is improved. Moreover, as the lowe

portion of the boiler is heated up uniformly with the upper portions, and as there is no inrush of cold air, since there are no furnace doors to be opened, there is practically none of that straining action which results from unequal expansion and contraction, due to rapid changes consequent on the opening of the door in coal stoking.

In the improved construction of the furnace front arrangement (fig. 32), which constitutes the principal feature of the arrangement, each of the oil fuel spraying nozzles projects through a

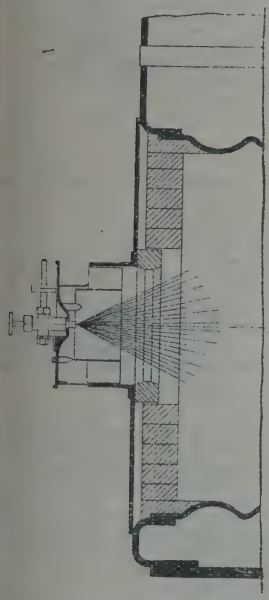

FIG. 32.—Arrangement for Working under Natural Draught or Closed Stokehold Draught.

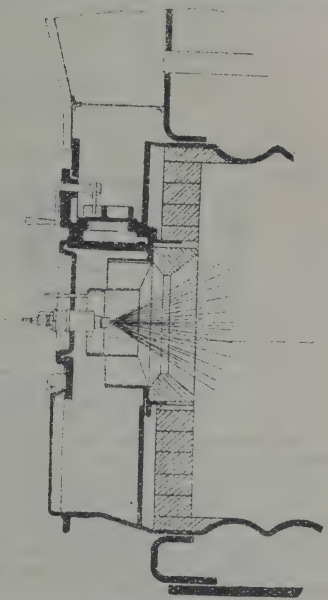

FIG. 33.—Arrangement for Working under Howden's Forced Draught.

baffle plate or the front plate of the casing into an air trunk having lateral openings at its outer end. This air trunk projects concentrically with a second air trunk carried by the furnace front, and the annular space between the inner and outer air trunks is fitted with deflectors constructed in such a manner as to give the air passing through the annulus a spiral motion. One result of this arrangement is, that the openings for the supply of air are so disposed that direct radiation of heat from the furnace is prevented. The admission of air through the second or outer air trunk keeps the outer casing cool, and hence radiation from this part is reduced to a minimum. A feature of the arrangement is the small amount of brickwork required.

With this system steam can be raised on any boiler from the start by means of oil fuel. This advantage is obtained by means of a special design of auxiliary heater and pump.

The Wallsend System is specially adapted for burning oil in conjunction with coal.

When burning liquid fuel on this system with Howden's Forced Draught, fig. 33, 16·22 pounds of water were evaporated (from and at 212° F.) per pound of oil burnt. The calorific value of the liquid fuel was 18,770 British Thermal Units, giving a boiler efficiency of 83·9 per cent.

THORNYCROFT OIL FUEL SYSTEM.

In this system, fig. 34, the oil is sprayed under pressure into the furnace by means of special patent sprayer having both edges of supply grooves tangential to the whirling chamber, the spray being produced within a steel cone of special construction which introduces and mixes the air and the oil-spray in such a manner as to produce perfect combustion. The system can be applied to either water-tube or marine type boilers. Water-tube boilers can be arranged for either oil only or coal combined with oil.

The oil, which may be of any crude description such as Texas, Borneo, Mazout, or Shale s stored in tanks in any part of the ship, and is drawn to the stokehold by a pump which for it through the necessary strainers and the tubular steam-heater to the sprayers.

Lighting up is effected with crude oil by means of a U tube and hand-pump. Steam can e raised in from half to three-quarters of an hour.

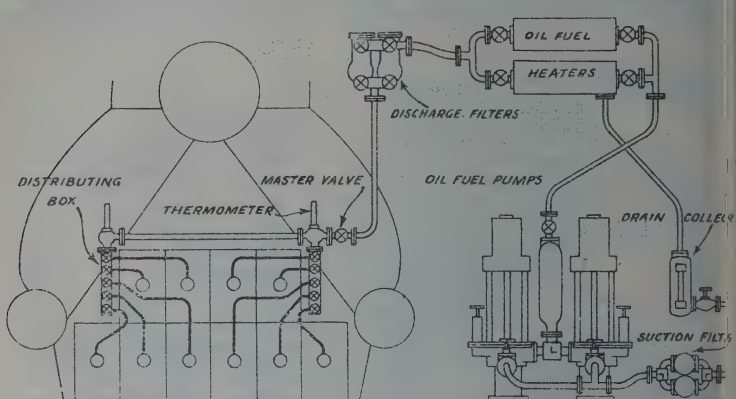

FIG. 34.—The Thornycroft Oil Fuel System.

When fitted in conjunction with Thornycroft boilers of latest design and fairly large size makers are prepared to guarantee that the equivalent evaporation will be at least 16 lbs. water from and at 212° F. per lb. of oil per hour, if the rate of evaporation does not exceed 4 t lbs. per sq. ft. from and at 212°, and they can guarantee a maximum output of 18½ lbs. sq. ft. from and at with an evaporation of 14 lbs. per lb. of oil from and at. This rapid rate evaporation has no detrimental effect on the boiler if the arrangement is properly designe while the combustion is smokeless up to moderate powers, and smoke is only just visible at t highest powers. These results enable very large powers to be developed on small weight, a with the highest efficiency, and at small cost. The number of men necessary for a stokeh developing 16,000 h.p. is only 3.

THE SMITH PATENT FUEL-BURNING SYSTEM.

(Swinney Bros. Ltd., Wansbeck Iron Works, Morpeth.)

With this system it is possible to burn oil or coal with the types of furnace fronts shown figs. 35 and 36, under forced or natural draught, and with a minimum of alteration necessary convert from one fuel to another; this is made possible by the arrangement of the burners, whic are placed at each side of the fire door; the system also allows the burning of coal and o together when necessary.

Furnace fronts designed for burning oil fuel only are also used with this system, and the (as well as those mentioned above) are made to suit all types of boilers for sea or land purpose such as those of the 'marine multitubular,' 'water tube,' Lancashire, etc., types.

When the 'Pressure Jet' system (fig. 37) is in operation, the oil is drawn from a storage tan through a suction filter by means of a pump; it is then delivered through the steam heater, whe the oil is raised to the required temperature, after which it passes through the delivery filter the burners, which project through the furnace fronts.

The 'suction filter' consists of two independent chambers, each having separate contr valves for the inlet and outlet, so that one chamber may be shut off for cleaning whilst the oth is in use.

Although any make of 'oil pump' can be fitted in connection with this system, it is usual fit the well-known Weir's make.

The patent 'oil fuel heaters' are suitable for any class of light or heavy liquid fuel, and a also capable of dealing with any mixture of pitch and creosote.

The design of the heater is somewhat similar to the Admiralty type, as far as the tubes an method of securing them in the tube plates is concerned, but its special feature is that the nest tubes is not permanently fixed to the body flanges, but is so arranged that the nest may be with drawn at any time for cleaning or examination. As the inner tube plate and cover are not fixe to the heater body, but are moveable or 'floating,' this allows perfect expansion and contractio

of the tubes to take place, and prevents all possibility of 'working' of the tubes in the tube pla which would cause leakage.

A very important point in this design of heater is that as there are no coils or bends in tubes, they can be cleaned at once of any oil deposits which may lodge on the tube walls wh using heavy oils, such as Mexican flux, or pitch and creosote mixtures.

Each tube is fitted internally with a withdrawable retarder which allows only a flat spi ribbon of oil to come in contact with the tube walls, thereby ensuring the highest efficiency.

The 'delivery filter' is made on exactly similar lines to the suction filter except that t strainers are perforated with much smaller holes, and are able to collect the very fine partic of grit and foreign matter which may pass through the suction filter and pump.

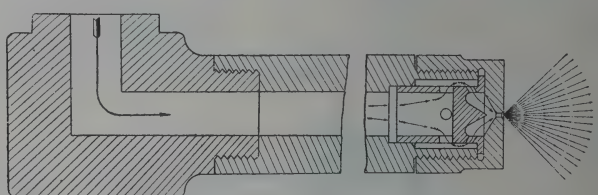

FIG. 39.—Thompson Patent Oil Fuel Atomiser.

The 'burner,' fig. 39, is of extremely simple design, there being only three component par *i.e.* the body, the nozzle, and the diaphragm. The atomising of the oil is obtained solely by t pump pressure forcing the heated oil through the tangential orifices in the diaphragm into the sw chamber, where a rotary motion of exceedingly high velocity is attained; this breaks up the so finely that on issuing from the nozzle it forms a hollow cone of oil mist or vapour which ligl up without noise or explosion when a lighted torch is applied. This burner is highly efficie and on actual service test has given results equal to 85 per cent. boiler efficiency.

For 'lighting up' boilers from cold without the use of steam or any outside source of power 'lighting up heater,' fig. 38, is used; this consists of a small straight tube heater made on the sar principle as the larger steam heaters, but the necessary heat is obtained by two self-heati paraffin lamps which are fixed below the heating tubes, and are also attached to a tank belo which contains the supply of paraffin. The tank is also provided with an air pump for putti air pressure on the paraffin to force the same through the lamps. The flame from these paraf lamps passes through and over the nest of tubes in the heater, thereby heating the fuel oil, whi is circulated through the same by means of a special valveless rotary hand pump; the hot is then led back through connections to the main oil supply lines in order to distribute it any of the furnaces of the boilers. With this apparatus it is possible to start up the fires in abo five minutes from the time of opening out the connections. The whole arrangement is specia designed for safety, and for this reason is connected up in a permanent manner to the oil-delive lines, so that the use of portable pipes and connections is avoided, which prevents any oil bei spilt about the stokehold floor plates, with the consequent danger of fire.

The steam that has been used for heating the oil in the main fuel heaters is drained off throu a 'collector,' which prevents the passing of live steam, and then to a 'filtering observation tan which is specially designed to prevent oil which may be contained in the drain water being pass back into the boiler as feed; as this tank works under atmospheric pressure, the contents a open to observation at any moment. An arrangement of division plates causes an under-wat circulation and allows the oil to float to the top of the various compartments. A filter chamb is provided near the outlet end, and is usually fitted with coke breeze, which can be removed any time for cleaning.

In cases where an extremely small amount of oil is to be consumed, as in small heating boile galley ranges, rivet-heating furnaces, etc., a steam or air jet burner is often advisable, and Smith installations of these types have been specially adapted for this class of work.

FILMA OIL-BURNING SYSTEM.

The Filma oil burners are distinct from marine oil-burning equipment, being intended primari for industrial application for manufacturing and steam-raising processes.

The burners are of three types, but all operate on the system of low pressure atomisation b means of multiple converging steam or air streams.

The oil before atomisation is spread out into a wide continuous flowing film, and is allowed o fall into the paths of atomising streams, which converge in one plane and diverge in the other.

The oil is therefore atomised between the opposing streams as they collide in one plane, and is ıen diffused by their divergence in the other.

Illustrations of this action are shown below.

The collision of the atomising streams causes them to give up the major part of their velocity, ıd the consequent oil mist resulting from the impact drifts forward and outwards at a rate hich permits perfect combustion with a soft flame; thus avoiding the local overheating or ıtting action which results from high velocity flames of concentrated energy.

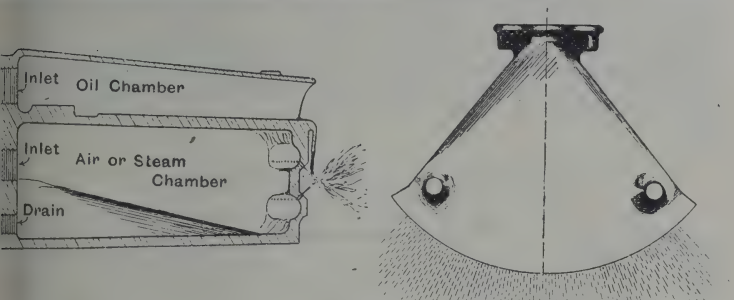

FIG. 39A.

The application of this system of atomisation is made in burners with fan blast, low-pressure and steam for horizontal, vertical, and downward firing.

The same system is also in extensive use for domestic heating appliances, quite apart from ınace and boiler work.

With these burners the quantity of atomising agent for power generation, calculated on ver available for steam generation, is with fan air about ½ per cent., with compressed air 2 per ıt., and with steam 4 per cent.

THE PRIOR OIL FUEL SYSTEM.

The burner in this system (which has been introduced by the Akt. Ges. Prior, of Lugano) has ough-like form and the oil flows into it by gravity. Air for burning the fuel is supplied through 's of holes drilled in the hollow walls. By varying the positions of these air apertures and the pe of the trough the burner can be adapted, it is claimed, for widely different services.

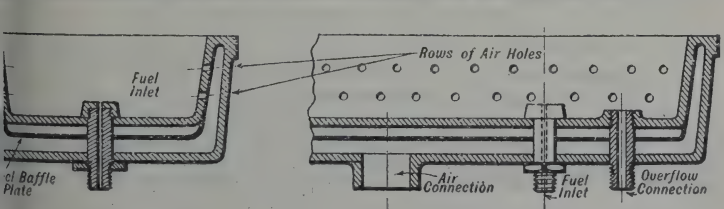

FIG. 39B.

The oil to be burned is fed by gravity, and an air pressure of about 8 in. water column is ided by a fan. The burner itself (fig. 39B) consists of an open cast-iron trough with hollow ls which serve as air-heating spaces. The oil is delivered at the bottom of the trough through or more inlet connections with approximately a $\frac{3}{16}$ in. aperture, terminating about ½ in. ve the bottom of the trough. There is also an oil overflow connection, which is lower. Air

to support the combustion of the oil is supplied through two rows of staggered holes which are arranged in the sides of the trough, and are given such an angle that the air jets tend to pick up the gasified fuel from the bottom of the burner. Below the bottom of the trough a steel baffle plate is welded on to the inner wall for the purpose of preventing undue heat from penetrating down to the air preheating spaces.

The burner is lighted by placing a piece of oily waste in the trough and turning on the fuel supply with a reduced quantity of air. Starting from cold the time taken may be only four to five minutes before the flame is brought up to a normal working height. If the burner has been previously in use the lighting-up period will be still shorter, while with a thoroughly hot burner the flame can be shut off and instantaneously re-ignited. A feature of the burner is the way in which the height of the flame can be regulated from only a few inches or about the height of the trough, to its full height of about 3 ft. Under varying loads a bright and smokeless flame can be maintained. An indexed fuel cock enables a constant flame height to be maintained without any attention on the part of the attendant.

A wide variety of oil fuels has been tested with the arrangement, and it has been found possible to burn heavy Mexican oils without trouble. With such oils there is a slight asphaltic deposit on the inner surfaces of the burners, which, however, can be easily removed. When using ordinary furnace oils the deposit is of a sooty nature and is dispersed automatically by the action of the flame.

Air Required for Oil Fuel Combustion.

The amount of air required in practice at normal atmospheric temperature for the combustion of 1 lb. of oil fuel, is from 250 to 450 cub. ft.; this is 1·6 to 2·5 times the theoretical amount.

British Admiralty Specification for Oil Fuel for the Navy.

(*Abstract.*)

'The oil fuel supplied shall consist of liquid hydrocarbons, and may be either (*a*) shale oil or (*b*) petroleum, as may be required, or (*c*) a distillate or a residual product of petroleum, and shall comply with the Admiralty requirements as regards flash-point, fluidity at low temperatures percentage of sulphur, presence of water, acidity, and freedom from impurities.

'The flash-point shall not be lower than 175° Fahr., close test (Abel or Pensky-Martens). 'The proportion of sulphur contained in the oil shall not exceed 3·00 per cent. The oil fuel supplied shall be as free as possible from acid, and in any case the quantity of acid must not exceed 0·03 per cent., calculated as oleic acid when tested by shaking up the oil with distilled water, and determining by titration with decinormal alkali the amount of acid extracted by the water methyl orange being used as indicator. The quantity of water delivered with the oil shall not exceed 0·5 per cent.

'The vicosity of the oil supplied shall not exceed 2,000 secs. for an outflow of 50 cubic centimetres at a temperature of 32° Fahr., as determined by Sir Boverton Redwood's standard viscometer (Admiralty type for testing oil fuel). The oil supplied shall be free from earthy carbonaceous, or fibrous matter, or other impurities which are likely to choke the burners.'

British Admiralty Specification for Oil Fuel for use in Diesel Engines.

'Quality :—The oil fuel supplied shall consist of liquid hydrocarbons, and may be either (*a*) shale oil, or (*b*) petroleum, as may be required, or (*c*) a distillate, or a residual product of petroleum, and shall comply with the Admiralty requirements as regards flash-point, fluidity at low temperatures, percentage of sulphur, presence of water, acidity and freedom from impurities.

'The flash-point shall not be lower than 175° Fahr., close test (Abel or Pensky-Martens). (This compares with a flash-point of 200° Fahr. in 1910.)

'The proportion of sulphur contained in the oil shall not exceed 3·00 per cent. (as against 0·75 in 1910).

'The oil fuel supplied shall be as free as possible from acid, and in any case the quantity of acid must not exceed 0·05 per cent., calculated as oleic acid when tested by shaking up the oil with distilled water, and determining by titration with decinormal alkali the amount of acid

extracted by the water, methyl orange being used as indicator. (In 1910 it was required that the oil should be free from acidity.)

'The quantity of water delivered with the oil shall not exceed 0·5 per cent.

'The viscosity of the oil supplied shall not exceed 2,000 secs. for an outflow of 50 cubic centimetres at a temperature of 32° Fahr., as determined by Sir Boverton Redwood's standard viscometer (Admiralty type for testing oil fuel).

'The oil supplied shall be free from earthy, carbonaceous, or fibrous matter, or other impurities which are likely to choke the burners.

'The oil shall, if required by the inspecting officer, be strained by being pumped on discharge from the tanks, or tank steamer, through filters of wire gauze having 16 meshes to the inch.

'The quality and kind of oil supplied shall be fully described. The original source from which the oil has been obtained shall be stated in detail, as well as the treatment to which it has been subjected and the place at which it has been treated. The ratio which the oil supplied bears to the original crude oil should also be stated as a percentage.'

Special Oil Mixtures used for External Combustion.

Pitch-Creosote Mixtures.

Recently the use of mixtures of pitch and coal tar creosote has become common for furnace firing.

The pitch creosote oils are marketed in three grades containing 25 per cent., 50 per cent., and 75 per cent. pitch respectively. As pitch is but little lower than creosote in heat value, and generally commands about half the price, there is a pronounced economic advantage in burning pitch mixtures wherever possible.

Petroleum-Tar Mixtures.

The addition of tar or tar products to heavy petroleum oils causes a thick semi-solid deposit of pitch to separate, and this has till recently prevented the use of such mixtures. This difficulty has recently been overcome by the use of emulsifying agents which are capable of maintaining the constituents in a state of emulsion for prolonged periods.

Coal Dust-Petroleum Mixtures.

The U.S. Navy authorities have met with success in preparing fuel mixtures from very fine coal dust mixed with petroleum fuel oil. The coal is prevented from settling by the action of emulsifying agents. Such oils are claimed to have given satisfaction for boiler firing on the U.S. warships.

Safety in Use of Oil Burners.

Serious accidents to engineers and firemen have frequently occurred from the practice of improper methods of lighting and handling oil fires.

In starting a new fire the steam should be turned on and the bypass opened in order that the oil and steam passage may be cleaned out and warmed up. The bypass should then be closed and the steam shut off. Then the damper must be opened ; on no account try to start a fire with a damper closed. Next light a torch or bunch of oily waste and place about 10 ins. to 12 ins. in front of the burner, turn on a small amount of steam (just enough to carry the oil from the burner tip to the torch) and crack the oil control valve a little. As it generally takes some little time for the oil to fill the burner passage, do not turn on more fuel but wait until the passage is filled, when the fire will light easily.

The moment the fire is out, either intentionally or accidentally, the oil should be shut off and the door opened. After a few minutes the gases (which are violently explosive) will have passed off and the fire may be rekindled.

In regulating a fire the attendant should hold the door open just enough to enable him to watch the flame and be in a position to duck his head in case of a flare back. To increase the fire the oil valve should be operated first, then the steam turned on until the flame is clear. If

not enough steam is used, the flame will appear red and smoky ; too much steam will cause the fire to look ragged and will have a tendency to extinguish it. In reducing the flame the steam is throttled down first, then the oil is reduced.

Once the fires have been set, they may be regulated over quite a range by increasing or decreasing the pressure applied to the oil supply without opening the fire-door or changing the steam supply. This can be done by manipulating the pump throttle or a bypass valve between the suction and discharge lines.

When extinguishing a fire, the flame should be cut down as low as possible ; then by opening the bypass immediately after shutting the oil valve, the oil passage will be blown out without danger, as the flame will not be extinguished until the passage is clear.—*A. C. McHugh.*

Automatic Regulation of Oil Burners.

The operation of oil burners can be made completely automatic by using in steam boilers the steam pressure, in water boilers the water temperature, and in furnaces the furnace temperature, for controlling automatic oil and steam or air valves. When air from an independently driven compressor or blower is used for atomising, it is important to provide automatic means for shutting off oil in case of failure of air supply, in order to avoid explosions.

For automatic control, oil must be kept at a constant temperature by automatically controlling the steam coil or electric heater in an oil-heating tank, otherwise control on account of viscosity changing with temperature is rendered difficult.

The Drayton Regulator and Instrument Co., Ltd., West Drayton, supply complete automatic regulating outfits.

Notes on Oil Fuel.

At a large London factory at which some Lancashire boilers were converted from coal to fuel oil firing, the water evaporation per lb. of coal, having a calorific value of 11,451 B.Th.U., was 7·22, whereas when working with the pressure system of oil burning, using an oil having a calorific value of 18,750, the evaporation per lb. of oil reached 14·44 lbs. The quantity of water evaporated per sq. ft. of heating surface with coal was 3·3 lbs., whereas, according to Mr. A. F. Baillie in a paper read before the Manchester Association of Engineers, the quantity evaporated with oil was over 7 lbs., thereby increasing the boiler rating by over 100 per cent.

In most engines of the hot-bulb type, oil fuel commonly known as gas oil or residuum is employed, this having a specific gravity of between 0·86 and 0·9. In some motors Tarakan crude oil has been used with success, whilst the other Mexican fuel oil, in spite of its relatively high percentage of sulphur, has operated very successfully. Paraffin is, of course, also suitable for these motors, but owing to its high price it is not often made use of.

Oil fuel heaters should be opened up and cleaned out periodically. In the operation of the average plant this should be done at intervals of not less than three months. Deposits of carbonised oil and other impurities quickly lower the efficiency of the heater by preventing the passage of the heat from the steam through the heater walls to the oil.

The fuel oil of oil-fired boilers is often maintained at too high a temperature. The best results are obtained where the oil is at a temperature just sufficient to insure proper and complete atomization. If too hot, the oil tends to turn into vapour and the burners puff and feed irregularly.

GASEOUS FUELS.

The more important gaseous fuels used commercially are generally mixtures. The combustible gases found in such mixtures are hydrogen, carbon monoxide together with the three hydrocarbons—methane, ethylene, and acetylene—also higher hydrocarbons of the series of which these are examples, together with benzene vapour, and occasionally other hydrocarbons.

Calorific Values, etc., of Gaseous Fuels.

In the table, p. 2157, the calorific values per lb. of the usual fuels are given, together with the weight of the products of combustion, both when burnt in pure oxygen and also when burnt in dry air. The 'higher value' is that obtained when the water produced in the combustion is considered as having been condensed to the liquid condition, thus yielding up heat at the rate of about 970 B.Th.U. per lb. produced.

Usually in calculations relating to internal combustion engines it is found more convenient to deal with the volume rather than the mass of the gaseous mixture ; accordingly in the

† Of mixture with air. * Lower values.

Hydrogen.

From the above table it will be noted that a hydrogen-air mixture contracts after combustion to only ·853 of its initial volume, the pressure of the explosion being correspondingly reduced. Further, notwithstanding the very high calorific value of hydrogen *per pound*, its excessive bulkiness results in a heat evolution of only 82 B.Th.U. *per cubic foot* of its admixture with air at 60°F. and atmospheric pressure. Hydrogen-air mixtures are also very sharply explosive and trouble is experienced in engines from pre-ignition at the compression pressures usual in practice when hydrogen is present in large proportion in a gaseous fuel. Thus it is clear that hydrogen alone would be a comparatively poor and very troublesome fuel to employ for power purposes, though its presence is often beneficial in conferring sufficiently prompt inflammability upon dilute mixtures of other gases. For heating purposes a large hydrogen content is advantageous on account of the high temperature obtained in its combustion. Hydrogen constitutes about 45 per cent. by volume of modern coal gas, on the average.

Marsh Gas.

Marsh Gas (Methane) is an excellent fuel for power purposes; it has a greater heat value per cubic foot of air mixture than hydrogen, and the volume of the products of combustion is equal to that of the mixture before combustion.

The 'natural gas' so largely used in the United States consists principally of marsh gas at of Olean (N.Y.), for example, containing no less than 96½ per cent. of this constituent. In 08 more than 100,000 horse-power was developed by engines operated by natural gas in the nited States; the gas usually issues from the wells at high pressure, occasionally approaching 000 lbs. per sq. in. The Snow engine of the N.Y. & Penn. Traction Co. at Olean is supplied r natural gas issuing at a pressure of 200 lbs. per sq. in., which is reduced down to 1·8 lb. per in. before being admitted, mixed with air, to the engine. With natural gas compression essures of 150 lbs. per sq. in. are common, and mean effective pressures of 80 lbs. per sq. in. e often attained.

Acetylene.

Acetylene has so far been but little used as a fuel for internal combustion engines. It is very olently explosive when mixed with air, and owing to its endothermic nature the pressure veloped is unusually high.

The range of explosive mixtures with air is also considerable; Grover found that at atmoheric pressure explosive mixtures were produced with one volume of acetylene to from 4 to volumes of air; at a compression of three atmospheres even a 30 : 1 air-acetylene mixture as found to be explosive.

Acetylene is soluble in water to the extent of 1·1 volume; in alcohol to about 6 volumes : nile acetone at 60°F. and atmospheric pressure absorbs about twenty-five times its volume the gas, and at a pressure of about 180 lbs. per sq. in., about 300 volumes. A solution of etylene in acetone contained in a porous matrix under a pressure of 150 lbs. per sq. in., is sold mmercially as dissolved acetylene ('D. A.'); the 'D. A.' cylinders contain 100 times their vn volume of acetylene at 60°F. and ten atmospheres. Commercial calcium carbide on ldition of water usually yields about 4½ cubic feet of acetylene per lb.

If bubbled through petrol, acetylene gas becomes heavily 'carburetted'; 100 cubic feet acetylene thus treated will produce about 150 cubic feet of 'carburetted' acetylene. ccording to Dr. Caro, as a heating agent this exceeds pure acetylene about in the ratio of 3 : 2.

Used as a fuel for internal combustion engines some remarkable results have been obtained ith acetylene. Some early tests on a 2 h.p. engine showed that only 8¾ cub. ft. of the gas were quired per b.h.p. hour, as against 35 cub. ft. of coal gas. In another case 6·35 cub. ft. of acetyne yielded 1 b.h.p. hour. And with a 6 h.p. engine using a 20 : 1 mixture, and a compression essure of 115 lbs. per sq. in., Cuinat found that only 6·26 cub. ft. of acetylene were consumed r b.h.p. hour, the consumption by volume of coal gas being about three times as great. Specially signed acetylene engines of from 1 to 10 b.h.p. are built; these are mainly employed in pumpg water for the generators of large village installations. The average consumption is about cub. ft. of acetylene per b.h.p. hour, costing about 2½*d.*; it is thus an expensive fuel for power rposes, as at present produced.

Several types of acetylene self-starting devices for the engines of motor vehicles have appeared ring recent years, but unless caution be exercised in their use the extreme suddenness and olence of the starting explosion may result in damage to piston or cylinder.

See also Index.

Carbon Monoxide.

Carbon Monoxide yields the large return of 95·2 B.Th.U. per cubic foot of mixture with r, notwithstanding its low calorific value per lb.; this results from its weight being fourteen mes that of hydrogen. The products of combustion occupy, however, only 0·835 of the volume the original mixture; it is the principal combustible constituent of producer and blast furnace as. Carbon monoxide is extremely poisonous, forming with the red corpuscles of the blood a able chemical compound of a bright red colour termed carboxyhæmoglobin; care must always e taken to prevent any leakage of the gas into the atmosphere, and all engine and producer ouses should be freely ventilated.

Olefiant Gas.

Olefiant Gas (Ethylene) is usually present to a small extent (up to about 4 per cent. by olume) in coal gas, and is a valuable producer of heat.

Owing to Government restrictions on the use of petrol during the war, many trials were made n the use of coal gas as a fuel for motors designed for the use of liquid fuels. Large gas-proof ags have been attached to the roofs of taxi-cabs, or placed underneath motor buses, and good nning obtained by filling up with coal gas at frequent stopping stations. Needless to say, the ileage of such an arrangement is very limited; otherwise its performance is quite satisfactory, nd, at present prices, considerably more economical than the use of petrol.

GASEOUS FUELS EMPLOYED IN GAS ENGINES.

1. Natural Gas.
2. Coal Gas. (See p. 2160.)
3. Coke-oven Gas. (See p. 2161.)
4. Acetylene Gas. (See p. 2161.)
5. Producer Gas. (See p. 2161.)
6. Blast Furnace Gas. (See p. 2177.)

1. NATURAL GAS.

Natural Gas.—Large quantities of natural gas are evolved in most petroleum oilfields. The composition of the gas varies in different localities, but it always contains a high percentage f methane. The net calorific power is usually 750 to 950 B.Th.U. per cubic foot. It is used n gas engines and for heating and illuminating purposes.

2. COAL GAS.

Coal Gas is still almost exclusively used in the smaller sized stationary gas engines, especially in towns ; it is an admirable fuel for internal combustion engines of any size, however large but its use for considerable powers is usually precluded by its relatively high cost. The introduction of the Welsbach mantle, and the largely increased use of gas for domestic heating and cooking, has enabled the gas companies within recent years to supply a gas of lower intrinsic calorific power than formerly at less cost to the consumer, and this reduction in cost has done much to encourage its use for power purposes.

Calorific Power of Coal Gas.

Since the introduction of the Gas Regulation Act in 1920 the gas undertakings in Great Britain ceased to operate on official standards of candle power and are now subject to penalties in default of maintaining their respective standards of calorific power. The choice of calorific power of the gas which is distributed is left in the hands of individual undertakings, thus a wide range of quality is found throughout the country. When utilised in gas engines the factor of calorific power plays an important part, so that the operating data and adjustment of the engine must depend largely on the quality of the gas supply in any particular district. In general, it may be said that the calorific power of the gas supplied by undertakings in the country varies between 470 and 500 B.Th.U. per cubic foot, but there are a few outstanding exceptions, as, for example, the South Metropolitan Gas Company of London which distributes a gas of 560 B.Th.U. per cubic foot, and the Nuneaton Gas Company whose standard is 280 B.Th.U.

CALORIFIC STANDARDS.

	Calorific value of gas.
London (Gaslight & Coke Company)	500 B.Th.U. per cu. ft.
,, (South Metropolitan Gas Company)	560 ,, ,, ,,
,, (Commercial Gas Company)	500 ,, ,, ,,
,, (Wandsworth Gas Company)	470 ,, ,, ,,
,, (South Suburban Gas Company)	500 ,, ,, ,,
,, (Tottenham Gas Company)	500 ,, ,, ,,
Manchester	450 ,, ,, ,,
Liverpool	475 ,, ,, ,,
Birmingham	500 ,, ,, ,,
Bristol	480 ,, ,, ,,

So far as the composition of towns' gas is concerned, it is not possible to lay down any arbitrary figures for the reason that the ultimate analysis varies not only in different localities, but it varies to some degree even in the same locality in accordance with the proportion of water-gas which is added to the mixture of coal-gas and water-gas distributed. As a general guide, however, the analysis given below represents the composition of a normal straight coal-gas having a calorific power of 520 B.Th.U. per cubic foot.

Composition of 520 B.Th.U. Coal-Gas.

	Per cent. by Volume.
Hydrogen	47·0
Methane	27·5
Unsaturated hydrocarbons	3·5
Carbon monoxide	7·75
Carbon dioxide	3·5
Nitrogen	10·5
Oxygen	0·25
	100·00

The gas supplied to-day by nearly all the principal undertakings consists, however, of a mixture of from 75 to 80 per cent. of straight coal-gas (of above analysis) and 20 to 25 per cent. of either blue or carburetted water-gas. In this case the typical composition will be represented by the following analysis :—

Composition of Mixed Gas consisting of 80 per cent. Straight Coal-Gas and 20 per cent. Blue Water-Gas. (480 B.Th.U.)

	Per cent. by Volume.
Hydrogen	48·0
Methane	22·2
Unsaturated hydrocarbons	2·8
Carbon monoxide	13·8
Carbon dioxide	3·7
Nitrogen	9·3
Oxygen	0·2
	100·0

It is important for the gas-engine user to bear in mind that in recent years it has been established at one B.Th.U. will always give the same service irrespective of the quality or concentration of a mixture. In other words, from the point of view of efficiency a poorer mixture (say, 400 Th.U.) can be utilised as efficiently as a rich one (say, 550 B.Th.U.) so long, of course, that combustion is always complete. Proper adjustment depends, therefore, on the variation of the air supply in accordance with the quality of the gas in any particular locality. The volume of air theoretically just necessary for complete combustion may be estimated by aid of the second table page 2158.

Increased economy in consumption is obtained by using mixtures of gas with such excess air, or other gases, that only about 50 B.Th.U. are introduced per cub. ft. of piston displacement for cylinders up to about 20 ins. diameter, while for larger cylinders (30 ins. dia. and above) the figure must be reduced to 40 or even 35 B.Th.U. in order to avoid overheating troubles.

When excess of oxygen is present in the mixture, practically no carbon monoxide is found in the exhaust; with deficiency of oxygen, or irregularity in the mixture, the contrary is to be expected.

Usually in practice the volume ratio of mixture employed is from 7 to 10 of air to 1 of coal gas; the richer mixture gives a greater power output, the more dilute a greater economy in consumption of gas per horse-power hour.

3. COKE-OVEN GAS.

Coke Oven Gas is produced in large quantities at many collieries in the process of manufacture of coke for metallurgical purposes; its composition varies somewhat widely, but it is usually specially characterised by its large content of hydrogen; this renders it peculiarly liable to pre-ignite on compression, and lower compression pressures than usual are generally adopted (to 100 lbs. per sq. in. only) on this account when coke-oven gas is used for power purposes.

Recently, however, the pre-ignition difficulty has been entirely overcome by Sir Dugald Clerk's patented process of introducing from 10 per cent. to 20 per cent. by volume of cooled *exhaust gas* into the inlet pipe; the addition of this inert gas reduces inflammability by diminishing the quantity of oxygen present, and diluting the charge without reduction of its mass. The application is very simple and easily made, and the maximum practicable power of the engine is materially increased.

An average characteristic composition by volume of coke-oven gas may be taken as:—

H, 50 per cent.; CH_4, 25 per cent.; CO, 5 per cent.; $CO_2 + N + O$, 20 per cent.

Such a gas has a lower calorific value per cub. ft. at 60° F. (15·5° C.) and 1 atm. of about 390 B.Th.U., and requires, roundly, 3¾ cub. ft. of air for complete combustion; the heat evolved per cubic foot of this maximum mixture is accordingly $\frac{390}{4{\cdot}75} = 82$ B.Th.U. Actually, the calorific value varies from 350 to 450 B.Th.U. per cub. ft. at 60° F. and 1 atm., and requires from 3 to 4 cub. ft. of air for complete combustion.

In a test by Prof. E. Meyer of a 500 h.p. two-stroke Borsig-Oechelhauser engine of 26½ ins. bore and 37½ ins. stroke (of each piston), running at about 106 revolutions per minute, and driven by coke-oven gas of 395 B.Th.U. (lower) value per cub. ft., the heat consumption per b.h.p. hour deduced from the blower driven by the engine amounted to 9,070 B.Th.U. corresponding to $\frac{9070}{395} = 23$ cub. ft. of coke-oven gas per b.h.p. hour only; the mean effective pressure averaged 70 lbs. per sq. in.

4. ACETYLENE GAS.

Experiments carried out in Germany with acetylene gas for internal combustion engines showed that the proportion of air to gas should be in the ratio of 12·02 to 1 to avoid the formation of soot. The maximum compression which may be used for a mixture of acetylene and air is about three atmospheres, compared with 4–5 atmospheres for petrol and 7 atmospheres for coal gas. One ton of carbide is sufficient to produce 10,000 cubic feet of acetylene.

5. PRODUCER GAS.

In normal combustion, when an excess of air is present in the combustion space, the carbon of the fuel is burnt to form carbon dioxide according to the reaction

$$C + O_2 \rightarrow CO_2.$$

Nitrogen from the air passes through the combustion space into the resulting gas without entering into the reaction. By this reaction one pound of carbon generates 14,647 B.Th.U.

By restricting the air supply and arranging to maintain a comparatively great depth of fuel on the grate the carbon may be burnt into carbon monoxide according to the reaction

$$2C + O_2 \rightarrow 2CO,$$

Nitrogen again passing through the grate without being affected.

By this latter reaction, 4,400 B.Th.U. are generated for each pound of carbon gasified the residual heat value obtainable from the carbon by complete combustion, *i.e* 14,647 − 4,400 = 10,247 B.Th.U., remaining in the resultant gas.

The greatest quantity of heat obtainable in the form of cool carbon monoxide from the air-carbon reaction is therefore only $\frac{10,247}{14,647} = 70$ per cent. of the heat originally available in the carbon.

Of the 30 per cent. of heat given out during the reaction, a large portion leaves the producer in the form of sensible heat.

The heat generated in the producer is sufficient to cause a temperature too high for satisfactory working.

In order to cool the producer and to utilise this excess of heat, steam is introduced into the combustion space, when, if conditions are favourable, the following reaction takes place:

$$C + H_2O \rightarrow CO + H_2$$

For each pound of fuel entering into the reaction 4,320 B.Th.U. *are absorbed* from the heated fuel.

By the use of air and steam in certain proportions, it is possible to absorb the excess heat generated by the air reaction and maintain a practically constant temperature in the producer.

By alternately blowing the producer with an excess of air and raising its temperature by the combustion of carbon, either to the monoxide or to the dioxide, and then cutting off the air supply and passing steam into the hot fuel until the producer temperature has again fallen, it is possible to generate water gas (the result of the steam-carbon reaction) which may be collected separately.

Water gas in conjunction with oil gas (generated by the cracking of heavy petroleum distillates) is largely used for the preparation of illuminating gas in normal times.

As the fuel used is not pure carbon, other considerations than those mentioned in the above theoretical outline affect producer design and working. As coals undergo a destructive distillation in the producers it is necessary to make use of special devices for the removal of tar from the producer gas. The recovery of ammonia generated from the nitrogen of the coal is also of the greatest importance in the economics of producer gas plants. These particulars are treated in greater detail in the following descriptions of various types of plant.

(*a*) Pressure producer gas from anthracite (Dowson).
(*b*) " " " " coke (")
(*c*) Suction and suction-pressure producer gas from anthracite (Dowson).
(*d*) " " " " wood, sawdust, chips (Dowson).
(*e*) " " " " charcoal (Dowson).
(*f*) " " " " coke and anthracite (Dowson).
(*g*) " " " " coke (Dowson).
(*h*) " " " " bituminous coal (Dowson).
(*i*) Pressure producer gas from bituminous coal (Mond).
(*j*) Suction and suction-pressure producer gas from anthracite (Mond).
(*k*) " " " " coke (")
(*l*) " " " " charcoal (")
(*m*) Suction-pressure producer gas from wood, semi-bituminous (")
(*n*) Suction producer gas from bituminous coal (Farnham).
(*o*) Producer gas from other substances, as colliery refuse, sawdust, wood chips, cocoanut shells, belt pickings, lignite, and peat.

In the table on page 2163 some results of analyses are given of producer gas from anthracite coke, and bituminous coal. The number of cu. ft. of air necessary for just complete combustion is obtained by aid of table on page 2158 from the formula :—

$$\text{Cu. ft. of air} = \frac{4{\cdot}8}{100}\left\{\tfrac{1}{2}(H + CO) + 2\,CH_4 - O\right\}$$

Gas Producers and Producer Gas.

Some account of producers and producer gases from material supplied by manufacturers of gas plant is given hereunder :—

Dowson Gas.

The Dowson gas is made by passing a mixture of superheated steam and air through incandescent fuel. There is no external fire, as in ordinary gas retorts, and no skilled labour is required to work the apparatus.

The original type of Dowson plant included a small steam boiler, to give the steam required and to work an air injector. Excellent results have been obtained in this way, and for some purposes it is still the best plant to use. It is now known as the 'Dowson Steam-jet Pressure Plant,' and is used when gas is required from one apparatus to serve several gas engines or one or more engines and heating appliances.

Another type of Dowson gas-making plant is the 'Dowson Suction Plant,' which has been installed in large numbers in this and many other countries. This type of apparatus requires no boiler or gas-holder, and the engine itself draws the air required through the fire in the gas generator: the engine, therefore, governs the rate of producing the gas to suit its varying consumption, and there can be no waste of gas. Moreover, the dry steam required is produced by waste heat, and the fuel which is to be converted into gas is also heated by waste heat before it reaches the combustion zone. Throughout the apparatus the loss of heat is therefore reduced to a minimum, and the efficiency is exceptionally high. Sir Dugald Clerk's 'James Forrest Lecture,' delivered in 1904 to the Institution of Civil Engineers, refers to exhaustive tests made by him with this suction plant, the heat efficiency being proved to be about 90 per cent.

In both types of the Dowson apparatus anthracite peas or nuts, charcoal, or coke can be used. The consumption depends somewhat on the type of plant and the kind of fuel used. With the suction plant the Dowson Company guarantee that the consumption of small coke of good quality will not exceed 1¼ lb. per b.h.p. per hour, at full load, with any good gas engine suitably adjusted for working with the plant.

If anthracite peas (from ⅜ in. to ¾ in. cube) are used, the consumption is guaranteed not to exceed 0·9 to 1 lb. per b.h.p. per hour.

As regards stand-by losses careful independent investigations have shown that at four different places Dowson gas generators, ranging from 100 to 375 b.h.p. each, during long stand-by hours, consumed an average of only 3 lbs. per generator per hour, while gas of good quality could be ready for use in about ten minutes. With steam power the stand-by loss is far greater.

A further important advantage of the gas is that it does not condense or lose power on its way to the engine; on the contrary, the more the gas is cooled the better it is for the engine, as each charge of gas which enters the cylinder is more dense, and has consequently greater energy. With steam the condensation in the pipes, etc., is considerable; with gas there is no such loss. It is easy to prevent leaks of gas from the piping, owing to the low pressure of the gas, whereas with steam there is often much loss and inconvenience on this account.

With the suction plant there cannot be a leak of gas when the engine is working, but piping, scrubbers, etc., must be absolutely tight to avoid air leaks.

The wages of firemen are about the same for the gas plant as for a steam boiler of equal power.

The quantity of water per b.h.p. per hour in the gas plant is about 1 gall.; with steam power it is usually two or three times as great. The cost of repairs (pre-war period) is approximately as follows:—

For 100 b.h.p.	£4 per annum.	For 400 b.h.p.	£12 per annum.
„ 200 „	6 „ „	„ 500 „	15 „ „
„ 300 „	9 „ „		

As regards labour, with the suction plant the usual allowance is one man for about an hour each day to start the fire, clean, etc., and about one hour per day to put fuel in the generator. When the plant is worked with a boiler the labour required is greater, but not more than for steam power of equal size.

Although about four volumes of Dowson gas are required to do the same work in a gas engine as one volume of town gas, yet Dowson gas is produced so cheaply that the equivalent of 1,000 cubic feet of ordinary town gas costs only seven to twelve pence, according to the scale of working and price of fuel.

With Dowson gas 1 lb. of coal will produce ·70 cubic feet of gas, and 1 cubic foot of this gas requires only 1·1 cubic foot of air for complete combustion, against 6 to 8 cubic feet for ordinary gas.

A complete Dowson apparatus does not occupy more space than that required for the boiler of a steam engine of the same power.

Dowson gas is used for heating and furnace work of all kinds, as it is a cheap and cleanly fuel, under perfect control.

Their latest plant for heating is known as the high pressure type wherein the gas can be boosted to any pressure up to 100 ins. w.g., delivering the gas clean and steady to the burners. The producer is of the open-hearth type similar to the producer used on their latest suction plant. Space will not permit giving varied examples of the performance of plant and the splendid results with the gas obtained, even for delicate work such as singeing.

The following comparative estimates (pre-war period), for 25 and 50 b.h.p., show that it is much cheaper to use gas power than electricity, even where the latter is sold at 2*d.* per unit:—

25 B.H.P.	Per week. £ *s.* *d.*	Per annum. £ *s.* *d.*
Electricity—25 B.H.P.=18¾ B.Th. units×50 hours =937½ units at 2*d.*	7 16 3	390 12 6
Town Gas Power.—25 B.H.P.×20 cubic ft.×50 hours=22,500 cubic ft. at 2*s.* 6*d.*	2 16 3	140 12 6
Dowson Gas Power.—25 B.H.P.×85 cubic ft.×50 hours=106,000 cubic ft. at 3*d.*	1 6 6	66 5 0

50 B.H.P.	Per week. £ s. d.	Per annum. £ s. d.
Electricity.—50 B.H.P. = 37½ B.Th.units × 50 hours = 1,875 units at 2*d.*	15 12 6	781 5 0
Town Gas Power.—50 B.H.P. × 20 cubic ft. × 50 hours = 45,000 cubic ft. at 2*s.* 6*d.* . . .	5 12 6	281 5 0
Dowson Gas Power.—50 B.H.P. × 85 cubic ft. × 50 hours = 212,000 cubic ft. at 3*d.*	2 13 0	132 10 0

More recently Mr. Dowson has introduced a new type of producer, to work with bituminous al, which is a new departure in several respects. In producers which are worked with bitumin- s coal the tarry vapours from the hydrocarbons in the fuel mix with the gas, and the tar is ually afterwards extracted in separate apparatus. Mr. Dowson has always held the opinion at the tar should be got rid of in the producer itself, and he has succeeded in doing this.

The producer is double-acting—*i.e.* air is drawn in through the top and through the bottom the fuel column. The coal is put in at the top, and the upper part of the fire burns down- ards. The hydrocarbons are distilled off and various reactions occur, the coke which remains aks downwards into the lower part of the producer. The coke is there converted into ordinary oducer gas by the upward current of air (accompanied by steam), which is drawn in at the ttom. The mixture of gases leaves the producer through an outlet about halfway between e top and bottom. There is no external fire, and the gas is made as quickly as it can be con- med, as in the other types of Dowson gas plant.

When working with ordinary bituminous coal, or with lignite and several other varieties of el, there is no tar; it is removed altogether in the producer, and no mechanical or other tar ttractor is required. After leaving the producer the hot gas passes through a vaporiser to ol the gas, and to raise the steam required for making the gas. It then passes through suitable rubbers and is ready for use in the engine to be worked with it.

This bituminous plant is worked by suction, and consequently there is no escape of gas; is also easy to work, and the cost of labour is about the same as with an ordinary plant orking with anthracite or coke.

When the plant is to be worked by the suction of an engine as in the smaller powers, viz., up to 100 h.p., there is a fan to start it, as in ordinary suction plants, and this is stopped when ne engine is running. For powers 100 h.p. and upwards there is a fan or blower to draw the as from the plant and deliver it to the various engines or heating apparatus requiring gas. ach fan or blower produces the suction on the plant and governs the make of gas. Of course ith all heating work and where there is more than one engine requiring gas, even for the small owers, a fan or blower is always installed to deliver the gas under pressure.

The quality of the gas made in this plant is about the same as that of gas made with coke ordinary suction plants. The heat efficiency of the new plant is exceptionally high, and with good engine under full load the consumption of fuel is little over 1 lb. per b.h.p. hour. The and-by losses are small, and after standing over-night or during meal hours, good gas can be eady for the engines in a few minutes.

Many plants of this description have been installed both at home and abroad for industrial nd municipal undertakings with splendid results, and in the case of the foreign installations the eal in some cases being much inferior to our British standard. These plants can be made in ny size from 25 to 500 b.h.p.

The Kerpely Revolving Grate Gas Producer.

The Kerpely Gas Producer, with its mechanical ash discharge and mechanical feed and gitators, is entirely mechanical in operation. It effectively gasifies good or bad fuels, even aste fuels containing nearly 50 per cent. ash. As an example of the latter fuel, mention is ade of an installation of Kerpely gas producers at a colliery in Scotland for gas-firing colliery oilers. The fuel gasified is unsaleable from the colliery and consists of 'parrot' and 'belt ickings of the following approximate analysis:—

Parrot and Belt Pickings Mixed.

Fixed carbon (by difference)	24·50
Volatile matter	23·22
Ash	48·10
Moisture	4·18
	100·00
Calorific value	6,580 B.Th.U. per lb.

It will be noted that the fuel contains *nearly* 50 *per cent. of ash.*

The following is an average analysis of the gas produced from this fuel by the Kerpely producers, viz.:

CO_2	5·80
O	0·58
CO	23·21
H	11·50
CH_4	2·85
N	56·06
	100·00

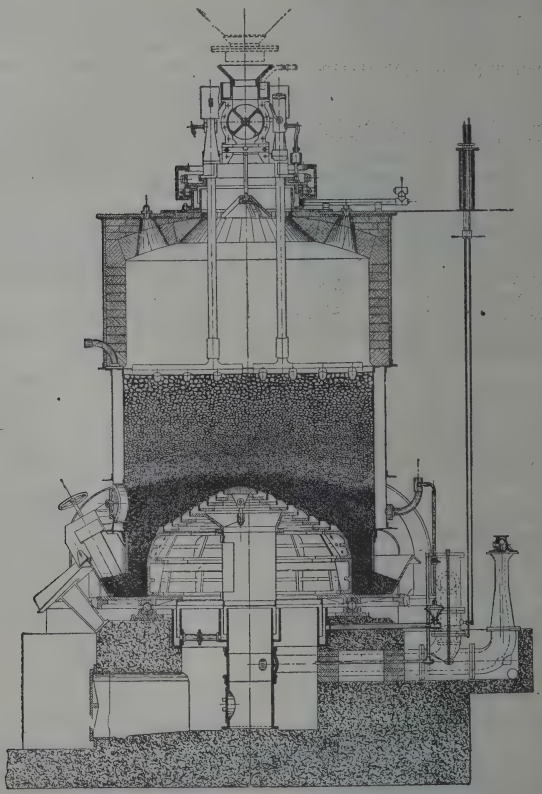

FIG. 40.—The Kerpely Revolving Grate Gas Producer.

The Kerpely grate, a sectional view of which (dimensioned for the standard 3-metre diameter producer) is shown by fig. 40, is of polygonal shape and is placed eccentrically on the water trough. It has a continuous and not an intermittent action in crushing any formation of clinker that may occur. The water-cooled jacket in the fire zone prevents the formation of clinker on the walls of the producer. The clinker, when entering the ash zone, is caught by the numerous edges of the revolving grate and pressed horizontally sideways against the seal apron, and is consequently broken or crushed into small fragments, which, dropping into the water trough, are removed by the ash scraper. The latter automatically discharges the ash and clinker accumulating in

he bottom of the producer, and, being constructed to suit the shape of the ash trough, the ash is ot only pushed aside, but is piled up and continuously discharged into an ash shoot. The auto- iatic discharge of the ash and clinker from the Kerpely producer results in considerable saving f labour in the removal of ash, and ensures continuous working of the producer and gas of uniform uality. Labour is saved in poking, a small amount only of steam is required, and a dry gas is btained, which ensures a prolonged life of the furnace linings. The supply of air and steam to he Kerpely producer is separately conveyed to the inner and outer sections of the grate, and, eing transmitted through spaces between the plates of the revolving grate, ensures uniform ombustion over the whole grate area, the maximum gasification capacity per square foot of grate rea, and effective control of the fuel bed.

The Kerpely producer can be fitted with the Appleby-Bentley Patent Mechanical Rotary uel Feed and Distributor, or this mechanical feed combined with patent balanced and adjust- ble fuel agitators and levellers, as the fuel conditions may determine.

These mechanical feeds and agitators are claimed to ensure greatly increased gasification 0 to 100 per cent., according to type of producer), constant high-value gas, saving of labour nd fuel, and greater production from furnaces. The following table gives daily working results aken over a period of one month with a Kerpely gas producer fitted with the Appleby-Bentley echanical feed and agitator:—

KERPELY PRODUCER WITH MECHANICAL FEED AND AGITATORS (BENTLEY'S SYSTEM).

APPLEBY-BENTLEY PATENT MECHANICAL GAS PRODUCER.

This producer is mechanical in its action, as regards fuel feeding, agitating and levelling, ash evelling and discharge. The fuel is carbonised, then gasified, producing high or low temperature as as desired from the same producer. The apparatus has an improved blast distribution, ffecting perfect combustion with high gasification. Cheap fuels can be effectively gasified y its means.

CAMPBELL GAS PRODUCERS.

The Campbell Gas Engine Co. are makers of several types of suction producers. They were among the pioneers of the enclosed type, which is still their standard for anthracite or coke and—with certain modifications—for charcoal.

Another type, first introduced by the Campbell Gas Engine Co., is the open-hearth suction gas plant, which is particularly suitable for inferior anthracite, collie coal, and small coke. It also works successfully with locomotive smoke-box char, and plants to use this fuel have been supplied to the leading British railways and to railways abroad.

A third type of gas plant built by this company is designed for working with bituminous non-caking coal, lignite, etc. This plant works on the double draught principle in order to convert a considerable proportion of the tarry matter from the fuel into a fixed gas in the producer, and thus dispense with complicated scrubbing and cooling apparatus.

A fourth type of suction gas producer with which this firm have achieved success is their refuse fuel plant. This as its name indicates is used for gasifying all descriptions of vegetable refuse in such forms as wood chips, sawdust, olive refuse, cotton seed, rice husks, etc. Plants of this type have been operated for considerable periods on sawdust alone with entirely satisfactory results. The consumption of such fuel varies considerably according to its quality, but averages about 3 lbs. per b.h.p. per hour.

These gas plants are supplied from 28 to 640 h.p. Several large plants have been supplied to leading British railway companies in conjunction with vertical gas engines and run entirely on the refuse produced in the wood-working shops, developing more than sufficient power to drive the whole of the machinery in these shops.

Ample 'scrubbing' capacity is provided in all types, and careful provision is made for easy access to all parts for cleaning, thus keeping running costs at a low level.

The 'Crossley' Suction Gas Plants.

Messrs. Crossley Brothers, Ltd., build several types of suction gas plants, each specially designed to suit the various classes of mineral and refuse fuels.

The producer manufactured by them to work on anthracite, coke, or charcoal is of the open-hearth type shown by fig. 41.

With this type of producer the fire is always in full view of the operator, the firegrate consisting of a number of annular cast iron plates arranged in the form of steps and so disposed that the outside edge of each succeeding lower plate lies beyond the angle of repose of the fuel which falls through the opening in the plate above. These grate plates are supported on cast iron legs which also support the producer itself, comprising a simple steel shell internally lined with firebricks.

The grates are cooled by water which is supplied by small drip pipes to the top plate, from whence it overflows on to each succeeding plate in turn; a certain amount of steam is thus generated which assists in the gas production.

As will be seen from the fig. the lower part of the fuel bed can at all times be readily cleaned of ash and clinker without interfering with the process of gas making or necessitating shutting down of the plant, indeed, numbers of these plants have worked continuously for over 12 months without the fire having to be withdrawn for any purpose whatever.

The absence of a vaporiser in the top of the producer enables the operator to use a poker in a direction parallel to the firebrick lining, the clinkers being thus very easily broken away, without injury to the brickwork, and allowed to drop on to the grate plates, from whence they can be removed at will.

From the producer the hot gas passes into an external vaporiser consisting of a casing supporting a cast iron box divided into compartments, to the under side of which a number of water tubes are fixed.

With the exception of the first and the last in the series, the tubes are provided with internal circulating tubes of the 'Field' type.

The water to be vaporised is carried to the bottom of the first tube through an internal feed pipe and then rises into the first compartment, from which it passes in through each succeeding compartment and tube in turn, until finally it is flashed into steam in the last tube, which also forms the steam connections between the vaporiser and the producer. The steam is taken from the vaporiser into an annular box-shaped casting situated at the base of the producer, from which it is distributed to the fuel bed through a number of small holes drilled around the inside edge.

In this design of plant the gas is external to the water to be heated, so that both the cooling of the gas and heating of the water are effectually provided for.

Leaving the producer, the partially cooled gas passes through two cascades of water produced by the overflow from the cooler and scrubber; these remove the heavier impurities from the gas. It is next passed through a cooler and scrubber consisting of two coke charged compartments, each

tted with separate cleaning and charging doors, so arranged that the coke in the lower compart-ent (which is the first to become fouled) can be removed without interfering with that in the

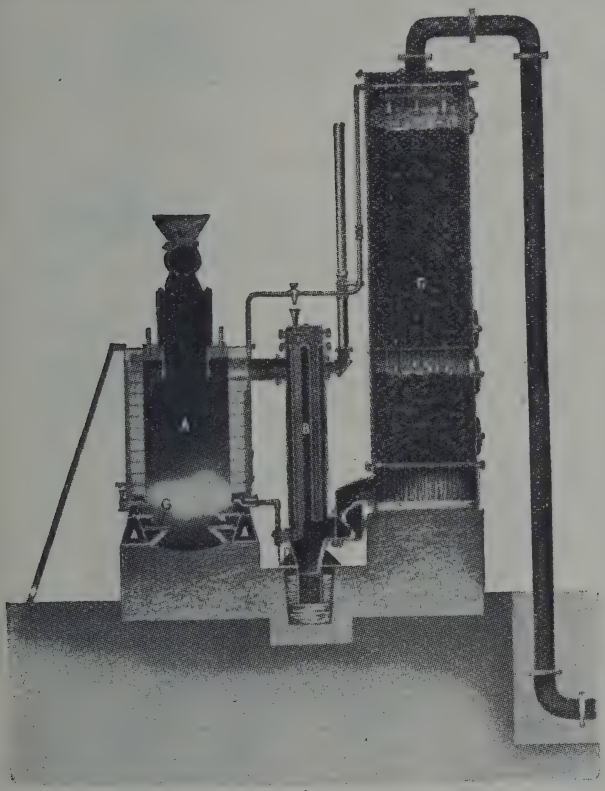

FIG. 41.—'Crossley' Suction Gas Plant.

pper compartment. During its passage through the coke the gas is thoroughly cooled by streams f water supplied by the spray situated above the top layer.

Leaving the scrubber the gas passes into a combined drier and expansion box and from thence o the engine.

'CROSSLEY' REFUSE FUEL PLANTS.

'Crossley' refuse fuel plants are designed to work on a variety of fuels, including waste wood f all kinds, spent tan, rice husks, olive refuse, sugar cane refuse, cocoanut shells, coir dust, cocoa nd coffee refuse, etc. Particular attention has been given by the designers to the removal of mpurities from the gas and to allow of continuous working of the plant by unskilled labour. A ectional view of a 'Crossley' Refuse Plant is shown by fig. 42.

The lower part of the producer is similar in design to that of the anthracite plant previously lescribed, with the exception that the grate is shielded by carrying the external shell to the oundation block.

Access to each section of the grate for removal of ash is provided for by large cleaning doors

CROSSLEY REFUSE FUEL PLANT.

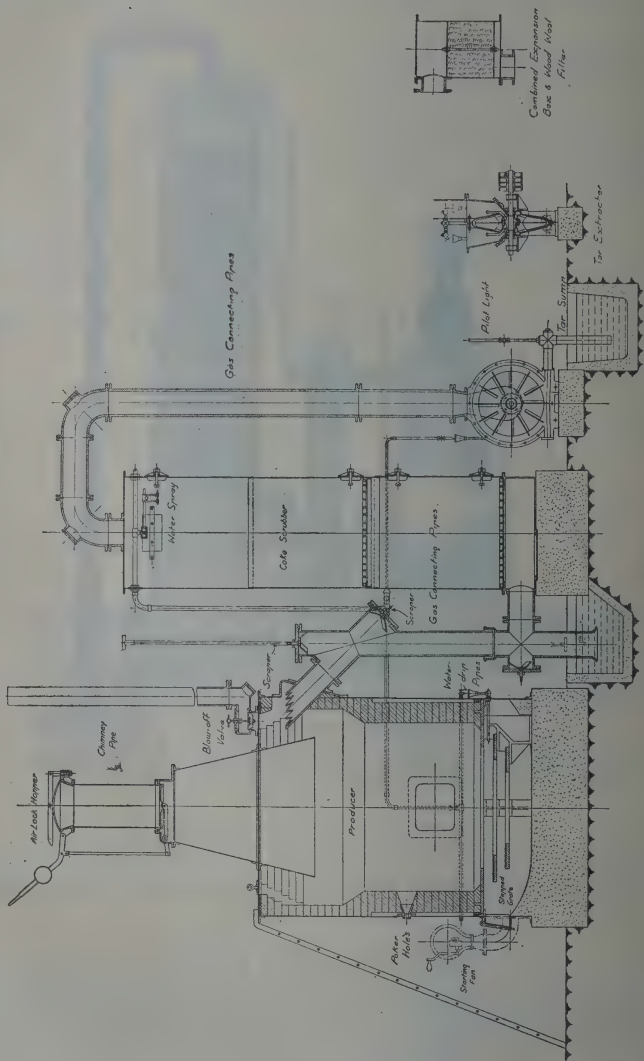

FIG. 42.

olted to the producer shell; these doors can be opened at any time whilst the plant is at work ithout disturbing the process of gas production.

Owing to the comparatively high moisture content of nearly all classes of waste fuels, little or o steam is required for gasification purposes, but when necessary, provision is made for generating supply of steam by feeding water on to the stepped grate plates.

One of the features of this plant is the provision of an Airlock fuel feeding hopper of large apacity and special design to allow of the plant being used for all classes of fuel without the lightest fear of explosion or interruption of gas supply when charging.

Other features of this producer are as follows:

(1) Provision for storing a large quantity of fuel in the producer itself, thus obviating the necessity of frequent charging.

(2) Exceptional facilities for spreading the fuel, thus ensuring a constant fuel depth and gas of constant calorific value.

(3) An effective design of mouthpiece for the gas outlet pipe, to reduce to a minimum any tendency for fine fuels, such as sawdust, to be drawn over with the gas.

(4) Gas outlet pipes from producer to scrubber are provided with scrapers for removing tarry deposit and dust whilst the plant is in operation. This device prevents the pipes from becoming choked and thus enables the installation to work continuously for long periods.

For cooling and washing the gas (preparatory to the removal of tar) a coke scrubber (of similar lesign and construction to that previously described) is provided.

Leaving the top of the scrubber and cooler, the gas is passed through a mechanically driven entrifugal tar extractor, where it is subjected to a combined heating and centrifugal action which hrows out the tar on to the inside of the casing, from whence it is washed into the tar collecting ump by a continuous spray of water.

Before the gas reaches the engine it is passed through a combined expansion box and wood ool filter which acts as a final drier.

Messrs. Crossley Brothers also manufacture suction plants for bituminous coal, lignite or peat; hese being of different design to suit the characteristics of the fuel to be gasified. The bituminous uel plant is provided with a central cone plate grate which allows of a continuous water lute around he base of the producer for the removal of ash and clinker.

All steam required for gasification purposes is generated in an annular steel boiler, situated near he base of the producer, the smooth surface of which prevents clinker from adhering. The steam nd air supply to the producer is controlled by a single valve, and the saturation temperature of he air can be regulated to a degree.

This design admits of free use of pokers through both the top and side poking holes.

For feeding the fuel a rotary barrel hopper is provided. The gas cleaning apparatus is very imilar to that supplied with the 'Crossley' Refuse Plant.

Mond Gas.

The Mond Gas-Producer Plant was originally developed by the late Dr. Ludwig Mond for the onversion of bituminous fuels into power and heating gas, along with the simultaneous recovery f the nitrogen in the form of sulphate of ammonia.

Plants of both the recovery and non-recovery type are constructed for power and for heating urposes, but considerations of economy rarely justify the installation of the recovery type n units of less than 2,000 h.p. or equivalent capacity. The non-recovery type, however, is nstalled in much smaller units.

Both types of plant can be adapted for utilising inferior fuel, such as the waste products from ollieries and coke ovens, and the gas used for gas-engine driving, industrial furnace heating r boiler firing, and in such cases with the recovery plant the return from the sulphate of mmonia will go a good way towards meeting the running expense of the plant.

The Mond Non-recovery Water-cooled Gas-Producer Plant.

(Mond and Lymn System.)

The modern type of Non-recovery Water-cooled Gas-Producer Plant, as installed for generating as from bituminous producer coal of suitable grading, quality, and condition for use in gas ngines or for other purposes where cleanliness equal to gas-engine practice is required, may be onsidered as composed of two sections: the 'Gas Generating Section'—comprising the pro- ucer and its accessories—and the 'Gas Cooling and Cleaning Section'—comprising vertical atic cooler and washer, centrifugal cleaners, and sawdust scrubber.

The producer is of the central blast type, with steel casing designed to sit on concrete foundations (provided by purchasers) and dip into a water-lute, formed in the foundations, and from which the ashes can be removed evenly all round without interrupting the working of the producer. The grate is conical in form, built up of two or more C.I. sections, and provided with air slots. It is located concentrically with the producer shell, and is connected up to the blast pipe which passes through the foundations to the outside of the producer. The lining of the producer is built of special quality firebricks and fireclay. The producer is fitted with a series of horizontal poke holes about the level of the air slots in the grate, and also with poke holes on the top giving access to the whole of the fuel bed, these top poke holes being fitted with spherical closers.

A fuel hopper is fitted on the top of the producer, with sliding cover and inner cone valve operated by lever and balance weight. The fuel in the hopper is discharged into a fuel container or inner bell, the top of which is provided with suitable poke holes, and from this container automatically on to the fuel bed; this method of charging ensuring a more constant quality of gas. The gas outlet branch is fitted on the side of the producer casing close to the top.

A steel chequer plate operating platform is arranged at the level of the top of the producer shell with suitable protecting handrailing and ladder giving access from ground level.

Fuel handling plant is frequently included, and the type usually recommended comprises a power-driven enclosed bucket type elevator, lifting the fuel from a boot at ground level into a bunker, which is mounted on substantial supports over the producer and fitted with a shute furnished with lever-operated discharge valve leading down to the producer hopper.

The air-blast for the producer is provided by a blower of the steam-jet type, arranged so as to ensure a thorough intermixture of air and steam before the blast reaches the grate, but in some installations a steam-driven Roots or turbo-type blower is included, the exhaust steam from the blower engine or turbine being led into the blast pipe.

Leaving the producer, the gas enters the cooler and washer, which is of patented design, and provides an effective means of gas washing by the employment of a novel and efficient method of utilising the momentum of upward flowing gases to atomise liquid falling in thin sheets, with a resultant intimate contact between gases and liquid without the use of any mechanical spraying device.

The apparatus consists of a cylindrical casing of mild steel, fitted with top and bottom plates, gas inlet and liquid outlet at the bottom, and with gas outlet and liquid inlet at the top. When desirable, the bottom of the casing can be arranged for water-luting.

A vertical stationary shaft is located in the centre of the apparatus, extending the height of the casing. At suitable distances from each other, a series of discs or distributing devices for the liquid are fixed on this shaft, and attached to the casing are a corresponding series of inverted truncated cones which serve as collecting devices, the design of these internal parts being varied to suit particular requirements.

Falling by gravity alternately from the distributors to the collectors and *vice versa*, the thin sheets of liquid are atomised, and in the form of fine spray actually driven by the gas—itself flowing in zigzag path in the opposite direction—on to the collectors and distributors, where the spray again forms into thin sheets of descending liquid. Each particle of gas is thus brought into contact with the liquid many times before it leaves the apparatus.

The distributors are constructed with diameters considerably smaller than the lower diameter of the collectors, and thus the gas passage is not restricted, and the loss of pressure occasioned is very small.

Packing or filling materials, such as coke, earthenware tiles, or wooden boards, which baffle the passage of the gas, are dispensed with, and the troubles of stoppage and renewals attendant upon such materials getting choked with tar and dust are thus eliminated.

This type of washer is of established efficiency, and the absence of moving parts, together with the freedom from possibilities of blockage, which is a feature of the design, make it a thoroughly reliable apparatus requiring a minimum of attention, with no upkeep charges for labour and material for packing or filling renewals such as have to be met with in other types of washer.

From the washer the gas passes to the first of two centrifugal cleaners. These two cleaners are normally arranged to work in series, but where desired, the requisite cross connections and valves can be added to enable either cleaner to be cut out of operation and by-passed for purposes of overhauling should such be necessary. Each cleaner has a tar drain water-sealed in a lute in the foundations, and the gas delivery branch of the second cleaner is joined up to a sawdust scrubber, to the outlet of which the gas main leading to the gas engines, etc., is connected.

The scrubber is a rectangular cast-iron box fitted with wooden grids, on which are spread layers of wood chips, shavings, and sawdust. The gas enters at the bottom, and passing up through these layers receives its final drying and purification.

The scrubber requires very little attention, only needing to be cleaned out and refilled a few es per year, according to the load on the plant. A special lifting arrangement is provided to ilitate the removal of the cover, and all the spent material taken out can be burnt under the ler which provides the steam for the plant.

The drains from the various parts of the plant are run to the settling tank, which takes the m of a concrete pit with iron or reinforced concrete partition plates, so arranged as to keep ck the tar and allow only the water to run to the drains. The tar is then scooped or run off d disposed of in the most convenient manner, either being sold, used for boiler-firing purposes, ydrated, or distilled, according to the quality and quantity available and local conditions.

The auxiliaries of the plant—elevator and centrifugal cleaners—can generally be most vantageously and economically driven by electric motors if electric supply is available, a ect or continuous current being preferable to an alternating current supply.

Where requirements call for a minimum fluctuation in the gas supply pressure, an automatic vernor can be added to plants in which a power-driven blower is installed. Such a governor uld be of the gas-holder type, but of small capacity, and hence of negligible storage value. ie bell of the holder would be so arranged that as it approaches its top position it actuates a lief valve connected to the air-blast main, reducing the blast supply to the producer when the s make is in excess of the requirements, and thus automatically controlling the gas production.

In installations where the gas generated is used to supply gas engines and also to fire furnaces, is advisable that a non-return valve should be provided in the gas main to the furnaces.

A suitable and sufficient supply of steam is required for blast saturation purposes, also suitable and sufficient supply of cold water to the washer, cleaners, and producer lute. Where ld water is scarce, water-cooling and circulating plant may be installed, and a considerable rtion of the water required can be used over and over again. Suitable motive power for the xiliaries is also required, in the form of electricity or steam.

This description is typical of units up to about 1,100 b.h.p. capacity, larger units being nerally similar but having two or more producers, gas main connections between producers d washer, to suit, and additional scrubber units.

Low Temperature By-product Recovery Gas-Producer Plant.

(Mond and Lymn System.)

Under normal circumstances, the installation of this type of plant is not, generally speaking, stified in units smaller than 2,000 b.h.p. in capacity, and local conditions and values may en require a larger unit, to afford an economical proposition. Thus, the usual plant of this pe comprises more than one producer unit with corresponding superheaters, etc., but, except plants of unusually large capacity, the washing, etc., vessels are installed in single units, th the scrubbers in multiple units, according to requirements.

This plant is made up to a certain extent of similar parts to the non-recovery type, but the sign of several of these parts is modified to suit the different working conditions, and additional paratus is included.

The plant may be considered as composed of four sections :—

(1) The Gas Generating Section, comprising producers.
(2) The Gas Washing and Cooling Section, comprising dust washer, ammonia absorber gas cooler, and in particular cases air saturator.
(3) The Gas Cleaning Section, comprising gas cleaners and scrubbers.
(4) The By-Product Recovery Section, comprising :—
    (*a*) Sulphate of ammonia, evaporating and drying plant.
    (*b*) Tar dehydration and/or distillation plant.

If the gas from the plant is required only for heating purposes, then Section (3), or, in some ses, the scrubber portion of this section, is not required.

The producers are generally similar to the non-recovery type, but with increased depth and her constructional modifications.

A steel chequer-plate operating platform common to the battery of producers is arranged the level of the top of the producer shells, with suitable protecting handrailing and ladder ving access from ground level.

Fuel-handling plant is generally included, and the type usually recommended comprises a ower-driven enclosed bucket type elevator, lifting the fuel from a boot at ground level into an erhead bunker, together with push-plate conveyor. The bunker, constructed of steel, is nerally of parabolic section, extending over the whole of the battery and suspended from ubstantial supports, which also carry the producer platform. The bunker is provided with scharge shutes leading down to the fuel hoppers of the producers, each shute being provided ith a lever-operated discharge valve. When required, a light iron framing and corrugated eet-iron covering is supplied to cover in the coal conveyor and bunker top. For large in-allations, fuel-handling plant of the travelling overhead crane and grab type offers advantages hich merit its adoption.

The air blast for the producers is provided by blower or blowers of either the turbo or Roots type, and after the necessary exhaust steam has been added to it to supply the vapour for blast saturation, it is passed into the producers. In certain cases some of the vapour required for blast saturation purposes is provided by means of an air saturator working in conjunction with the gas-washing plant.

The gas from each producer passes into a gas collecting main which joins up the various producer units and from which it enters the dust washer, where intimate contact with falling sprays of water wash out a large proportion of the dust. From this vessel the gas passes on to the ammonia absorber, which is the same type of patented vessel as used for the washer in the non-recovery gas producer plant.

From the absorber the gas passes to the final cooler, which again is a vessel of the patented washer type.

For certain heating purposes the gas may be taken off for use from the exit of this cooler but if further cleaning is required, it next passes forward to the first of two centrifugal cleaners which in detail and arrangement are exactly similar to those described as part of the non-recovery plant.

Where the gas is required to be of gas-engine cleanliness, the delivery branch of the second cleaner is connected to a bus-pipe joining up to the inlets of the scrubbers, the outlets of these vessels being connected with a bus-pipe, from which the main for the gas engines may be taken.

Where for special purposes the final cleaning in scrubbers is not required, then the gas may be taken off from the exit of the second centrifugal cleaner.

The scrubbers are formed in separate sections in a rectangular cast-iron box, each section being provided with wooden grids on which are spread layers of wood chips, shavings, and saw dust. The gas enters at the bottom, the various sections working in parallel, and the operation etc., being generally similar to this portion of the non-recovery plant.

The fourth section of the plant, in which the sulphate of ammonia is made in crystal form from the liquor obtained from the absorber, is generally housed in a building to itself.

The plant comprises stock liquor tanks, into which the liquor at suitable saturation is withdrawn from the circulating system of the absorber and stored. From these tanks the liquor is pumped up to overhead feed tanks, from which it is fed into the vacuum evaporator, which operates in conjunction with a condenser of the ejector-jet type. Here the liquor is evaporated and the crystals discharged from the base into a specially designed aspirator, and from thence passed on for final drying in power-driven hydro-extractor. The dry salt is then delivered into the store, usually arranged in the basement of the building, where it is packed in bags ready for distribution or shipment.

A steel circulating tank is provided for use in connection with the absorber, and located closely adjacent thereto, to contain the weak sulphuric acid solution which is used as the circulating liquor in this vessel, and a pump, constructed of acid-resisting metal, is provided for circulating this liquor, with the requisite connections between the tank, pump, and absorber and from the tank to the stock liquor tanks.

It is necessary for purchasers to provide acid and water supply pipes to this tank, to supply the make-up for the liquor withdrawn from circulation.

Suitable pumps are also provided for supplying the circulating water to the dust washer but it is usually left for purchasers to supply the cold water supply and pipe-line to the top of the final cooler, to the centrifugal gas cleaners, and to the jet condenser, as also the requisite drain connections for the disposal of the waste water from condenser and settling tanks.

The tar produced is collected from the various circulating tanks into a common settling tank. From this tank it is pumped to an overhead storage tank and dehydrated either by steam or by mechanical means. The dehydrated tar can either be sold as such or pumped forward to a distillation plant to yield oils suitable for fuel, disinfectants, wood preservatives, etc., and pitch.

The auxiliaries of the plant—elevator and conveyor, centrifugal cleaners, pumps, and hydro-extractor—can generally be most advantageously and economically driven by electric motors if electric supply is available, a direct or continuous current being preferable to an alternating current supply, but it is the usual practice to couple up the blowers to steam prime movers, the exhaust from which, as before mentioned, is utilised for blast saturation.

Automatic governor and non-return valve are provided when required to meet the same conditions as in the non-recovery type of plant, while steam, water, and motive power supplies will similarly be required.

Bituminous Suction Producers.

The production of a satisfactory suction plant using bituminous fuel has proved a problem of very great difficulty, but several types of such plant have recently appeared, and they are now built commercially by Messrs. Dowson, Messrs. Crossley, and others. In these the leading idea is to destroy any tar produced by distillation of the fuel *in the producer* before the crude gas enters the coolers and scrubbers. This is usually accomplished by taking the gas from the

t zone of the producer, and arranging the supply of air and steam from both above and below; e fuel enters from a hopper on top, and the gases coming off from the fresh coal pass down gether with some air and steam to the hot zone where reactions take place which destroy the r by converting it into useful gases. The fuel, now largely carbonised, passes slowly down- rds towards the grate supporting the whole mass, and being traversed by a current of mixed r and steam passing upwards yields carbonic oxide and hydrogen as usual.

Engines driven by these plants frequently require only about 1·2 lb. of slack to the producer r b.h.p. hour.

The 'Hornsby-Stockport' Suction Gas Plant for Anthracite, Coke, Charcoal, etc.

The outstanding features of this producer, fig. 43, are simplicity of design, ease in handling, d reliability under working conditions. Shaker grates to prevent the formation of clinker are ted on all producers of 37 b.h.p. and upwards. The blow-off pipe of the larger sized producers

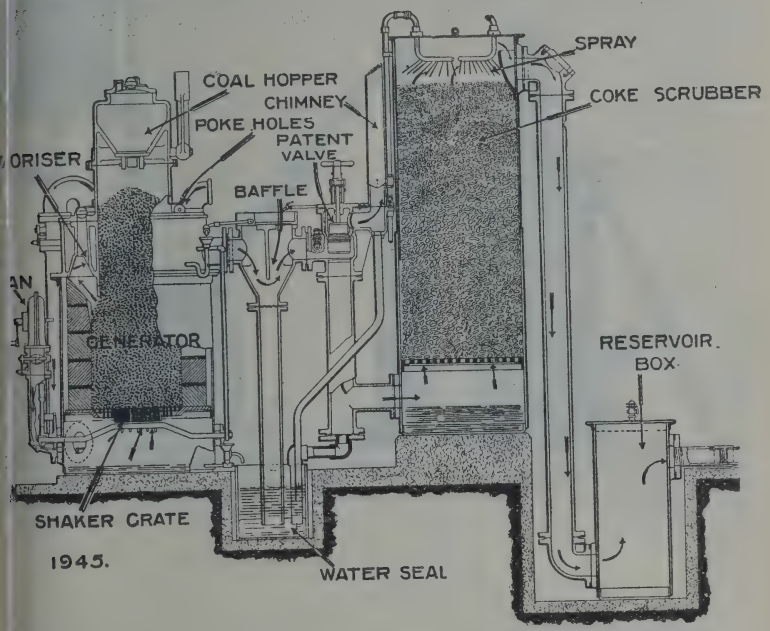

Fig. 43.—Hornsby-Stockport Improved Suction Gas Plant.

s fitted with a patented valve, closing the coke scrubber to the atmosphere when the generator s open to the blow-off pipe, thus keeping air from entering the coke scrubber.

Gas can be raised from cold in about 20 minutes.

The 'Ruston' Wood-Refuse Suction Gas Producer

This gas producer (*Ruston and Hornsby, Ltd.*), fig. 44, is for the purpose of dealing with wood refuse, non-caking bituminous coal, lignite, brown coal, anthracite, etc.

The chief endeavour has been to obviate the stoppages for cleaning usually necessary when working on such fuels. The little cleaning that is required is at the gas outlets from the generator, and this can be easily performed in a few minutes while the plant is in operation by means of special scrapers, so that the usual week-end cleaning is done away with, and the plant can be worked continuously if required.

A special feature of the producer is the multiple gas outlet pipes from the top of the generator, which ensure an evenly burning fire.

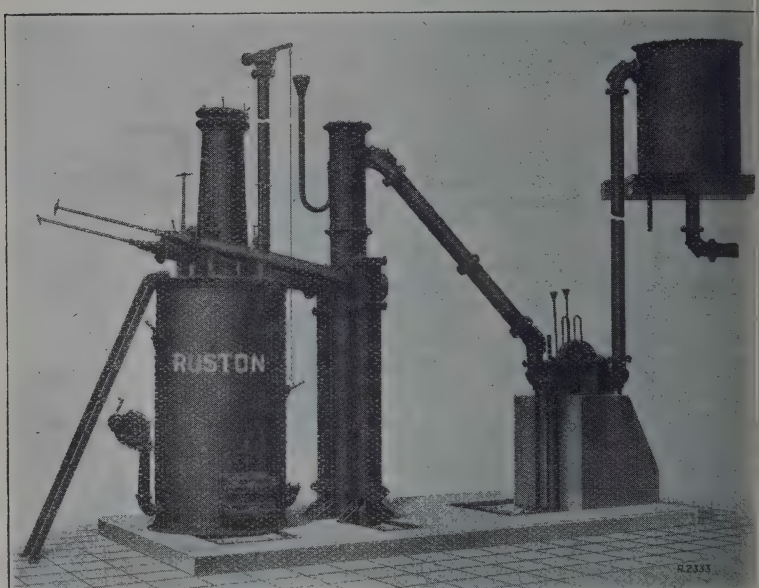

FIG. 44.—'Ruston' Wood-Refuse Gas Producer.

Other advantages claimed are as follows:—small space occupied, very little attention required, no coke scrubber to become clogged with tar, simple in design and construction, and gas free from grit, dust, or tar. The consumption of wood refuse is from $2\frac{1}{2}$ to $3\frac{1}{2}$ lbs. per b.h.p., according to the amount of moisture in the fuel, and the plant will produce four or five times the power as when the fuel is burned for direct steam raising.

When bituminous coal, lignite, anthracite, or coke is required to be used, solely or alternatively with refuse fuel, the details of the producer are somewhat modified. An annular steel vaporiser is arranged around the upper part of the generator, and an air lock feeding hopper is fitted. Poking holes are provided to give access to all parts of the fuel bed, and special facilities are given for the quick removal of ash and clinker.

A large number of these producers have been supplied at home and abroad, for a variety of refuse fuels, and for bituminous coals.

Water Gas.*

In 'Water Gas' producers the action is intermittent, the fuel being alternately raised to incandescence by an air blast which is then shut off and steam alone passed through the glowing mass; the steam is dissociated into free hydrogen and oxygen, and the oxygen combines with the carbon present in excess and forms CO; thus :—

$$H_2O + C = H_2 + CO$$
2 vols. + 1 vol. = 2 vols. + 2 vols.

In theory, therefore, water gas should contain 50 per cent. by volume each of hydrogen and carbon monoxide; practically a small quantity of CO_2, N and O generally appears, as shown by the analysis given below. The passage of the steam through the mass of incandescent coke soon cools it down, when the steam is cut off and the air blast again turned on; the cycle of operations is then repeated.

Water gas plants are frequently installed in gas works, and the water gas is often enriched or 'carburetted' by admixture of heavy hydrocarbon vapours and in this condition used either alone or mixed with coal gas for lighting, heating, and power purposes.

The following results of analyses suffice to give a general idea of the characteristic constitution of water gas, carburetted water gas, mixed gas (i.e. mixed water gas and coal gas), and normal coal gas :—

	H.	CH_4.	CO.	Heavy Hydrocarbons.	CO_2.	O.	N.
Water gas	48·6	0·4	44·0	—	3·3	—	3·7
Carburetted water gas	29·35	20·48	33·19	11·32	—	—	5·66
Mixed gas	46·73	24·57	14·46	4·91	1·45	0·73	7·15
Normal coal gas	45	33	10	5·3	0·5	0·3	5·9

6. BLAST FURNACE GAS.

In 1895 the late Mr. B. H. Thwaite showed that the hitherto waste gases from blast furnaces could be used in gas engines, and his discovery has stimulated the construction of the very large gas engines now becoming common.

The gas is taken from the gas main and forced by a blower through a scrubber into a holder regulator, and then to the engine. About 180,000 cubic feet of gas are produced per ton of fuel consumed in the furnace, and about 124 cubic feet of gas are used in the engine for each horse-power hour.

From tests made on Mr. Thwaite's first plant at Wishaw by Mr. W. H. Booth, it is estimated that for each ton of fuel used per week in a blast furnace, 10 horse-power may be continuously obtained by gas engines.

It is proposed to thus utilise the gases of all blast furnaces and so produce several millions of horse-power for distribution for railway, lighting, canal, traction, and general power purposes.

Table I. gives the analyses of blast furnace gas in two cases where the Thwaite system is in use, and a comparison with producer gas, while Table II. gives results of a volumetric analysis of the Wishaw gas.

* See also Section XXXVII, p. 2467.

				7·9038			

From 80 to 100 cubic feet of gas are obtained from each pound of fuel used. The foregoing table shows about 98 cubic feet of gas per pound of carbon, but some of the carbon comes from the limestone flux and from the ore, and even from the blast itself. In the gas engine, with the necessary enlargement of the gas inlet as compared with that necessary for town gas, and with a fair amount of initial compression, the action of blast-furnace gas is perfect, and no misfires are found to occur. The poverty of the gas is, in fact, no bar to its employment for power purposes. In fact the blast furnace is described in Mr. W. H. Booth's report as an ideal gas-producer. The employment of blast-furnace gas for power purposes enables cold-blast iron to be made, for with a sale for gas the economy of fuel per ton of iron ceases to be of importance.

Approximately each pound of carbon in the fuel used will produce about 98 cubic feet of gas and each 100 cubic feet of gas produced weighs nearly 8 lbs. The tests on the small engine at Wishaw showed only about 1½ lb. of coal per electrical horse-power, or 1·12 per i.h.p., assuming an efficiency of 75 per cent. between the cylinder and the terminals of the dynamo and allowing for temperature. Approximately each ton of fuel used per week in a furnace would give continuously 10 horse-power.

There has been a very considerable extension of the use of blast-furnace gas in Germany, where full advantage was promptly taken of Thwaite's teachings, and after a period of attempting to work with uncleaned gas Thwaite's method of cleaning was practically adopted. It is very important that the gas should be cleaned of its dust. Failure has occurred at an American iron works where the engine valves became heavily loaded with dust. Fans may be employed through which the gas is circulated, jets of water being entered at the side of the fan casing. Rotating gas washers also are employed, and washer boxes in which the gas is passed under diaphragms which project an inch or two below water and compel the gas to bubble up through the water

ge scrubbers with cellular work of light athwork with water trickling over them will arrest ch dust. Thwaite employed a sawdust filter as a final catcher, arranged so that the sawdust ld be rapidly changed. Thwaite relied much on sawdust for removal of the tar, of which it ifficult to get rid. Though blast-furnace gas may contain as little as 27 per cent. of combustible it presents no ignition difficulties when electrically fired in a state of compression in the nder. A. Witz has shown that the average calorific value of the gas from twenty-seven Belgian naces was 111 B.Th.U. per cubic foot, while nineteen Luxembourg samples showed 114 B.Th.U., nty-three German furnaces showed 108 B.Th.U., and nine French and Spanish furnaces B.Th.U. He takes a general average of 110, but the value may fall to 97 with an acid flux. h poor gas will bear high compression, and will safely bear 7 to 9 atmospheres. No matter y poor a gas it will ignite if sufficiently compressed, and at Seraing as high as 11 atmospheres e employed in 1901. Hence the excellent efficiency that is obtained with blast-furnace gas.

Blast-furnace gas contains but little hydrogen, as no steam is used in the blast furnace; it proximates, in fact, closely to the gas that would be given by an ordinary producer supplied h air only. The small hydrogen content enables very high compression pressures to be used hout danger of pre-ignition; when well cleaned, this gas is an excellent fuel for large engines, heat evolved per cubic foot of maximum mixture at 60° F. and 1 atm. being about 57 B.Th.U. an average lower value; as already pointed out in an earlier part of this section, with cylinders 30 ins. in diameter and over, in order to avoid overheating troubles it is found desirable in ctice to introduce only from 35 to 40 B.Th.U. per cubic foot of piston displacement; thus, ough low in comparison with most other gaseous fuels, the heat evolution per cubic foot blast-furnace gas mixture is fully adequate to the needs of large gas engines.

Some average results for the principal gaseous fuels used at the present day are given in following table :—

HEAT VALUE AND COMBUSTION OF USUAL GASEOUS FUELS.

THE KIRKE PATENT GAS-FIRED BOILER.

The Kirke Patent Gas-fired Boiler, invented by Mr. P. St. G. Kirke, M.A., A.M.I.C.E., M.I.M.E., etc., is manufactured by *Spencer-Bonecourt, Ltd., Parliament Mansions, Victoria Street, London, S.W.* 1.

Fig. 45 shows a Kirke Patent Gas-fired Steam Boiler. The design is based on the discovery that, if such gases as coal gas, coke-oven gas, blue water gas, producer gas, and natural gas are induced into empty tubes of great length relative to their bore, together with the air theoretically required for combustion, or some 10 per cent. in excess thereof, they can be completely burnt in the tubes without being previously mixed, and the resulting products of combustion reduced to 70° C., or less, above the temperature of the water in the boiler. Further, that this can be done either with natural draft or with high induced draft of 4 ins. of water and over, provided that the length of the tubes is greater relative to their bore the higher the draft adopted.

The Kirke Patent Gas-fired Boiler in its simplest form consists of a drum traversed by a number of long tubes with nothing in them, which function as combustion chambers, as mixing chambers, and as extractors of the sensible heat remaining in the resulting products of combustion

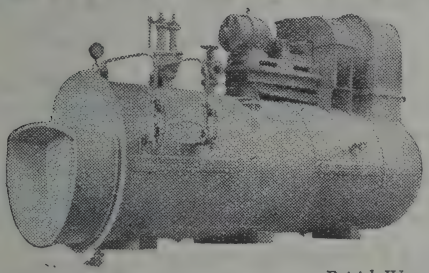
STEAM for NOTHING!



British Waste Heat Boiler
Patents Nos. 130234, 140851, 172752, 186801, 193895, etc.

Do you know that

KIRKE PATENT WASTE HEAT BOILERS

are generating steam from the waste heat discharged from furnaces in almost every industry?

STEEL WORKS.
pen Hearth Furnaces. Puddling Furnaces. Coke Ovens. Re-heating Furnaces.

GAS WORKS.
ertical Retorts. Horizontal Retorts. Inclined Retorts. Water Gas Plants Chamber Ovens.

PAPER MILLS.
Rotary Roasters.

They can also be used for generating steam at moderate pressure for:

ELECTRIC GENERATING STATIONS
in place of Economisers and Air Heaters.

BLAST FURNACE GAS, PRODUCER GAS from all sources, and COKE BREEZE may also be used.

A recent example of costs-reduction is the case of a 100-ton steel furnace where the coal consumption has been HALVED. One instance from many. Write for further particulars.

LONDON

CROSBY LOCKWOOD & SON

STATIONERS' HALL COURT, LUDGATE HILL, E.C. 4

At the inlet end of the tube is a patent gas burner or distributor which discharges a jet of s into each tube, the amount of which is determined by the size of the holes from which the s issues and the pressure of the gas in the burner, the latter being controlled by the large gas et valve at the bottom of the burner. The requisite air for combustion enters each tube m the atmosphere, the quantity being controlled by the amount of draft which is varied to it the load.

The following are figures obtained from a single tube evaporating water in an open wood nk lined with zinc :—

Gas burnt in cubic feet per hour	230
Steam raised from and at 212° F. in lbs. per hour	104
Cubic feet of gas per lb. of steam from and at 212° F.	2·21
Temperature of gases leaving the boiler	188° C.
Suction in inches of water	8
Gas pressure in inches of water	4
Evaporation per sq. ft. of heating surface in lbs. from and at 212° F. per hour	18
Net calorific value of the gas in B.Th.U.'s.	480
Thermal efficiency without economiser	91 per cent.

A single drum boiler of this type 7 ft. diameter by 21 ft. long, fired with coke-oven gas, will vaporate 21,000 lbs. of steam per hour with a suction of 4 ins. ; 16,000 lbs. with a suction of s ins. ; and 10,500 lbs. with a suction of 1 in. The radiation loss from the shell when completely gged (except for the front tube plate) is only ¼ per cent. at full load and under 3 per cent. when lagged.

The following table gives the power required by the fan, assuming 15½ lbs. of steam from nd at 212° F. are required to generate 1 b.h.p.

Nature of Fuel burnt in Kirke Patent Fuel-fired Boilers.	Draft.	Percentage of Boiler Output required to create 4 in. suction.	Approximate B.H.P. required by the Exhauster for an Evaporation of 10,000 lbs. of steam from and at 212° F. per hour.
	Ins.	Per Cent.	
Water gas	4	0·93	6
Coke oven gas	4	1·00	6½
Producer gas	4	1·25	8
Crude oil	4	1·35	8¾
Coal	4	1·71	11
Blast-furnace gas	4	2·00	13

When the floor space is very restricted, it is easy to put one drum on the top of another. n this way, for a given evaporation only one-fifteenth of the floor space required by Lancashire oilers for the same evaporation is required.

The cleaning of the tubes on the water side is made easy by division of the tubes into two ests. A man can enter the boiler through the manhole and walk along the whole length of the oiler between the two nests, so that he can scrape the surface of all the tubes for their entire ength, the distance between the tube centres being sufficiently great to enable him to get a uitably shaped scraper to all the tubes. This, however, is better avoided by softening the water r using a suitable boiler fluid. An internal scale-separating device is also fitted.

For superheating the steam a separate chamber containing fire tubes fired in the same way, ut with natural draft, is used, the temperature being kept constant by a thermostat operating he gas valve.

The following are the approximate fuel consumptions per lb. of steam raised from and at 212° F. for various fuels burnt in Kirke patent boilers without economisers :—

Producer gas	8 cubic ft.	Poor coal gas	2·7 cubic ft.
Coke oven gas	2½ ,,	Natural gas	1·2 ,,
Water gas	3⅝ ,,	Crude oil	$\frac{1}{17}$th lb.
Rich coal gas	2·2 ,,		

Kirke Patent Fire-Tube Boiler.

This boiler, fig. 46 (Patents numbered 140,851, 209,878, etc.), consists of one or more drums having inlet products chambers at one end and outlet products chambers at the other, connected together by a number of empty and straight fire tubes of great length relative to their bore through which the hot gases are drawn at a high vocity by means of an induced draught fan.

The high velocity enables large volumes to be handled in a boiler of comparatively small dimensions, and prevents most of the dust from lodging on, and insulating, the heating surface. It also reduces the cost of the boiler, and increases the return on the capital expenditure.

Notwithstanding the high velocity at which the gases flow over the heating surfaces, the great length of the tubes relative to their bore enables the temperature of the hot products to be reduced to about 30° C. above the temperature of the water in the boiler, before they enter the fan impeller. Consequently an economiser—although sometimes a good investment—is not essential, and higher thermal efficiencies can be obtained than have ever been obtained before.

Cleaning.—The fire tubes are arranged in two or more nests, between which it is possible for a man to enter, so that the tubes are exposed for cleaning on the water side over the whole of their length.

As the interior of the fire tubes is smooth, round, and straight, and the induced draught causes the hot products to travel through them at a high velocity, without changing their direction, there is nothing to catch the dust, which consequently is carried straight through to the outlet products chamber, from which it can be easily removed from time to time. To deal with dirty gases containing very large quantities of dust—such as are obtained from cement kilns—an arrangement (Patent No. 186,801) for enabling these boilers to be cleaned while they are running is now being fitted to all these boilers. The fan is arranged at the top or at the side of the boiler so as to leave the cover plate of the outlet products chamber unobstructed. In this cover plate small holes are drilled large enough to pass a tube brush or steam lance through for pushing through the whole length of tubes. One of these little holes will allow some air tubes to be cleaned, and, while leakage of air into several of the holes is not sufficient to reduce the draught, it is not necessary to open more than one at a time for cleaning purposes.

Circulation.—The circulation in the Kirke boilers is particularly good. About 70 per cent. of the evaporation occurs in the first third of the tubes, and only about 10 per cent. in the last third. Consequently there are strong convection currents upwards at the front end and downward at the rear end.

Dry Steam.—By taking the steam off at the back end of the boiler, where the circulation is downward, and by the use of an efficient anti-primer, the steam is rendered remarkably dry. In an independent test on a boiler of this type unlagged, the steam was found to be 99·3 per cent. dry. In a second independent test carried out on a lagged boiler of this type, the moisture in the steam was so small that it could not be measured and was reported to be 'practically quite dry.' In a third case, where water-tube boilers were giving trouble with priming, it was found impossible to make a boiler of this type prime even under conditions which no boiler would be put to in practice—namely, when supplying steam to a number of colliery winding engines, all of which were purposely started up at once.

Combustion Chamber.—The combustion chamber is very simple and may be supplied with mechanical stoker, grate for hand-firing, or gas burners, as shown. Pulverised fuel, wood, and blast-furnace gas may also be used.

Even when the drop of water gauge through the boiler tubes is raised to 4 ins. of water, that through the combustion chamber is a fraction of an inch, so that there is little chance of air leakages through the brickwork. Further, as the combustion chamber is comparatively small for the duty it is not a costly matter to encase it completely in metal.

The provisional patented superheater is arranged out of the path of flow of hot gases from the grate, but can receive radiant heat from the combustion chamber walls, which can be limited to any desired extent by armouring or screening the coils. Low-grade heat, if any, from the industrial furnace, may, however, pass over the coils.

Loss due to Radiation.—In Kirke boilers the radiation loss is extremely small, owing to the fact that, except for the front tube plate, the whole of the shell may be lagged. With air at 72° F., the heat loss from uncovered steam pipes carrying steam at 100 pounds per sq. in. is 1,170 B.Th.U.'s per sq. ft., and this is reduced to 100·2 B.Th.U.'s when 2 ins. of magnesia lagging is used to cover them (see 'Mechanical Engineers' Handbook,' by S. Marks). In the case of a large standard pattern Kirke gas-fired boiler, 6½ ft. diameter, evaporating 18,000 lbs. of steam

KIRKE PATENT FIRE-TUBE BOILER FOR WASTE HEAT, COAL, BLAST-FURNACE GAS, OR PULVERISED FUEL. (Patents No. 140,851, etc.)

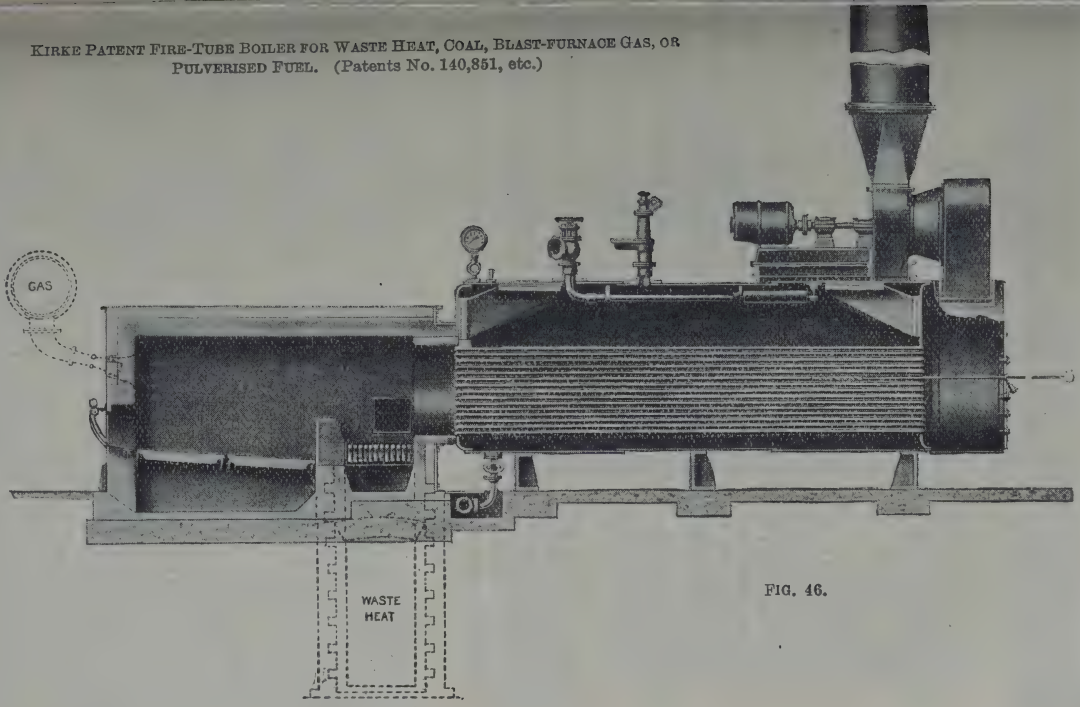

FIG. 46.

from and at 212° F. per hour with 4 ins. induced draught, the loss of steam due to radiation is however, only 2¾ per cent. before the boiler is lagged and about ½ per cent. after the boiler i lagged.

Efficiency.—Two Spencer-Bonecourt Kirke patent waste heat boilers which are generatin steam from the waste heat discharged from 10 settings of Glover-West retorts at the Stratfor works of the Gas Light and Coke Co., gave the following figures when tested by the staff of th Gas Light and Coke Co. :—

Date of test, November 19, 1923.

Duration of test, 24 hours.

Temperature of the products entering the boilers	689° C.
Temperature of the products leaving the boilers	225° C.
Steam pressure in lbs. per sq. in.	115
*Mean tube efficiency of the boilers	90·3 per cen
Suction in the outlet products chamber of the boiler in inches of water	1·4 ins.
Suction in the inlet products chamber available for the settings and collecting flues	1·4 ins.
B.H.P. consumed by the motor for the retorts	11½
B.H.P. consumed by the motor for the boilers	24½
Water evaporated per hour in lbs. actual	16,783
Water evaporated from and at 212° F. per hour in lbs.	18,500
Percentage of power absorbed by the draught for boiler (assuming 15 lbs. of steam from and at 212° F.) per b.h.p. hour	2 per cent.
Percentage of power developed absorbed by the draught for collecting flues and settings (assuming 15 lbs. of steam from and at 212° F. per b.h.p. hour)	0·93 per cen
Estimated saving in small coke and breeze per annum of 300 days freed for market in tons (assuming 6 lbs. of steam from and at 212° F. per lb. of this fuel)	10,000 tons
Steam produced from and at 212° F. per lb. of coke used in the producers	5·8
Steam produced from and at 212° F. per lb. of coal carbonised	0·9 lb.
Heat loss between the outlet of the settings and the inlet of the boiler due to radiation from the steel flues	4·9 per cent

One of these boilers fitted to a Talbot steel furnace at another works brought down th consumption of coal per ton of steel to 3½ cwts. Before the Kirke boiler was installed the co consumption was 5 cwts. per ton of steel.

These waste heat boilers have been successfully installed on horizontal retort benches, incline retort benches, vertical retort benches, open hearth steel furnaces, soaking pits, cement kiln water gas plants, puddling furnaces, etc.

The boilers have also been installed in Europe, Asia, Africa, America, and Australia.

THE CLARKSON BOILER.

(*The Clarkson Thimble Tube Boiler Co., Ltd.*, 613 *Australia House, Strand, London, W.C.* 2.)

The 'Clarkson Thimble Tube Boiler' has been evolved to meet the requirements of stea users who require all the advantages that an ordinary quick steaming water-tube boiler provide and for whom other considerations render inadvisable the use of such a boiler.

The boiler can be used for many duties and with various fuels, although the most suitable u for it is the extraction of the waste heat from engine exhaust gases. The makers claim that f this duty the boiler is the most serviceable on the market from almost every point of vie Installations on engines of all sizes from 30 b.h.p. to 5,000 b.h.p. have been successfully carri out.

The Clarkson Thimble Tube Boiler is of the vertical water-tube type, the general constructi of which is shown in fig. 47, page 2185. The tubes, being thimble shaped, are expanded into cylindrical shell sheet at one end only, so that the troubles caused by the expansion and co traction of water-tubes in ordinary boilers do not exist for the Clarkson Boiler, whilst at the san time quick steaming properties and other advantages of water-tube boilers are retained.

The boiler unit consists of two cylindrical shell plates, through the centre of which the fl gases pass. Several hundred thimble tubes are expanded into holes in the inner plate, ea successive ring being staggered. A centre core fills up the cylindrical space between the tu ends and compels the exhaust gases to travel tortuously through the nest of tubes which compri the heating surface (see page 2185). The water space is thus annular in shape with projectio inside each thimble.

The usual boiler or heater fittings are mounted on the shell. A combustion chamber and burners are added to the boiler unit, and make a highly efficient steam generator.

* To obtain tube efficiency, divide difference between the temperature of the gases enteri and leaving the tubes by the difference between the temperature of gases entering the tubes a that of the water in the boiler.

OIL BURNER

FIG. 47.

Non-Scaling.—It will be realised that steam is generated inside the thimbles, and therefore when a certain amount of steam is generated it blows the water back out of the mouth of the tube. The water then returns into the tube when the steam has escaped. The pulsating action thus set up has a frequency of the order of 90 to 160 per minute, and effectively scours the tube of scale. The scale-forming matter is then directed to the foot of the boiler by the cylindrical baffle plate which also prevents the cold feed water from impinging direct on to the tube ends, and helps an effective circulation.

Thimble Tubes.—There are 272 tubes, 1 in. diameter by 2 $\frac{3}{8}$ ins. long on the smallest heater of 10 sq. ft. heating surface, and about 1,150 tubes, 3$\frac{1}{4}$ in. diameter by 12 ins. long on the largest boiler, which has a heating surface of about 700 sq. ft. Each tube is tested to a pressure of 1,000 lbs. per sq. in. before leaving the Works.

Soot Cleaning.—Should the outside of the thimble tubes foul, as may happen when running off a dirty engine exhaust, the boiler can be emptied, a wad of oil-soaked waste ignited and put at the foot of the tube nest, and the impurities burnt off with no danger of damage occurring.

Accessibility.—The tubes are easily accessible on the steam side, by raising the outer shell, and on the inner side, by removing the centre core.

Centre Core.—The centre core or gas baffle, of the best fire-resisting material, forces the exhaust gases to travel tortuously through the nest of tubes, and is suspended from the uptake, being steadied by three to six steady pins, screwed into the inner shell.

Exhaust Heat Extraction.

Silencing.—The Clarkson Boiler is an efficient exhaust silencer, and when run off, exhaust gases may be allowed to run dry, with no ill effects, and can be put on to steaming load at short notice.

No Back Pressure.—In estimating the size of boiler required for extracting heat from exhaust gases, the main consideration is the avoidance of any extra back pressure on the engine. The contraction of the gases as they cool in the boiler assists the exhaust from the engine cylinders, tending to reduce back pressure.

Boilers of this type have been fitted by the British Admiralty to provide steam for evaporators on submarines, and have given efficient and satisfactory service.

Fuel Firing.

Owing to the quick steaming properties and strong design of the Clarkson Boiler, it was found necessary to adapt the unit for coal or oil firing, and a range of thimble tube boilers with water legs has been built and have given satisfactory service as donkey boilers, galley boilers, and dredging duties. Types of these boilers, used on steam waggons, have withstood successfully for many years the rough treatment that is often met with in road work.

The makers claim the following advantages for this boiler:

1. A smaller size of thimble tube boiler will do the work of steam generation more efficiently and at less cost than is possible with any other type of boiler, especially other vertical boilers.
2. In consequence of low size and weight, it can be fitted in the place of silencers, in the exhaust pipe run above the engine room.
3. Silencer boilers may be fitted with alternative oil firing, for use in port.
4. Ample accessibility for cleaning and inspection of all internal parts.

Summary of Test Results when Oil Firing.

Clarkson Silencer Boiler: Type Begatoo-400.

Boiler.—Clarkson Patent Vertical Thimble Tube, 5 ft. diam. by 17 ft. high; 100 lbs. per sq. in. working pressure.

Heating Surface.—402 sq. ft., 2 oil burners, Todd's pressure system.

Utility.—Silencer for 2 main engines, total 4,500 h.p. or oil-fired donkey boiler.

Oil used.—Shell Mex. Spec. grav. 0·936 at 60° F.; calorific value, 18,600 B.Th.U.

Guaranteed Evaporation.—4,000 lbs. of water from and at 212° F. with oil of above calorific value

Evaporation per hour from and at 212° F.	4,273 lbs
Total evaporation in 2 hours' test at 100 lbs. per sq. in.	7,130 „
Total evaporation per hour at 100 lbs. per sq. in.	3,565 „
Oil consumed per hour	327 „
Water evaporated at 100 lbs. per sq. in. per hour per lb. of oil	10·9 „
Water evaporated from and at 212° F. per hour per lb. of oil	13·0 „
Water evaporated from and at 212° F. per sq. ft. of heating surface per hour	10·2 „
Thermal efficiency of boiler—unlagged	65·9%

WASTE HEAT RECOVERY.

(Contributed by Chas. F. Wade, A.M.I.Mech.E., A.M.I.E.E.)

The directions in which profitable recovery of waste heat must be looked for are

(i) Waste heat from various metallurgical and other furnaces

(Ii) Waste gases from internal combustion engines;

(iii) Exhaust steam from non-condensing engines, steam hammers, steam-hydraulic intensifiers, etc.

Waste heat from high temperature metallurgical operations, such as open-hearth melting rnaces, consists of the sensible heat of the waste gases and the heat carried away by radiation id convection from the furnace walls. The latter is permitted deliberately in order to prevent necessarily rapid burning of the walls. The heat of the waste gases is generally utilised for e purpose of preheating the incoming air and gas by means of regenerators and reversing lves. By jacketing the furnace walls and utilising the heat formerly wasted in radiation r air preheating, thus releasing approximately 50 per cent. of the heat of the waste gases for eam-raising in a waste heat boiler, a very substantial saving of fuel will result. The loss of at by radiation and convection from unjacketed furnaces is certainly not less than 25 per nt. of the total heat of the fuel used. Even in a reheating furnace working at 1000° C., jacketing the furnaces instead of regeneration in chequer chambers will often give an air temperature over 300° C.

Small reheating furnaces for light forgings and similar work air-jacketed at the sides only ll often give a temperature of over 150° C. in the air supplied for combustion. In all cases e result will be that the final temperature of the gases will be sufficient to make a waste heat iler a profitable investment.

In metallurgical furnaces wherein the process requires a densely smoky atmosphere and the r supply is deliberately restricted, the use of a waste heat boiler for the products of combustion gether with a supplementary coal fire, through which an excess of air is passed, will not only ad to large recovery of heat in the form of steam, but will also furnish a solution to the smoke-atement problem. Without the supplementary fire-grate a supply of highly preheated air ought through ducts on the furnace settings will usually ensure reignition of the combustible atter in the smoky gases. Cold air will not do this owing to the low temperature of the gases begin with, thus keeping the products below ignition point.

For ordinary waste heat boiler work without supplementary firing a temperature of at least)0° C. is needed to make the proposition profitable. With tubular boilers of the Cochran pe the usual evaporation per pound of coal consumed in the furnace is:—

Temperature of Waste Gases.	1500° F.	1800° F.	2000° F.
Lbs. water per lb. of coal from water at 62° F.	3·08	4·25	5·00

Using boilers of the 'Bonecourt' type, in its more modern developments, wherein gas at a gh velocity, aided by mechanical draught, is in use, gases with an initial temperature of 350° C. ay be used profitably.

Gases from internal combustion engines usually allowed to expand in a silencer, with corre-ponding fall of temperature, are maintained at smaller volume and part with their heat to the ater in the boiler with a final temperature of about 75° C.

This system is of considerable value also in dealing with the waste heat from gas retort rnaces.

Where low-temperature furnaces are in use only the waste gases may be used for heating water for shop and office heating by means of economisers, and where both high- and low-mperature furnaces are worked, the hot water from the latter should be used for feed to the gh-temperature waste heat boilers. An interchange of heat and power from waste sources etween adjoining establishments is often a practicable proposition where the means of power id heat generation and utilisation are collectively equal.

The heat wasted in exhaust steam can be applied to the drive of low or mixed pressure rbines, which latter will have the additional economical effect of levelling out the load on ie boiler plant, in that a falling-off of the supply of exhaust steam will cause the turbine to raw on the boilers directly for a high pressure supply. Other important advantages are the sturning of soft water to the boilers for feeding purposes, either with or without preliminary ectrolytic treatment for oil elimination.

Other applications of the heat of exhaust steam are for heating processes in manufacture heating of buildings, etc., all of which permit of the return of the condensate for boiler fee purposes.

All proposals for the utilisation of waste heat of any kind require to be dealt with individuall on their merits, the conditions being so variable that no hard and fast rules can be laid dow which will be universally applicable.

Generation of Electricity in Great Britain by Waste Heat.

In the Annual Report of the Electricity Commission * it is stated that the total units generate by waste heat during the year ending March 31, 1926, was 178,159,230 (from 17 stations), a against 186,289,858 (from 19 stations) in 1925.

THE SEACOMBE FLOATING BRIDGE

Sea and Sand

THE opening of the Floating Roadway at Seacombe, and its subsequent operation, marked the success of an enterprising scheme. The roadway forms part of the Seacombe Ferry Improvements rendered necessary by the great increase in traffic across the Mersey. It is 600 ft. long and 56 ft. wide, carrying three roads. Five floating spans rest on pontoons which rise and fall with the tide, grounding at low tide. So far as is known this bridge is the largest of its type yet constructed. The photograph shows the brilliant lighting of the bridge by night. The cables for supplying the current were run under the roadway on wooden battens and taken up the inside of each pillar. Thus the cables have no protection and are washed twice daily for considerable periods by the sea and by the sand which comes under the roadway at each side. For this reason "Maconite" Insulated Cables were chosen. They were chosen by reason of their known ability to withstand such conditions, proved by exhaustive tests and by long experience of actual installations in the most exacting situations.

Electrical Units.

Unit.	Symbol.	Name.	Value in C.G.S. Units.	Dimensions in terms of Length Time Mass.	Dimensions in terms of Length Time Force Velocity.
Electromotive force	E	Volt	10^8	$L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-2}$	$V\sqrt{F}$
Current	I	Ampere	10^{-1}	$L^{\frac{1}{2}}M^{\frac{1}{2}}T^{-1}$	$\sqrt{F}$
Quantity	Q	Coulomb	10^{-1}	$L^{\frac{1}{2}}M^{\frac{1}{2}}$	$T\sqrt{F}$
Resistance	R	Ohm	10^9	LT^{-1}	V
Capacity	C	Farad	10^{-9}	$L^{-1}T^2$	TV^{-1}
Inductance	L	Henry	10^9	L	L
Power or rate of working	P	Watt	10^7	L^2MT^{-3}	VF
Energy	W	Joule	10^7	L^2MT^{-2}	LF

The values of these units are as follows:—

One Ampere (international) is the unvarying electric current which, when passed through a olution of nitrate of silver in water, deposits silver at the rate of 0·001118 gramme per Second.

One Coulomb is the quantity of electricity represented by 1 Ampere passing for 1 Second.

One Ohm (international) is the resistance to an unvarying electric current of a column of ercury of uniform cross-section and length equal to 106·3 cm. whose mass is 14·4521 grammes t the temperature of melting ice.

One Volt (international) is the electrical pressure which, when steadily applied to a conductor hose resistance is one international Ohm, will produce a current of one international Ampere.

One Farad is that capacity which is charged to a potential of 1 Volt by a current of 1 Ampere owing for 1 Second.

One Henry is the inductance of a circuit in which an E.M.F. of 1 Volt is induced by a current ariation of 1 Ampere per Second.

One Watt is the power, or the rate at which work is being done, when a current of 1 Ampere asses through a resistance of 1 Ohm.

One Joule is the amount of work done, or heat generated, by 1 Ampere flowing for 1 Second hrough a resistance of 1 Ohm.

The following multiples and sub-multiples of these units are in common use :—

One millivolt = one-thousandth of a volt.
One milliampere = one-thousandth of an ampere.
One megohm = one million ohms.
One microhm = one-millionth of an ohm.
One microfarad = one-millionth of a farad.
One millihenry = one-thousandth of a henry.
One kilowatt = one thousand watts.

The following relations will be found useful :—

One horse-power is equal to 746 watts.

One foot-pound is equal to 1·356 joules = 0·323 calorie.

One joule is equal to 0·238 calorie.

One (gm.) calorie is the work done in raising 1 gramme of water 1° C., = 4·2 joules.

One (kg.) calorie = 1000 (gm.) calorie.

One joule is equal to 0·7373 foot-pound.

One dyne is the force which, acting on a mass of 1 gramme for 1 second, will give it a velocity of 1 cm. per second.

One erg is the work done by 1 dyne acting through 1 centimetre.

One watt = 0·00134 horse-power = 0·7373 ft.-lb. per second = 44·24 ft. lb. per minute = 0·057 British thermal unit per minute = 1 joule per second.

One kilowatt-hour = 1,000 watt-hours = one Board of Trade Unit = 1·34 horse-power-hour = 2,656,400 ft.-lb. = 3,415* British thermal units = 860,600 calories.

The practical standard of electromotive force is the Weston Normal cell, which has an E.M.F. of 1·0185 volts at 15° C., decreasing by 0·00004 volt per degree C. rise of temperature.

Laws of Currents in Conductors.

Ohm's law states that: Voltage = Current × Resistance, or V = I × R.

Kirchhoff's first law states that : The algebraic sum of the currents meeting at any point of a network of conductors is zero.

Kirchhoff's second law states that: The algebraic sum of all the products of resistances and currents in all the wires forming a closed network equals the algebraic sum of all the electromotive forces in the network.

RESISTIVITY OF PURE ANNEALED METALS, AND ALLOYS, AT 0° C. (32° F.).

* British Engineering Standards Association, 'Glossary of Terms used in Electrical Engineering' (Publication No. 205—1926). The Electricity Commissioners have adopted the value '341' which takes the *mean* British thermal unit to be $\frac{1}{180}$ of the quantity of heat required to raise the temperature of 1 lb. of water from 32° F. to 212° F. See also p. 1593.

Lenz's law states that : The current induced in a conductor flows in such a direction that its action opposes the change of position or state by which it is produced.

The power represented by a current of I amperes flowing under a difference of potential of volts through a conductor of resistance R ohms $= I \times V = I^2R = V^2/R$ watts.

The heat energy generated by a current of I amperes flowing through a conductor of resistance R ohms for t seconds $= I^2Rt$ in joules.

Effect of Temperature on Resistance.

The resistance of metals increases with the temperature in accordance with the approximate formula

$$R_t = R_o (1 + kt)$$

where k is the coefficient given in col. 5 or 6 (according to the temperature scale employed) divided by 100.

If the resistance R_1 at temperature t in ° C. be known, then for copper the resistance R_2 at temperature t_2 in ° C. will be :—

$$R_2 = R_1 \left(\frac{234{\cdot}5 + t_2}{234{\cdot}5 + t_1}\right)$$

Metallic Resistance Materials.

Metallic resistance materials are classified by the British Engineering Standards Association for maximum temperatures of 60, 200, 300, 700, and 1,000° C. respectively. According to Report No. 115—1924, the resistivity at 20° C. is not to differ more than 5 per cent. from that declared by the supplier, and the material must be uniform in resistance within 5 per cent. ; the temperature coefficents in the two low-temperature classes must not exceed 0·00002 and 0·00004 respectively for ten hours without the resistance changing more than 0·01 per cent. Lists of standard sizes of wires, sheets, and tapes are given in the Report.

Note on Fusing Currents.

The fusing currents in the tables may be taken to be correct where the fuse wire passes through an asbestos tube and does not closely touch the tube, but they do not apply where a substantial length of the wire is in contact with a porcelain holder. With the latter, more current is needed to melt the fuse.

For copper wires, the values of the current given are those necessary to fuse the wire in one minute, and are not appreciably different for other periods. For the lead-tin alloys, the fusing time is two minutes. Under normal running conditions, the actual temperature-rise at the hottest part of the fuse wire will be 100 to 150° C. for copper and 50 to 75° C. for the lead-tin alloy.

Supplementing "Kempe's"

A set of our catalogues will be found a valuable supplement to the electrical engineering sections of the "Engineers' Year Book." The principal catalogues are:—

Main Cables (Paper Insulated).
Rubber Cables.
C.T.S. Cables.
Bitumen Cables (and Elastumen Bitumen, for Colliery use).
Trailing Cables.
Semaphite Cables (acid-resisting).
The J. & P. Wiring System.
Some Examples of Switchboards by J. & P.
Ironclad Switchgear (Industrial and Mining Types).
Outdoor Switchgear.
Oil Switches.
Truck Type Switchboards.
Examples of Modern Transformer Practice.
Overhead Line Material.
Instruments.
Junction Boxes.

These publications are not bare catalogues, but contain much useful information. They will be sent on request to all interested in the transmission, transformation and control of electricity. In addition, we publish the J. & P. Transformer and Switchgear books, veritable text-books which we will also present to those directly interested in the purchase of transformers and switchgear.

British Standards for Insulated Annealed Copper Conductors for Electric Power and Light.*

No. 7—1926—(*Abstract.*)

The International Standards of Resistance for Copper are as follows:—At 20° C. (68° F.), th resistance of a wire of standard annealed copper 1 metre long and of 1 sq. millimetre cros section is $\frac{1}{58}$ (0·017241) ohm. The density of such copper at 20° C. is 8·89 grams per cub. centi metre, and the temperature coefficient of resistance is 0·00393 per degree C. At 60° F. (15·56° C. the resistance of a solid conductor of standard annealed copper 1,000 yards long and of 1 sq. in cross-section is 0·0240079 ohm; the density is 8·892015, and the temperature coefficient c resistance is 0·0022221 per degree F.

At 15·5° C. (60° F.), the resistance of a copper conductor is accurately given by th expression:

Resistance in microhms = 8 × length in feet/cross section in square inches.

For the purposes of the specification an increase of 2 per cent. in the length of each wire in th stranded conductor has been assumed, and the area of the stranded conductor has been taken t be that of the solid wire which has the same resistance. In the case of multicore cables, a increase of 2 per cent. has been taken, to allow for the laying-up of the cores.

Tolerances allowed on solid conductors are, in weight, 3 per cent.; in resistance, 3 per cent plain, 4 per cent. tinned (0·036 in. diameter upwards), 5 per cent. (below 0·036 in.). On strande wires, in weight 2 per cent.; in resistance, 2 per cent. plain, 3 per cent. tinned (0·036 in. diamete upwards), 4 per cent. (below 0·036 in.).

The resistance of hard-drawn copper is about 3 per cent. higher than that of annealed coppe conductors.

This specification also gives tables of sizes, resistances and weights of standard solid an stranded circular copper conductors, flexible cords and cables. Details of standard thickness c dielectric for paper, rubber and vulcanised bitumen insulated cables, the sizes and thickness c lead and tough rubber coverings, galvanised steel wire and tape for armouring are tabulated fc cables up to 11,000 volts. Pressure tests are specified together with the method of procedur An appendix contains diagrams showing sections of single and multicore cables and an extrac from the British Standard Glossary of Electrical Terms and Definitions.

Flexible Cables.

A flexible cable is one in which the conductor (or conductors) exceeds 0·007 sq. in. in cross section, and comprises a number of wires, the diameter of the wires and the material of the dielectri being such as to ensure flexibility.

A ONE MAN JOB

C.T.S. the Ideal Wiring System, but it should be St Helens

'Tis Better to be Safe than Sorry.

The old days of the Mechanical Engineers' share of the work in connection with Electric Wiring for factories and workshops have gone, to be replaced altogether by the Electrical Engineer where St. Helens C.T.S. is used.

No Casing or Conduits required.
No Screwing, Sawing or Bench Work.
No Remering or Bending in Vices.
No Bonding or Earthing needed

Because
St. Helens C.T.S. has its own protection against damage and corrosion incorporated in the cable.

St. Helens C.T.S. can be safely buried in Wet Plaster.

ST. HELENS Cable & Rubber Co. Ltd., SLOUGH.

The figures for vulcanised rubber cables apply to single cables run in pairs in iron conduits o in wood casing, and to single cables sheathed with tough rubber compound, and to concentri twin, and three-core cables of any finish run singly.

The maximum permissible currents (subject to voltage drop) given in the table for conducto up to 1 square inch in area allow for a rise in temperature of 20° F. (11·1° C.) For sizes belo 0·007 square inch the table is based on a current density of 4,000 amperes per square inch. Th length of lead and return given in the last column is based on the figures in the third column.

Where the temperature of the air exceeds 80° F. (26·6° C.), the current should be reduced s that the normal maximum running temperature does not exceed 100° F. (37·7° C.). Rubbe insulated cables should not be allowed to attain a temperature higher than 120° F. (48·8° C for long periods.

The figures for impregnated-paper and rubber-insulated cables apply to single cables run in airs, and to concentric, twin, and three-core cables run singly.

The maximum permissible currents (subject to voltage drop) given in the table for conductor p to 1 square inch in area allow for a rise in temperature of 50° F. (27·7° C.). For sizes elow 0·007 square inch, the table is based on a current density of 4,000 amperes per square inch. The length of lead and return given in the last column is based on the figures in the third column.

Where the temperature of the air exceeds 80° F. (26·6° C.), the current should be reduced so hat the normal maximum running temperature does not exceed 130° F. (54·4° C.). Impregnated-aper lead-covered cables, for pressures not exceeding 660 volts, should not be allowed to attain , permanent temperature higher than 176° F. (80° C.).

THE CALLENDER KALEECO WIRING SYSTEM is specially designed to eliminate the possibility of damage or interference with existing structure. Its adaptability is such that Castles, Churches, Mansions and Houses of all sizes and periods have been equipped efficiently at a reasonable cost and without disturbance. The wires employed in this system are rubber covered, taped and metal sheathed. These are clipped to wall surfaces, and although stiff enough to prevent sagging are easily bent round mouldings. When enamelled or distempered to tone with the decorative scheme the wires are practically invisible.

Illustrated Booklets showing various installations and price list giving full details will be sent willingly on application.

ALUMINIUM CONDUCTORS.*

Conductivity.

The conductivity of aluminium depends upon the purity, and, to a less extent, upon t amount of work put upon the metal in its evolution from billet to the finished wire or bar. T British standard of resistance for hard copper is 2 per cent. higher than that of soft, and t difference also applies to hard and soft aluminium. The conductivity of all materials is norma compared with that of the International Standard for annealed copper, and on this basis ha drawn aluminium will have a minimum conductivity of 60 per cent. Hard-drawn copper w have a conductivity of about 98 per cent. and hence compared with hard-drawn copper, ha drawn aluminium will have a conductivity of 61·3 per cent.

Weight.

The specific gravity of aluminium wire is about 2·71. As the specific gravity of copper w is about 8·89, the relative weight of a given volume of each metal is in the ratio of 8·89 to 2·71 3·3. In other words, a copper wire of any given size and length will weigh 3·3 times as much an aluminium wire of the same size and length. Aluminium, therefore, having a conductivity 61 per cent. of that of copper, will have a sectional area 1·642 times as great as a copper conduc of the same resistance and length, and the ratio of the weights will be 3·3 to 1·642 = 2·01; th is to say, a copper conductor of any given resistance and length will weigh approximately tw as much as an aluminium conductor of the same resistance and length.

The ratios are therefore as follows :—

	Copper.	Aluminium.
Conductance for equal section	1	0·61
Section for equal conductance	1	1·642
Diameter for equal conductance	1	1·28
Weight for equal bulk	3·3	1
Weight for equal conductance	2·0	1

Tensile Strength.

Although the tensile strength of aluminium in the annealed state is low, the strength aluminium in the form of wire is greatly increased owing to the work put upon it during roll and drawing. The strength can be increased more than 100 per cent. without making elongation too small for engineering purposes.

Durability.

Aluminium has withstood the test of varying and severe climatic conditions. Lines h been in operation for over twenty years in exposed positions on the sea coast which show li signs of deterioration. The metal is less affected by sulphurous and sulphuric fumes than copp and shows less deterioration in the presence of any of the commoner acids. On the other ha aluminium is attacked by strong alkalies, and should not be used in such circumstances with efficient painting.

Increase of Resistance with Temperature.

The coefficient of increase of resistance with temperature varies somewhat with the ext and nature of the impurities present and the temperature range over which it is taken. 20° C. the value for aluminium may be taken at 0·0040 per degree C.

Coefficient of Linear Expansion.

The coefficient of linear expansion being somewhat greater with aluminium than with copp due allowance should be made for this when installing long lines of solid feeders or bars.

Action of Acids.

Aluminium is not acted upon by any of the common acids in a cold state, with the except of hydrochloric acid, and withstands the effects of sea-water better than either copper or ir but galvanic action is set up between aluminium and any of the common metals in the prese

* See also B.E.S.A. Report No. 215—1925.

noisture, and for this reason, if iron and copper joints must be used, they should be thoroughly tected from moisture by taping or painting with bituminous paint. It is found that galvanised n parts can be used with aluminium owing to their closer proximity in the electro-chemical ies, and the hardware employed with aluminium overhead lines is usually of galvanised lleable iron.

Sulphur has no effect upon aluminium at ordinary temperatures, and consequently aluminium hstands the action of smoke and fog much better than either silver or copper. A thin trans-ent film of insoluble oxide forms immediately on the surface of aluminium when it is exposed the atmosphere, protecting it from further oxidisation or corrosion. This film of oxide is a od insulator and will withstand the application of considerable electrical pressure before aking down. Advantage is being taken of this feature in the manufacture of magnet ndings, etc., which are otherwise uninsulated.

Capacity and Inductance.

Aluminium being a non-magnetic material, the inductance or capacity of the line can only affected by the increased diameter. This increased diameter may decrease the inductance d increase the capacity by some 5 per cent., but as all transmission lines possess more inductance an capacity, this difference is in favour of aluminium, tending to improve the power factor the system and to reduce the pressure drop due to inductance.

Heating Effect.

Aluminium, having a larger surface than copper of equal conductance, is more easily a to get rid of its heat, and when transmitting a given current with a given I^2R loss, alumini will remain the cooler. This is a considerable advantage when installing electric apparatus a hot atmosphere, or where current-carrying capacity is of more importance than the permiss pressure drop. In any case aluminium will have a higher overload capacity, from a heat point of view, than copper of equal resistance. In consequence of this aluminium is being larg used for busbars and solid rod battery connections. Erection on site is facilitated by the e with which bends and joints can be made.

Corona Losses.—With a high voltage overhead line a serious loss of energy may occur in form of a luminous discharge due to the breakdown of the air surrounding the conductors. point at which corona begins is a function of the conductor diameter, and the use of alumini or, better still, steel-cored aluminium, both of which involve a larger diameter than that of equivalent copper, will safely enable a higher working voltage to be employed.

ALUMINIUM CABLE, STEEL-CORED.

After the introduction of aluminium for electrical conductors it became apparent that conductor could be obtained, combining the advantages of lightness of aluminium with strength of high-grade steel now obtainable on the market, the highest efficiency would res Cables of this character were made up and have now been in service in such a variety of locali and conditions that their efficiency has been thoroughly demonstrated.

The cables consist of a steel core about which the aluminium is stranded. The steel for smaller size cables consists of a single strand, while for the larger sizes several strands are u These are composed of patent steel, having an ultimate strength of 160,000 lbs. per square i to 200,000 lbs. per square inch, according to the diameter, an elastic limit of 70 per cent. of ultimate strength, and an elongation of 4 to 6 per cent. on 10 inches. The wires are hea galvanised, and after the aluminium strands are in place over the steel, around which they closely by reason of the stress resulting from the load on the cable, the steel is to a large ext protected from corrosive action. This protection is due to the almost complete exclusion moisture from the steel core by the aluminium envelope, and further on account of the insula oxide film on the aluminium, which tends to prevent the flow of small local electric curre Another feature which adds to this desirable condition is the fact that zinc and aluminium closer together in the electro-chemical series than any other two metals in common use.

The following table shows at a glance the superiority in mechanical characteristics of st cored conductors over all-aluminium, or copper of equivalent conductance.

Size.	—	Aluminium.	Steel-cored Aluminium.	Copper.
0·025 sq. ins. copper area	Weight	1·0	1·48	2·04
	Diameter	1·0	0·98	0·79
	Ultimate load	1·0	2·19	1·52
0·10 sq. ins. copper area	Weight	1·0	1·37	2·04
	Diameter	1·0	1·07	0·79
	Ultimate load	1·0	1·95	1·55
0·40 sq. ins. copper area	Weight	1·0	1·68	2·04
	Diameter	1·0	1·11	0·79
	Ultimate load	1·0	2·58	1·58

PHYSICAL PROPERTIES OF STEEL-CORED ALUMINIUM CONDUCTORS.

The strength of a steel-cored aluminium conductor is somewhat less than the sum of strengths of the component wires, owing to the fact that the aluminium wires will break before

el wire reaches its ultimate stress. The strength of the composite conductor may be taken 35 per cent. of the strength of the steel core plus 98 per cent. of the strength of the aluminium res.

The stress is not distributed uniformly over the different wires, and the stress in the steel l normally be about three times the stress in the aluminium.

The coefficient of expansion and modulus of elasticity of the composite conductor are culated upon the assumption that there will be no relative movement between the aluminium l steel wires. This is found to be the case in practice, and calculations based on 'virtual' ues of the constants as so determined are found to conform with sensible accuracy to observed ues. The constants depend upon the ratio of steel section to aluminium section in the con- ction, and the following values apply to standard forms:

No. of Wires.	Coefficient of linear expansion per F°.	Modulus of elasticity, lbs. per square inch.
7	$10{\cdot}55 \times 10^{-6}$	$12{\cdot}51 \times 10^{6}$
37	$10{\cdot}02 \times 10^{-6}$	$13{\cdot}45 \times 10^{6}$
61	$10{\cdot}90 \times 10^{-6}$	$11{\cdot}95 \times 10^{6}$

Splicing.

Small sizes of aluminium and steel-cored aluminium conductors are joined by aluminium Intyre Joints of the same form as commonly employed with copper. For larger sizes of steel- ed aluminium conductors different systems are employed, in all of which the aluminium and steel are joined separately. Among the methods employed may be mentioned the 'Pairard' at, which employs the principle of wedging cones, and the compression joint, in which the steel es are joined by a steel McIntyre joint, which is enclosed in an aluminium sleeve pressed on the aluminium wires.

Aluminium Overhead Lines.

Span Length.

With short spans where a large cross section is required, all-aluminium conductors have a g differing but little from that of copper, while in the case of a small cross section steel-cored uminium may be installed with a smaller sag and lower poles. In the case of long spans steel- ed aluminium is also employed, but in this case the span length may be increased. This leads a reduction of capital outlay and upkeep expenses owing to the reduced number of insulators.

Sag.

Various countries have regulations governing the erection of overhead lines, in which th factors of safety in the various components are fixed under certain specified weather conditions Under the British Regulations the spans must be such that the stress does not exceed one-half o the ultimate load when the conductors are loaded with a ½ in. radial thickness of ice and a simu taneous wind pressure of 8 lbs. per sq. ft., on the projected area of the ice-loaded conductors at temperature of 22° F. The fulfilment of these conditions necessitates that during the erectin the conductors shall be pulled up with a definite sag which will depend upon the temperature a the time. The maximum sag usually occurs at the maximum summer temperature, and it i upon this maximum sag that the height of the supports above ground depends. The table o p. 2205 gives the maximum summer sags, calculated at 122° F., for copper, aluminium, an steel-cored aluminium conductors of exactly equivalent conductivity:

Steel Overhead Lines.

The Pacific Companies are giving considerable attention to the use of steel in place c copper for transmission lines. Steel conductors not only effect a saving due to reduced cost pe unit of length, but also because of the longer spans permissible. Standard spans of 350 ft. t 450 ft. have been used extensively in the past; with the introduction of steel a 700-ft. span wa selected as standard, and many miles of line have been built with spans of this length. The span necessitate large sags, and the old style triangular construction, with pole-top pin, has bee adopted, to give greater clearances between conductors.

Owing to the greater strains, more careful guying is required at corners, and at sharp corne four to six anchors to the pole are occasionally required. The San Diego Co. has installed i main or branch lines, wire of ¼-in., $\frac{5}{16}$-in. or ⅜-in. standard steel, and of ¼-in. steel in constant current series circuits. Most of the constant pressure circuits are at 11,000 volts, though a fe are at 2,300 volts.

The world's longest span of overhead h.t. transmission wires has recently been built in Norway by the Stavanger Electric Power Company. It was required to transmit 12,000 h.p. from th power station at Lysefjord across Hoegsfjord to a transforming station at Oltedal, and from th station over 50,000 volt-lines to Stavanger. The three wires of the transmission line are supporte from three steel towers 7 m. high on each side of the fjord. The total free span is 1,384 m., th sag is 80 m., and the distance to the water surface 40 m. at the centre of the fjord and 80 m. at or side. The biggest span previously built was 1,350 m. across the Strait of Carquinez, in Americ The steel cable has 19 strands and a diameter of 16 mm., the breaking strength being 15 kg. p sq. mm. When no wind is blowing the total stress in the cables is 4 tons, but with maximu wind pressure the stress is 7 tons.

Copper Overhead Lines.

British Standard Specification for Hard-Drawn Copper Solid and Stranded Circul Conductors for Overhead Power Transmission Lines. No. 125—1924.*

The resistance of hard-drawn copper at 60° F. (15·6° C.) is based upon the resistance Standard Annealed Copper at 60° F. (see p. 2081). Weight 554·98232 lb. per cubic ft. C efficient of linear expansion between 32° F. (0° C.) and 86° F. (30° C.) = $9 \cdot 222 \times 10^{-6}$ p degree F. ($16 \cdot 6 \times 10^{-6}$ per degree C.).

Samples for mechanical tests to be taken on component wires of stranded conductors, and te sile strength of any wire must not differ from values in Tables I. and II. by more than 10 per cent average of all wires by not more than 8 per cent. Wires of less than 0·204 in. diameter sh withstand being closely lapped six times round wire of its own diameter, unlapped and similar lapped in same direction without breaking. Joints in wires before stranding must comply wi all requirements of specification. No joints permitted except before stranding in any wire of stranded conductor containing 7 wires or less. Joints (other than before stranding) in co ductors of more than 7 wires must not be closer together than 50 ft. The wires in strand conductors before stranding must fulfil requirements for solid wires. The primary standa sizes in Tables I. and II. (pp. 2209, 2210) are recommended to be used wherever possible.

Porcelain Insulators for Overhead Lines.

BRITISH STANDARD SPECIFICATION FOR PORCELAIN INSULATORS FOR OVERHEAD POWER LINE (3,000–150,000 VOLTS). No. 137—1922.*

The porcelain must be white, sound, completely vitrified, with insulation independent of the glazing, which must cover all exposed parts. The electrical design must conform to requirements in Table I., and when of more than one part the voltage drop across the assembled part shall be proportional to their thickness. Mechanical factor of safety to be not less than 2. The porcelain must not engage directly with a metal screw, and must be unaffected by stresses set up by temperature changes. Every insulator shall be impressed with the manufacturer's mark before fixing, and, when conforming to this specification, bear the Association's brand. Type tests to be carried out on not less than three samples completely fitted in the following order. In tests 1 to 4, failure shall not occur below the appropriate values in Table I.

1. *Inherent Stresses.*—Insulator and glaze to withstand test voltages in columns 2, 3, or 4 of Table I. (applied as for Test 2) after being heated in water at 50° C. for one hour and immediately immersed in ice and water for one hour, the test being repeated three times.

2. *Dry Spark-over Tests.*—Testing pressure to be applied between the support and a wire of 0·4 inch diameter attached to insulator. Test to begin at one-third full voltage, and increased at 1 k.v. per second until spark-over occurs.

3. *Rain Tests.*—Insulator to be tested as in Test 2, but subjected to artificial rain at 15° of 1 inch in 5 minutes directed downwards at 45° from vertical. Specific resistance of the water to be not more than 20,000 ohms per cm. cube.

4. *Puncture Test.*—Insulator to be tested as in Test 2 while immersed in oil.

Note I.—The term 'Delivered Voltage' denotes the normal voltage between conductors at the delivery end.

For the purposes of this Specification the Working Voltage is assumed not to exceed the Delivered Voltage by more than 10 per cent.

Note II.—Test voltages for special insulators required for intermediate voltages may be ascertained from a curve prepared from the above figures.

Note III.—In cases where testing apparatus is not available for puncture tests at pressures exceeding 310 k.v., arrangements may be made to test the insulator units separately and to estimate the equivalent puncture test voltage of the complete insulator from these individual tests.

* By permission of the British Engineering Standards Association.

† These four voltages are not included in B.S. Specification No. 77—Standard Pressures for New Systems and Installations.

5. *Mechanical Test.*—Complete insulator with metal fittings must withstand loads in accord-e with Table II. For a pin insulator the tension is applied by a flexible wire rope placed round r, and for tensioning and suspension types the load is applied between metal connecting parts either side. Any permanent deformation constitutes failure.

3. *Porosity Test.*—The finished porcelain shall show no signs of impregnation when broken es free from external glaze are immersed for twenty-four hours in a 0·5 per cent. alcoholic tion of fuchsin under a pressure of 2,000 lbs. per sq. in.

Routine Tests.—Every complete pin insulator shall be inverted in water, and withstand, iout puncture, for five minutes the spark-over voltage between testing terminal and wire ched to neck groove. Every unit of a tension or suspension insulator must withstand for minutes the spark-over voltage of that unit without puncture, and the complete insulator a 20 per cent. above maximum working load applied vertically for one minute.

Appendices to specification give experimental methods of carrying out mechanical and trical tests.

TABLE II.

Electricity Supply.

The standard voltages of supply laid down by the British Engineering Standards Association port No. 77—1925) for new systems and installations are as follows (at consumers' terminals):—

Direct current, 230 and 460 volts; alternating current, 230 volts between neutral wire and of the principal conductors, 400 volts between any two of the principal conductors.

The standard high voltages for new systems and installations are: 3,000, 6,000, 10,000, 00, 60,000, 100,000, and 120,000 volts.

In each case the approximate station voltage is assumed to be 10 per cent. higher at full load.

Periods allowed by the Electricity Commissioners for Repayment of Loans.

d—	Years.		Years.
reehold	60*a*	Mains and services	25
easehold (subject to duration of lease)	30	Meters	10
stantial buildings	30	Wiring of premises	10
nt and machinery	20	Apparatus to be let on hire	7–10
P. trunk transmission mains	40*a*		

(*a*) Except in Scottish cases, for which the present maximum period is 30 years.

Generation of Electricity in Great Britain.*

The total units generated in Great Britain up to March 31, 1926, were 8,122,961,823. In 1925 total was 7,415,375,529. The total number of stations in 1926 was 584, which was also the l number for 1925.

The steam stations in 1926 generated 96·08 per cent. of the total; gas-producer stations, 5 per cent.; oil engine stations, 0·56 per cent.; waste heat, 2·19 per cent.; refuse destructors, 2 per cent.; gas engines using town's gas, 0·04 per cent.; water power, 0·56 per cent. In 5 the steam percentage was slightly less, viz. 95·63 per cent., water power slightly more, 0·69 per cent.

According to Mr. H. Quigley, Chief Economist of the British Electrical and Allied Manufac-ers' Association, during 1927 there has been a 25 per cent. increase in the output of electricity reat Britain, the total being 10,500,000,000 units, approximately.—*Times, Jan. 21st, 1928.*

* *Generation of Electricity in Great Britain, Year ending March* 31, 1926. Electricity Com-sion, H.M. Stationery Office, Adastral House, Kingsway, London, W.C. 2. Price 1*s.* 6*d.* net.

Ministry of Transport Regulations in reference to Overhead Electric Lines.

Every application for the consent of the Electricity Commissioners to the placing of electr lines above ground should be accompanied by the following particulars :—

1. Where the undertakers are a company, or a local authority supplying outside their ow area, evidence of consent of the local authority for the district.

2. A statement showing commercial or other considerations why underground cables shoul not be used.

3. A brief description of the proposed system, whether by continuous or by alternating current the working voltage ; the kind of wire, whether copper or aluminium ; whether solid or strandec the total sectional area ; tensile strength and elongation ; average and maximum length of span minimum height of wires from the ground ; name or description of automatic protective devic if any.

4. A statement whether the supply is to form (1) an extension of an existing system of unde ground cables, or (2) of an existing traction system, or (3) an independent system.

5. An ordnance map on a scale of 6 ins. to the mile, showing the proposed route of the ove head lines and any existing overhead lines. The sheets of these maps must be fastened togethe

6. In the case of high and extra high pressure, plans of construction of poles, etc., on a sca of about 1 in. to the ft., or a reference to previously deposited plans where these are identic with the proposed work.

Regulations of the Electricity Commissioners. (El.C. 38–1926).

Regulations for Securing the Safety of the Public.

1. Supply pressure shall not exceed the low-pressure limit of 250 volts, except for power or a lamps in series, when the medium pressure limit of 650 volts is permissible under the followi conditions. Machine frames must be earthed, motor leads enclosed in earthed metal casing wi enclosed fireproof and shockproof switches and fuses, switch when opened must completely c off motor and all auxiliary devices. Similar conditions apply to arc lamps and incandescent lam in series. Regulations 1 and 2 do not apply to a factory, workshop, mine, or quarry.

2. Where the voltage between the outer conductors of a 3-wire system exceeds 250 volts a is taken into premises, two pairs of terminals shall be provided and the wiring from these ke distinct.

3. The Commissioners reserve their consent to the supply of extra high pressure to consume premises.

4. Minimum area of conductor installed in street line to be 7/20 gauge except for lamp-p wiring.

5 Supply mains to be tested at at least 200 volts, and results of tests to be recorded before t supply is begun.

6. Insulation of every complete circuit used for supply of energy to be maintained so th leakage current never exceeds $\frac{1}{1000}$ part of maximum supply current. Measurements must made weekly, records kept, leakage remedied without delay, and means provided for indicati and localisation of leakage.

7. High-pressure circuits (650 to 3,000 volts) must not be brought into use until successfu tested for ½ hour at twice the maximum working pressure in the case of lines and 50 per ce excess of normal for machines and apparatus. Results to be recorded.

8. Every high-pressure main, etc., to be fitted with fuse or automatic circuit breaker, exc the outer earth conductor of a concentric main.

9. Automatic quick-acting device must be fitted on transformer circuits to prevent cont or leakage from high-pressure circuit to consumers' wires.

10. All metallic portions (except conductors) of high-pressure transformers to be earthed.

11. Exposed lines and their supports to be protected from injury by lightning.

12. The undertakers must inform Commissioners of all accidents.

Overhead Lines.

13. Overhead lines erected after this date (1926) to be in accordance with Commission Regulations.

Electric Lines other than Overhead.

14. Conduits, street boxes, etc., to be constructed of durable material, and where laid und ground to be unaffected by heavy traffic. Accumulation of gas must be prevented.

15. Precautions must be taken to prevent the charging of any metallic substance directly indirectly from any electric line.

16. All high-pressure conductors carrying conduits to be jointed, connected across street-box and efficiently earthed.

17. Bare conductors in conduit must not exceed 300 volts to earth, and must be secured position. Such conduits must be moisture proof and insulators so placed that they can inspected.

8. High-pressure lines on ground surface or public subway must either be enclosed in insulating embedded in brickwork, masonry or concrete, or in an earthed metal casing.
9. Means must be taken to prevent the ground surface or other conductors becoming charged eakage from a high-pressure line.
0. A high-pressure line must be properly laid, jointed, examined, and tested and in the sole ge of the undertakers before being used for supply of energy.

Sub-stations and Street Boxes.

1. To be in sole occupation and charge of the undertakers and placed above ground wherever sible: if underground, provision must be made for ventilation and drainage.
2. In addition to regulation 14, (*a*) covers of street boxes only to be opened by special liance; (*b*) covers of street boxes containing high-pressure apparatus other than cables must n connection with metal strips laid immediately underneath the street, and means taken to vent all exposed material, including the street surface, becoming charged by any means; treet boxes used as transformer chambers must not be subject to influx of water, and when of ater size than one cubic yard must be adequately ventilated; (*d*) street boxes must be regularly ected for the presence of gas, and notice of gas influx must be immediately given to the gas ority concerned; (*e*) mains at different pressures in the same street box must be readily inguishable.
3. Maximum power supplied to underground sub-station or street box containing one trans- er must not exceed 30 k.w., or 75 k.w., if with two or more transformers, without consent of mmissioners.

Consumers' Premises.

4. The undertakers shall be responsible for maintenance of their property on consumers' mises.
5. The undertakers must guard against fire risks in delivering energy to premises.
6. Fuse or automatic circuit breaker in fireproof, sealed receptacle to be fitted near entry of h service main if latter is unprotected by fuse in the street box. No fuse or circuit breaker st be inserted in intermediate conductor of a 3-wire system.
7. Service lines and apparatus on consumers' premises must be highly insulated, moisture- of and all exposed bare metal forming part of a circuit, efficiently earthed. Lines must be d and protected to prevent electrical discharge to nearby metal.
9. Consumers' wires must not be connected to undertaker's mains unless the resulting kage is not in excess of one ten-thousandth of maximum current supplied to the premises. tice of objection must be served upon the consumer.
0. Undertakers have the right, after giving notice to consumer, to test wires and fittings leakage and to discontinue supply if excessive leakage is found (see 29), or facilities for testing l inspection are refused.
1. Consumer may appeal for an independent test to an electrical inspector on payment of scribed fee. This regulation must be endorsed on every notice served under regulations 29 d 30.

Arc Lighting.

2 and 33 respectively fix the minimum height of any part of an arc lamp 10 feet above ground. l provide for the provision of arc lamp guards, forbidding the use of arc lamps where explosive t or gas may be present.

Connection of Circuits with Earth.

4. Where supply pressure between adjacent conductors of a 3-wire system of mains exceeds volts, the intermediate conductor for each distinct circuit shall be earthed at one point only, nely, at generating station, sub-station or transformer, the insulation being maintained else- ere. The earth current from intermediate conductor must be continually recorded and must exceed at any time one-thousandth of maximum supply current.
5. Penalties are provided for default of regulations 1 to 35.

Regulations for Ensuring a Proper and Sufficient Supply of Electrical Energy.

1. Supply must be constantly maintained, and in case of d.c. without change of polarity. tice of any interruption for testing purposes or polarity change must be given to consumer.
2. Distribution mains must be sectionalised on their respective feeders and connected only ough circuit breakers or fuses.
3. Variation from declared pressure of supply shall not exceed $\pm$ 4 per cent. Public notice th consent of Commissioners is required for any alteration of conditions.
4. The system and frequency of supply (in a.c. systems) must be declared. Variation of quency from declared value must not exceed $\pm$ 2½ per cent. Notice and consent required for eration (see 3).
5. Penalties are prescribed for default of regulations 1 to 5.

Regulations of Electricity Commissioners for Overhead Lines. (El.C. 39–1924).

General Regulations.

1. Conductors to be of copper, aluminium, or other approved material.

2. Conductors to conform to B.E.S.A. specification for elongation, breaking load, and elasticity If no specification be in force at time of erection, characteristics measured on a single wire sha not be less than :—

Material.	Elongation in length of 10 inches. Per cent.	Breaking Load. Tons per sq. in.	Young's Modulus of Elasticity. Lbs. per sq. in.
Copper	1	24	10×10^6
Aluminium	4	11	10×10^6

3. Minimum permissible size for copper and aluminium conductors must have an actu breaking load of not less than 650 lbs. Minimum areas for copper and aluminium : 0·0098 sq. i and 0·0237 sq. in. respectively.

4. Conductors must be rendered inaccessible to persons not having the use of appliance Regard must be paid to the normal use of his land or premises by the occupier. See 17.

5. Except in the case of contact between broken conductors and earth were on the same suppor precautions must be taken by the undertakers against contact between line conductor and an other overhead wire.

6. Line insulators to be carried on supports of wood, iron, steel, or reinforced concrete. Co rosion of metal work on or below ground surface to be prevented. Wooden supports must be red fir, except oak or hardwood cross arms.

7. Supports, in conjunction with any struts or stays, shall take all loads without damage movement in the ground. Strength in direction of line must not be less than one quarter transverse strength. Factor of safety for iron and steel 2·5, for wood and reinforced concrete 3· These factors to be calculated for 22° F. with ice covering specified in 11 and 14, and with a win pressure of 8 lbs. per sq. ft. on whole of the projected surface, corresponding to a velocity of m.p.h. at right angles to the line. Strength of foundations under these conditions to give factor of safety of 2·5 against overturning. Wind pressure on lee side members of lattice other compound structures, A and H poles, to be taken as one-half that on windward side, an factor of safety calculated on crippling load of struts and upon elastic limit of tension members.

8. Service lines to be connected only at a point of support, and fixed to insulators on consumer premises. Service lines (other than an earthed neutral conductor) which are accessible from building must be protected by insulating material or otherwise.

Service lines over carriage ways must not be lower than 20 ft. from the ground except wit consent of Commissioners.

9. The whole structure with all appliances must be regularly inspected and maintained.

10. Materials must conform at time of erection to B.E.S.A. specifications and to the Po Office Technical Instructions of Aerial Lines.

Specific Regulations.

A. For pressures not exceeding 650 volts d.c. and 325 volts a.c.

11. Factor of safety of line conductors, 2, based on breaking load at 22° F., with ½ in. radi thickness of ice and simultaneous wind pressure as in 7.

12. Minimum height of any wire (except service) not to be less than 20 ft. at temperatur below 122° F.

13. Where pressure to earth exceeds 250 volts d.c. or 125 volts a.c., precautions shall be tak to prevent danger

(*a*) from a broken conductor ; by earth wire suitably disposed or other approved metho

(*b*) from leakage : in cases of metal poles, by provision of earthed wire connecting t poles, or by supporting the insulators on insulated metallic frame connected neutral conductor. With wooden poles by a bonding wire connected to supporti metal of all insulators and terminating at lowest part thereof and not less th 10 ft. from ground. Other means may be approved.

Where lighting or uninsulated conductors are run down wooden poles to within 10 ft. of t ground, precautions against leakage must be as for metallic poles. Unearthed stay wires mu be insulated by insulator placed not less than 10 ft. above ground.

B. For pressures exceeding 650 volts d.c. and 325 volts a.c.

14. Factor of safety of conductors as in 11, except that for ½ in. ice, read ½ in.

15. Minimum heights of conductors above ground at temperatures below 122° F. are 20 ft. for ssures not exceeding 66,000 volts, 21 ft. exceeding 66,000 and below 110,000 volts, 22 ft. ,000 to 165,000 volts, and 23 ft. above 165,000 volts.
16. Means must be taken to render broken conductors dead. All other metal work to be thed by continuous earth wire earthed at four equidistant points per mile; alternatively tal shall be effectively earthed at each support. When earth contact is made by a line ductor, leakage current must be at least twice that required to operate safety devices.
17. At road, canal, or railway crossings, in addition to 15, there shall be provided (*a*) duplicate insulators with automatic earthing of a fallen conductor or (*b*) duplicate insulators tied at ervals not exceeding 5 ft.

Where line is erected along or within 50 ft. of road, canal, or railway, (*a*) duplicate insulators (*b*) automatic earthing for fallen conductor shall be provided. Other means may be approved.
18. Supports must be consecutively numbered, carry permanent danger notice, and guarded n unauthorised climbing.

Regulations Relating to Extra High Pressure. (El.C. 13–1920).

The following *additional* regulations relating to *extra high pressure* have been issued by the nmissioners.

A. *Regulations for Securing the Safety of the Public.*

3. An extra-high-pressure main before being brought into use shall be tested in position to hstand for half an hour continously a pressure of 10,000 volts in excess of the working voltage, en this exceeds 10,000 volts, or twice the working pressure when this is less than 10,000 volts. sults of tests must be recorded.
4. Suitable fuse or circuit breaker must be provided for every main, but not in earthed outer nductor of concentric mains.
8. Where leakage from 3-phase mains is prevented by a copper strip under the lead sheath of ble, this shall not be less that 0·016 in. thick, and where steel wires are thus employed outside a d sheath, each shall not be less than 0·1 in. in diameter. A lead sheath must be efficiently thed and not less than 0·1 in. thick.
9. Single-phase supply mains to consist of two concentric conductors or separate conductors. ters of concentrics to be earthed at one point: with separate conductors, leakage to be pre- ted as with 3-phase mains.

Street Mains.

11. These mains must be enclosed in strong metal casing where passing through street box with ier mains: boxes must not contain any other undertaker's electric mains, nor water or gas es. Telephone wires belonging to the undertakers are allowed.

Sub-stations.

12. Must be in sole or joint occupation of the undertakers or authorised distributor.
13. When constructed below streets, must contain no switches or apparatus other than nsformers.
14. The transforming apparatus must be arranged to avoid danger of excessive voltage on nected mains.
15. Precautions must be taken against fire risks.
17. Gives right of entry and examination to the Commissioners.

Connection of Circuits with Earth.

18. Earth connection to be made at only one point on a circuit, viz. generating station, sub- tion or transformer. Insulation must be maintained elsewhere.
19. When neutral star point of each distinct 3-phase circuit is earthed through a resistance, s must be low enough to ensure the action of the cut-out in the mains.
Separate electrostatic voltmeters must be connected in the generating station between each tinct circuit and earth to act as leakage indicators. Faulty circuit insulation must be mediately restored.
20. Penalties are prescribed against default which are not to affect liability of undertakers respect of damages caused by default.

B. *Regulations for Ensuring a Proper and Sufficient Supply of Electrical Energy.*

1. Undertakers must maintain sufficient and constant supply from the main to authorised stributors and consumers.
2. Maximum load on a main not to exceed 1,000 k.w. without consent of Commissioners, less provision is made for alternative supply in the event of breakdown.
3. Minimum pressure to be declared. Pressure at authorised distributors' terminals must t be less than this minimum, and not exceed it by more than 12½ per cent. Alteration of mini- um to be allowed only by consent of Commissioners after one month's public notice of such plication.

4. Frequency to be declared 50 or 25 cycles per second; 2½ per cent. variation allowed. Co
sent and notice of alteration as in 3.

5. Penalties are prescribed for default.

These regulations are in addition to any regulations relating to mines and factories made b
any Act, and also include regulations 9, 16, 18, 20, and 27 of El.C. 38, summarised above.

The Electrical Equipment of Buildings,

REGULATIONS ISSUED BY THE INSTITUTION OF ELECTRICAL ENGINEERS.

(Ninth Edition, 1927.)

(*Abbreviated.*)

SUPPLY PRESSURE.

These regulations provide for wiring based on the following pressures of supply :—

Medium pressure, i.e. above 250 volts and below 650 volts.
Low pressure, i.e. above 30 volts a.c or 100 volts d.c., but not exceeding 250 volts.
Extra low pressure, i.e. below 30 volts a.c. or 100 volts d.c.

GENERATING PLANT.

Generators must comply with the following :—

(*a*) They must be placed in well-ventilated rooms where inflammable dust or gases cann
accumulate.

(*b*) They must be protected from damp, dust, or mechanical injury.

(*c*) No unprotected woodwork or other combustible material shall be within a distance
12 ins. from them measured horizontally, or within 4 ft. measured vertically above them.

(*d*) When the supply is at medium pressure, the generating plant shall have its frame an
bedplate earthed.

SECONDARY BATTERIES.

(*a*) A p.d. exceeding 50 volts must not exist between adjacent cells without adequat
protection. Each cell shall be readily accessible from the top and at least from one side.

(*b*) In a lead-sulphuric acid battery with more than 33 cells, and in a nickel-iron alkalin
battery with more than 53 cells, the cells shall be supported on glass or vitreous porcelai
insulators. The stands shall also be insulated if there are more than 56 and 88 cells respectively

(*c*) When acid is used as an electrolyte for the cells, the battery-connecting bolts, unless
non-corrosive type, shall be kept covered with petroleum jelly.

(*d*) Cells having containers not sealed nor provided with screw-down covers shall have spra
arrestors.

(*e*) Celluloid shall not be employed for non-portable batteries.

(*f*) The battery-room shall be well ventilated.

(*g*) As a minimum, the gear controlling the current shall comprise an automatic cut-in an
cut-out switch and fusible cut-out, or a circuit breaker with overload and reverse-current trip

SWITCHBOARDS.

(*a*) Must be placed in dry and well-ventilated situations away from explosive dust or aci
fumes.

(*b*) Must be constructed wholly of durable, non-ignitable, non-absorbent materials.

(*c*) If marble or slate be used, all conducting parts shall be insulated with mica or othe
non-hygroscopic substance.

(*d*) Terminals must be provided for earth connection.

(*e*) Live parts must be spaced or shielded so that an arc cannot be maintained.

(*f*) All connections shall be readily traced.

(*g*) All parts shall be readily accessible, and no fuse shall be fixed at the back of the board.

(*h*) All nuts at back of board must be effectively locked.

(*i*) All circuits, instruments, etc., shall be clearly labelled.

(*j*) Connecting wires to every voltmeter and earth lamp must be protected by a fuse on eac
insulated pole.

(*k*) The moving parts of switch, in the ' off ' position, must be disconnected from the supply.

(*l*) With fuses and switches on same pole, the fuses must be disconnected from supply whe
their respective switches are in the ' off ' position.

MAIN SWITCHGEAR.

Every main switchboard must be fitted with the following switchgear as a minimum :—

1. *Two-wire Systems of Wiring.*

(*a*) When supply is obtained from one generator or a single service main, for these and fo
each outgoing circuit either a double pole overload circuit breaker or a linked switch with
fuse on each pole. (For earthed system, single pole on the insulated main.)

(*b*) With several generators not running in parallel or with duplicate service mains, changeer switches must be used, in addition, on each outgoing circuit.
(*c*) With generators in parallel, a double-pole circuit breaker (single-pole for earthed system) ted with overload and reverse-current trips. For compound-wound machines an additional igle-pole equaliser switch interlocked so that equaliser must be closed before and opened after e main circuit breaker.

2. Three-wire Systems of Wiring.

Each generator or each side of service mains and each two- or three-wire outgoing circuit ouble-pole apparatus as for two-wire system. No fuse or unlinked switch on neutral. When eutral is known to be directly earthed, a two-conductor earthed circuit may have single-pole verload circuit breaker or switch and fuse in outer conductor.

3. Two-phase Three-wire Systems of Wiring.

Each generator or service main and each outgoing three-conductor circuit a triple-pole circuit reaker with overload trips on each phase or a triple-pole linked switch with a fuse on each nductor except the neutral. Each outgoing two-wire circuit, double-pole circuit breaker ith overload trip on at least one conductor or double-pole switch and fuse.

4. Three-phase Three-wire Systems of Wiring.

For each generator or service main and each outgoing three-conductor circuit, either a triple-ole circuit breaker with overload trips on at least two phases, or a triple-pole linked switch with fuse on each conductor. For each two-wire outgoing circuit these to be double-pole.

5. Two-phase Four-wire Systems of Wiring.

Each generator or service main and each outgoing four-conductor circuit, either a four-pole rcuit breaker with overload trip coil on each phase or a four-pole linked switch with a fuse on ch conductor. For each two-wire outgoing circuit double-pole circuit breaker with overload ip on at least one conductor or double-pole switch and fuse.

6. Three-phase Four-wire Systems of Wiring.

For each generator or service main, a triple-pole circuit breaker with overload trips on each hase (at least on two phases for outgoing three-conductor circuit), or a triple-pole linked switch ith a fuse on each phase. For each outgoing two-wire circuit supplied from one phase and irectly earthed neutral, single-pole gear as above connected in the phase conductor. (Double-ole with unearthed neutral.) For four-wire outgoing circuits supplying a distribution board, iple-pole gear as above, but no fuse or unlinked switch in neutral conductor, except for testing.

INSTRUMENTS.

Every main switchboard not supplied from an external source must have the following inimum:—

Two-wire Systems of Wiring.

For a single generator an ammeter and voltmeter. For generators not to be run in parallel, ne ammeter for each machine and a voltmeter to be fitted with multiple-way switch or plug. For parallel running, an ammeter for each machine and two voltmeters, one being connected to us-bars and the other arranged for use on any generator. Alternators to have synchronising evice. The ammeter in the circuit of compound wound machines to be connected in opposite ole to equaliser connection.

Three-wire Systems of Wiring.

An additional voltmeter to be connected between neutral and each outer bus-bar and a entral-zero ammeter for d.c. or central-zero wattmeter for a.c. in main neutral conductor.

Two-phase and Three-phase Systems of Wiring.

For a single generator an ammeter on each phase and one voltmeter. For each generator running in parallel, an ammeter in each phase; one voltmeter on bus-bar and one on multiple-way switch, for use on one phase of any generator. A synchronising device.
Instruments should conform to British Standard Specification No. 89.

Earth Testing.

Except for extra low pressure plant of less than 5 kw. capacity, the switchboards of private installations must have suitable means for indication insulation.

Switches and Circuit Breakers.

(*a*) Must be able to carry working current continuously with a temperature rise above the air of not more than 36° F. (20° C.), if rated at less than 100 amperes, and 54° F. (30° C.), for ratings of 100 amperes or more.

(*b*) Must not arc over when breaking 50 per cent. excess current at a pressure 50 per cent. above that of the supply. Fuse switches and circuit breakers must fulfil regulations for fusible cut-outs. (See British Standard Specifications 109 and 110.)

(*c*) Accidental closing impossible.

(*d*) Provision for renewal of main arcing contacts.

(*e*) Handles must be robust and must not be operated through unprotected slots. Operator must be protected from live metal or any injury from adjacent apparatus.

(*f*) Bases to be of durable, fireproof, non-absorbent insulating material. Slates to be planed all over, free from metallic veins, and if of slate must be treated (including holes) with damp-proof medium after drying. All bolts fixing slate or marble slabs must be insulated from slab, and the latter similarly from metallic frame by non-hygroscopic insulating bushes and washers.

(*g*) The live parts of switches not mounted on a switchboard must be enclosed by metal or fireproof insulating covers, guarded from mechanical injury, and giving proper clearance from live parts and protection against arcing.

(*h*) When placed out of doors or in damp places, must have weather-proof cases and proper provision for leading-in cables. Suitable glands are given in British Standard Specification No. 94.

(*j*) Operating current must be adjustable on electromagnetic circuit breakers, and latter must be incapable of being held in against this current.

(*k*) Arrangements and position must avoid all risk of fire.

Fusible Cut-outs.

A. *For Extra Low Pressure.*

(*a*) Temperature rise of any part of the fitting above air not to be more than 54° F. (30° C.), with normal current continuously.

(*b*) Fusing current to be double the current capacity of the smallest cable controlled by the fuse when fusing time is one minute (two minutes for a lead-tin alloy fuse). No fuse to blow at less than 7 amperes need be inserted in final sub-circuits.

(*c*) The base to be of durable, fireproof, non-absorbent insulating material, and all construction must avoid arcing and scattering of metal.

(*d*) No fuse to be placed in ceiling roses, wall plugs, or sockets, or in switches other than fuse-switches of regulation patterns with metal covers. A fuse rated at not more than 5 amperes may be used in projecting wall socket adapters taking the pins of a smaller plug.

(*e*) Cut-outs not fixed on switchboard must be grouped on distribution boards or contained in regulation cases unless completely enclosed.

(*f*) Removable carriers to be used except where the covers provide against scattering of metal, and the maximum power in the building does not exceed 1000 watts.

B. *Low-pressure Cut-outs must in addition :*

(*a*) Be provided with safe insulating carrier for the fuse, with convenient contacts for the wire.

(*b*) Base contact to be unaffected by vibration.

(*c*) Risk of contact with any live metal to be avoided when handling a carrier.

(*d*) Cut-outs and carriers to be graded ' Ordinary Duty ' and ' Heavy Duty.'

Maximum working current.	Maximum short-circuit current for ' Ordinary Duty ' cut-outs.
10 amperes	1,000 amperes
30 ,,	2,000 ,,
60 ,,	4,000 ,,
100 ,,	6,500 ,,

' Heavy Duty ' cut-outs to be used where ' Ordinary Duty ' cut-outs are inadmissible.

C. *Medium-pressure cut-outs must fulfil conditions* A (*a*) *to* (*f*) *and* B (*a*) *to* (*e*).

(See British Standard Specification No. 88 for Low-pressure Electric Cut-outs.)

Section and Distribution Boards.

A. Must generally comply with all regulations for switchboard, circuit breakers, and fusible ıt-outs, except for final sub-circuits carrying less than 20 amperes.

B. Unless current-carrying parts of all accessories are permanently protected, they must ave a protecting case, which with earthed concentric wiring systems must provide, if of metal, or attachment to case of all external conductors; if of wood, an interposing metal sheet between and the support not less than $\frac{1}{16}$ in. thick, to which all external conductors are connected.

C. Arcing under short-circuit conditions must be impossible.

D. Cases of soft wood to have fire-proof insulating lining, and all boxes not provided with ıcks shall be so shielded from the supports. A glass front must have 1 in. (2·5 cm.) clearance om live parts.

E. When placed out of doors or in damp places, must be weatherproof with proper provision r leading-in.

F. Dimensions must allow of easy access for connecting.

G. Cut-outs must be grouped vertically with fire-proof insulating material between opposite ıles.

Conductors of Cables.

(*a*) All conductors, other than the outer conductors of earthed concentric systems, shall be of nnealed copper.

(*b*) The sizes of conductors set out in the table on p. 2193 are recognised as standard. The andard sizes and resistances of conductors for flexible cables and flexible cords are set out in ıbles on pp. 2196 and 2197.

(*c*) No cable having a conductor of nominal sectional area less than 0·0015 sq. in. (1/·044 in.) ıall be used except for wiring fittings.

(*d*) All conductors having a nominal sectional area exceeding 0·003 sq. in. (1/·064 in.) shall ə stranded.

(*e*) For lighting, the drop from the consumer's terminals to any and every point in the stallation shall not exceed 1 volt plus 3 per cent. of the pressure at the consumer's terminals hen the conductors are carrying the maximum demand under the practical conditions of service. he current shall not exceed that in tables on pp. 2198–2199. For flexible cables the permissible ırrents are given in tables on pp. 2197 and 2200.

Insulation and Protective Covering of Conductors.

The following types have been approved :—

A. *Vulcanised Rubber-insulated Cables*—(*a*) insulated with a layer of pure rubber, an inter- ıediate layer of vulcanising rubber, and an outer jacket of vulcanising rubber and compounded r, alternatively, a homogeneous dielectric of vulcanised rubber free from corrosion of tinning— the latter is used as protective covering it must conform to the requirements of the tough rubber ompound (see p. 2235); (*b*) taped as (*a*) and braided; (*c*) sheathed with a closely fitting seamless overing of commercially pure lead, having a smooth exterior surface and of uniform radial hickness; (*d*) lead-covered as above and bedded and armoured, with or without serving or raiding over the armour; (*e*) bedded and armoured with or without serving or braiding over ne armour; (*f*) encased in a closely fitting covering of brass, copper, or equally hard incorrodible ıetal: (*g*) sheathed with a closely fitting seamless covering containing not less than 95 per cent. f commercially pure lead; (*h*) covered with tough rubber compound.

B. *Paper-insulated Cables*: as (*c*), (*d*), (*f*), and (*g*).

C. Of the types in A, the following shall not be used for a.c. except in connection with an arthed concentric system in which the sheathing forms one conductor; single cables armoured rith steel wire or tape or encased in a ferrous sheath, or single, unarmoured, lead-covered cables aving a conductor of area exceeding 0·25 sq. in.; or brass, copper or equally hard incorrodible ıetal with conductor above 0·1 sq. in.

Twin Flexible Cords.

(*a*) Twin twisted flexible cords shall be used only for fixed wiring, fixed fittings and portable ımp standards; in all other positions and for all other purposes, flexible cords made up to a ircular or oval section shall be employed—the use of circular or oval section flexible cords is ecommended for all portable fittings.

(*b*) The maximum weight carried by a twin-twisted flexible cord shall be as follows :—

Number and diameter of wires in conductor.	Maximum weight.
14/·0076 ins.	3 lbs.
23/·0076 ,,	5 ,,
40/·0076 ,,	10 ,,

Installing and Fixing of Conductors and Cables.

Bare conductors may be used as collectors on trolley wires for cranes, etc., and for battery connections, supported on insulators and spaced so that risk of accidental contact is reduced to a minimum. At the ends of each conductor, straining gear with double insulation to be used. The supply circuit must be protected as for insulated conductors. Lightning arresters on each pole or phase to be used where necessary. Wall supports for span wires must not be within 12 ins. of any gas pipe. Except as above, bare conductors shall only be used in positions not ordinarily accessible to unauthorised persons and under conditions sanctioned by fire offices.

Taped and Braided Cables (Class L) may be used without conduit or casing provided that they are:—

(i) Open to view throughout their length and not installed under floors or buried in plaster.
(ii) Kept away from structural metal work.
(iii) They are protected where within 6 ft. above the floor or when liable to mechanical damage.
(iv) Kept away from gas and water pipes.
(v) Secured by porcelain cleats, clips, saddles, or clamps to prevent the cables coming into contact.
(vi) In damp situations, not less than ¼ in. away from wall.
(vii) Protected by non-absorbent, non-ignitable conduits when passing through floors, walls, or ceilings.
(viii) When passing through party walls or fireproof floors, the conduits to be close-fitting and holes plugged with non-ignitable material.

Metal-sheathed Cables (Class M1) may be used without conduit or casing provided they are in accordance with condition (iv) above and
(ix) Secured by clips, saddles, or clamps to prevent appreciable sagging or damage to cable.
(x) Vertical cables are fixed in the same way as horizontal. When inaccessible, 10 ft. allowed between supports.
(xi) All metallic envelopes of cables to be effectively earthed and made electrically continuous throughout by means of soldered joints or bonding clamps or joint boxes.
(xii) The resistance of the metallic envelope in a complete installation, between the main switch and any other point in the installation must not exceed 2 ohms.
(xiii) If liable to mechanical damage they are to be adequately protected.
(xiv) In damp and exposed situations, saddles and fixings to be of non-rusting material.
(xv) Bushed holes to be used when passing through steel or iron structures.
(xvi) Holes through party walls or fire-resisting floors to be plugged with non-ignitable material.
(xvii) When run under floors or behind partitions, all connections to be made in boxes of ample capacity and of non-absorbent, non-ignitable material.

Hard Metal-sheathed Cables (Class M2) may be used without conduit or casing provided they are in accordance with conditions (iv) and (ix) to (xvii) inclusive.

Armoured Cables (Class R) may be used without conduit or casing provided they are in accordance with conditions (iv), (ix), (x), (xiii), (xiv), (xvi), and (xvii). When lead sheathed, such sheathing shall comply with (xi) and (xii), and when not lead sheathed the armouring shall so comply.

Cables covered with Tough Rubber Compound (Class S) may be used without conduit or casing provided they are in accordance with conditions (iv), (ix), (x), and (xiii) to (xvii) inclusive.

Conduits Screwed (Class T1). All approved classes of cable may be enclosed in steel conduits provided that the conduits are in accordance with conditions (iv), (xiii), (xiv), (xvi), and (xvii), and in addition:

(xviii) The conduits and fittings are made in accordance with British Standard Specification No. 31, and if used on circuits of medium pressure are of heavy gauge. Metal bosses must be secured on both sides to conduit by screwing or nuts.
(xix) The conduits are mechanically and electrically continuous across all joints and are earthed.
(xx) The resistance of the conduit in a complete installation, between the main switch and any other point in the installation, does not exceed 2 ohms.
(xxi) Ventilating outlets are provided at the highest and lowest points of each circuit.
(xxii) The conduits of each circuit are erected complete before the cables are drawn in (see table on p. 2237).
(xxiii) Abrasion of covering of cables emerging from conduits must be prevented.
(xxiv) The end of conduits where terminating at accessories and fittings are screwed thereto or provided with lock-nuts, or are led into separate blocks, preferably of non-ignitable material.
(xxv) No elbows or tees, unless of the inspection type, are used except at the ends of conduits immediately behind fittings or accessories; and no bend has a radius less than 2½ times the outside diameter of the conduit.
(xxvi) In damp or exposed situations, the conduits are welded, brazed, or solid drawn.

Metal Conduits not Screwed (Class T2). All approved cables may be enclosed in conduits of eel or other metal provided that the conduits are in accordance with conditions (iv), (xiii), iv), (xvi), (xvii), (xix) to (xxiii), (xxv) and (xxvi), and (xxvii). The ends of the conduits where rminated at accessories and fittings are adequately clamped thereto, or are led into separate ocks, preferably of non-ignitable material.

NOTE.—Plain slip sockets do not comply with the above regulations—some form of screwed grip joint giving ample and permanent conductivity and rigidity throughout being necessary.

Non-metallic Conduits (Class T3). All approved cables may be enclosed in conduits of non-itable, non-absorbent damp-proof material, provided that such conduits are mechanically ntinuous and strong, and are in accordance with conditions (iv), (xiii), (xiv), (xvi), (xvii), (xxi) (xxiii), (xxv) and (xxvii).

Wood Casing (Class W). All approved cables may be enclosed in wood casing provided that

(xxviii) It is used in dry situations only.

(xxix) It is not buried in plaster or cement nor fixed in contact with gas or water pipes, nor mediately below water pipes.

(xxx) The capping is secured by screws.

(xxxi) If the casing forms part of ornamental woodwork, ready access to the cables is provided.

Flexible Cords (Class Z). High insulation twin or multicore flexible cords may, in addition being used for pendants and portable appliances, be used provided that conditions (iii) and r) are complied with, and in addition:

(xxxii) They are for low-pressure sub-circuits for currents not exceeding 6 amperes.

(xxxiii) If insulated with pure rubber, they are not used in damp situations.

(xxxiv) Insulating cleats not more than 3 ft. apart are used and placed so that the cords do ot come into contact with walls, ceilings, or structural metal work.

(xxxv) They are open to view.

(xxxvi) The premises do not come under the Factory and Workshop Acts and the Coal Mines egulation Acts.

(xxxvii) They are not used in shops, warehouses, or places of public resort.

(xxxviii) Where passing through walls or floors, they are protected by non-ignitable, damp-oof conduits.

(xxxix) Where issuing from fittings and unavoidably passing into ceilings they are enclosed . non-ignitable tubes terminating in non-ignitable junction boxes.

Bunching of Cables.—When installed in wooden casing, cables carrying direct or alternating rrent may, if desired, be bunched whatever their polarity, provided that the number of cables unched is not more than:

10	if the sectional area of each does not exceed				0·007	sq. in.
6	,,	,,	,,	,,	0·0025	,,
4	,,	,,	,,	,,	0·1	,,
3	,,	,,	,,	exceeds 0·1 sq. in.		

he size of the casing must not exceed that of the maximum number of cables permissible.

When installed in metal conduits, cables carrying direct current may, if desired, be bunched hatever their polarity; but if carrying alternating current, they shall always be bunched.

NOTE.—Where large cables are bunched, the rating should be reduced to prevent verheating.

Bell and Telephone Circuits in a building must not be run in casing or conduits used for the istribution of electricity supply throughout the building.

Cable Sockets and other Connections.—(*a*) The ends of all conductors exceeding 0·04 sq. in. hall be provided with a soldering socket.

(*b*) The dielectric shall not be removed farther than is necessary. Dielectric damaged by heat hall be cut away.

(*c*) The braid, lead, or other covering over the dielectric, including the tape, shall be cut back t least half an inch from the end of the dielectric.

(*d*) With paper-insulated cables, the exposed conductor and dielectric shall be protected from oisture by suitable sealing with insulating compound.

(*e*) The ends of stranded conductors unprovided with cable sockets shall be made solid by oldering in the case of paper insulation, and in the case of rubber when exposed to damp.

Connections between Cables other than flexible cords shall be made either by soldered joints r mechanical connectors.

(*a*) Every joint shall be easily accessible and mechanically and electrically sound.

(*b*) Every mechanical connector shall be enclosed in a non-ignitable box and made impervious o moisture.

(*c*) Connections between cables and flexible cords, or between lengths of flexible cords, shall e made by mechanical connectors shrouded in non-ignitable insulating material contained within uitable receptacles.

(*d*) Joint boxes shall be constructed wholly of durable, non-ignitable, non-absorbent materials.

Main Distribution.

Control of Main Supply.—Every installation shall be adequately protected by suitable controlling apparatus easily accessible to the consumer.

(*a*) If the normal current exceeds 100 amperes, there shall be provided, in addition to a fuse or circuit breaker with overload trip, an automatic device which shall operate in the event of a leakage to earth. The leakage current must not exceed 100 amperes.

(*b*) There shall be a circuit breaker or a switch and fuse on each insulated conductor, and all such poles shall be linked.

(*c*) No fuse or unlinked single-pole switch shall be inserted in a main circuit in that conductor which is direct earthed at the supply.

(*d*) The neutral conductor shall never be interrupted while the other conductors are closed.

(*e*) Wherever single-pole switches are required, they shall be on the same pole throughout the installation.

Subdivision of Circuits.—(*a*) The maximum number of points that may be connected in parallel to a final sub-circuit shall be as follows:

Where the total rating of the points supplied from the sub-circuit does not exceed

6	amperes	10	points
7	,,	6	,,
10	,,	4	,,
20	,,	2	,,

(*b*) Every final sub-circuit shall be connected to a sub-distribution board.

(*c*) Every sub-distribution board shall be connected to a separate way on a main distribution board.

Earthing.

Conditions where Earthing is Necessary.—(*a*) For all pressures of supply, earthing of metal objects other than the conductors shall be effected in the following cases:—In bathrooms, lift shafts, near running machinery, and in all places where even a slight shock might lead to serious accident, all exposed metal liable to become alive, or situated so that there is risk of contact with earthed metal, shall be earthed. The metal sheathings of cables shall be earthed.

(*b*) Where the pressure of supply exceeds the limits of extra low pressure, any damp plaster, concrete, or metal shall be earthed which is liable to become alive and touched by a person making contact with earth. All metal conduits shall be earthed.

Position of Metal in Bathrooms.—All exposed metal liable to become alive shall, in addition to being earthed, be placed out of reach of a person standing in the bath. Lampholders shall have their exposed metal parts efficiently earthed, or, alternatively, all parts liable to be handled when replacing a lamp shall be constructed of insulating material.

Earthing.—(*a*) The combined resistance of the earthing lead and system should be low enough to let enough current flow to operate the fuse or earth leakage trip.

(*b*) Water pipes used as an earthing system shall have metal joints throughout.

(*c*) Pipes conveying gas or an inflammable liquid shall not be used as an earthing system.

(*d*) An earthing lead shall be of high conductivity copper protected against mechanical injury and corrosion of not less than 0·0045 sq. in. (7/·029 in.). for the main connection. For flexible cords 0·0048 sq. in. and smaller, earth lead to be the same size as live conductors.

(*e*) All connections of the earthing lead shall be easily accessible.

(*f*) All domestic appliances, whether portable or fixed, for pressures exceeding 100 volts direct or 30 volts alternating current shall be provided with a terminal or other suitable means for earthing all exposed metal.

Fittings.

Portable Fittings which have to be earthed shall be connected to earth by means of a third conductor in the flexible cord.

Ceiling Roses shall not be used for pressures exceeding 250 volts, and not more than two pairs of flexible cords shall be attached to one ceiling rose, unless it be designed for multiple pendants.

Lampholders shall comply with the appropriate British Standard Specification. Switch lampholders shall be provided with further means of control in the same room. Lampholders in open-type portable fittings must be earthed as above or insulated from fitting.

Plugs and Sockets.—(*a*) Sockets shall be so constructed that they cannot be accidentally short-circuited whether the plug be in or out, and so that a pin of the plug cannot be made to earth either pole of the socket.

(*b*) Plugs connected to apparatus for currents between 1 and 10 amperes shall be constructed with (i) a hand shield, the entry for the flexible cable being at the side of the shield remote from the hand, and, if desired, a switch being fixed adjacent to the socket, or (ii) the plug so interlocked with a switch on the socket that it is impossible to insert or withdraw the plug when the

switch is in the 'on' position, provided that every socket, or group of sockets, carrying more than 300 watts shall have a switch in an accessible position.

(*c*) Plugs having a rated capacity exceeding 10 amperes shall, in addition to a hand shield, be provided with a switch immediately adjacent to the socket and preferably interlocked.

(*d*) The dimensions and clearances shall be in accordance with B.E.S.A. Report No. 73.

MOTORS.

Control of Motors.—(*a*) Every motor shall be protected by efficient means suitably placed and so connected that the motor and all apparatus in connection therewith may be isolated from the supply, except in the case of the earth point of an earthed system. For motors of less than 1 h.p. a plug and socket will be considered to be an efficient method of insulation from the supply.

(*b*) Every motor shall be provided with an efficient switch or switches for starting and stopping, so placed as to be easily operated by the person controlling the motor. Every motor rated over ½ h.p. shall also be provided with (i) means for automatically opening the circuit if the supply pressure falls sufficiently to cause the motor to stop; (ii) in the case of d.c. motors a starter or switch for limiting the current taken when starting and accelerating; (iii) in the case of a.c. motors, such starter or switch for limiting the current taken, when starting and accelerating, to the value (if any) required by the supply undertaking.

(*c*) In every place in which a machine is being driven by a motor there shall be means at hand for either switching off the motor or stopping the machine if necessary to prevent danger.

Electric Lifts.—Lifts to be operated from a circuit independent of lighting installation. Control and motor leads to be in separate conduit, and cables except trailing to be armoured or in metal conduits.

HEATING AND COOKING APPLIANCES.

Control of Heating and Cooking Appliances.—(*a*) Appliances shall be protected by a fuse on each insulated pole.

(*b*) Appliances, whether portable or fixed, shall be controlled as a whole by a switch, which in the cases of portable appliances shall be fitted on a wall.

(*c*) Where a switch or switches are fixed on the frame of a portable luminous heating appliance, at least one section of the heating element shall not be controlled by such switches, so that the luminous heating element is permanently connected to the wall-plug or similar device in order to indicate that the circuit is not broken and that the current is still flowing.

(*d*) The support and frame of every appliance shall be provided with a suitable terminal to which the earthing lead may be connected.

TESTING OF COMPLETED INSTALLATION.

NOTE.—The following tests are intended to ensure that the installation is in a satisfactory state at the time of completion.

The value of systematically inspecting and testing apparatus and circuits cannot be too strongly urged, and such periodical tests are essential if the installation is to be maintained in a sound condition and undue deterioration thereof detected.

All defects thus discovered should be made good without loss of time. The attention of consumers should be drawn to the importance of maintaining all apparatus and fittings in a clean and dry condition.

TESTS TO BE CARRIED OUT.

Before an installation is permanently put into service the following tests shall be carried out:—

Insulation Resistances.

(*a*) The insulation resistance shall be measured by applying a direct-current pressure of not less than twice the working pressure, between earth and the whole system of conductors or any section thereof with all fuses in place and all switches on. The working pressure is deemed to be that between outer or phase conductors and neutral, where latter is earthed.

(*b*) The insulation resistance of the lighting circuits measured as in (*a*) above shall not be less in megohms than 25 divided by the number of points on those circuits, except that the insulation resistance of any final lighting sub-circuit need not exceed 1 megohm.

(*c*) The insulation resistance between the case or framework and every live part of each individual dynamo, motor, heater, arc lamp, or other appliance complete with its switch and control gear, regulating resistance and similar accessories, shall not be less than half a megohm when measured as in (*a*) above.

(*d*) All lamps to be in place except on earthed concentric wiring systems. Heating and power circuits may be tested with appliances removed, but lamps (if any) in place.

NOTE.—In addition to the foregoing tests, it is advisable wherever practicable to take an insulation test between all the conductors connected to one pole or phase of a system and those on the other pole or phase.

Continuity of Metal Sheathing.

The metal conduits or metallic envelopes of cables in all cases where such methods are used for the mechanical protection of electrical conductors shall be tested for electrical continuity and the electrical resistance of such conduits or sheathing, measured between a point near the main switch and any other point of the completed installation, shall not exceed 2 ohms

The Electrical Equipment of Ships.

REGULATIONS ISSUED BY THE INSTITUTION OF ELECTRICAL ENGINEERS.
SECOND EDITION, JULY, 1926.

(*Abbreviated.*)

General.—These regulations apply to all sea-going ships except ships of war. They relate to the use of electrical energy for all purposes except the propulsion of ships, and comprise the main requirements for ensuring satisfactory results.

Nature of Supply.—Standard systems of distribution are two-wire d.c. or a.c., three-wire l.c. three-phase three- or four-wire. Standard pressures are 110, 220, 440 volts, and 650 volts for constant current series system 110 volts single-phase l.c. Standard pressures have not been fixed for polyphase currents, but must not exceed 150 volts for lighting and 250 volts for power and heating, except for oil ships. The standard frequency is 50 cycles per second.

Generating Plant.—Generators shall conform to the British Standardisation Rules, except that they shall be capable of sustaining an overload of 25 per cent. for two hours in temperate climates and cool situations on board ship. Generators shall be over-compounded 5 per cent.; they shall be placed where they do not affect the compasses, with their axis fore and aft, and the frames shall be efficiently earthed. Standard capacities for steam prime movers are 5, 10, 15, 20, 25, 30, 40, 50, 75, and 100 k.w. Steam pressures for single engines 100–120 and for compound engines 150 lb. per sq. in. Excluding turbines, the momentary and permanent speed regulations respectively must be within 10 and 5 per cent. for engines up to 50 k.w., and within 10 and 3 per cent. above 50 k.w. For internal combustion engines, these figures are 10 and 3 per cent. up to 10 k.w. and 10 and 2½ per cent. above 10 k.w. Standard capacities are 2, 3, 5, 7½, 10, 15, 20, 25, and 30 k.w.

Switchboards.—The requirements for switchboards, conductors, and distribution are in general those specified in the Regulations for the Electric Equipment of Buildings—see p. 2218. Where the load on a conductor is intermittent, the size of cables for such ratings is given in the following table:—

Rating of Conductors Intermittently Loaded.

Nominal Area of Conductor.	Permissible Current in Amperes.					
	Rubber Cables.			Paper Cables.		
Rating:	Half-hour.	One-hour.	Continuous.	Half-hour.	One-hour.	Continuous.

1·0	1,036	803	595	1,548	1,211	932

Cables in machinery spaces or exposed to weather or the action of salt water shall be lead overed and may be armoured in addition, with or without braiding over the armour. Cables n cold-storage chambers shall pass normally through the walls or lagging with continuous lead tube anged at each end. Such cables must be lead covered in full view throughout their length and upported by porcelain, hard wood, or other non-metallic, non-hygroscopic material.

Cables passing through decks or watertight bulkheads shall be provided with suitable glands r deck tubes—see B.E.S.A. Specification No. 94. Where unarmoured cables pass through eams and non-watertight partitions, the holes must be bushed with lead or other soft non-ferrous etal. Flexible cords with silk or cotton covering must not be used in crew or cargo spaces, or here exposed to mechanical damage.

Maximum Spacing of Clips securing Lead-covered or Armoured Cables.

Overall Diameter of Cable.	Lead-covered.	Armoured.
Under 0·3 inch . . .	8 inches	10 inches
0·3 to 0·5 inch . .	10 ,,	12 ,,
0·5 to 0·75 inch . .	12 ,,	14 ,,
0·75 to 1·25 inch . .	14 ,,	16 ,,
Over 1·25 inch . .	16 ,,	18 ,,

Earth Connections.—Only steel ships shall be wired on the single-conductor system. Earthing onnections carrying current shall be of the same size as the corresponding insulated conductor. Earthing connections not normally carrying current shall be of copper of the same size as the orking conductor (but not less than 0·003 sq. in.) up to 0·007 sq. in., and above that size not ss than 0·007 sq. in. for every 50 amperes of working current or part thereof, but need not exceed ·1 sq. in. Earth connections shall be accessible and secured by screws not less than $\frac{3}{8}$ in. in iameter.

Interference with Compasses.—Dynamos, batteries, and all apparatus producing an external agnetic field shall be fixed at such a distance from the compass that the magnetic field produced hereat has a negligible value. No single-conductor cable carrying continuous current shall be tted within 30 ft. of standard and steering compasses. Conductors in the vicinity of the compass hall be twin, or as close together as possible. Incandescent lamps used for lighting the compass hall not consume more than 0·6 ampere, and no live part shall be less than 7 ins. from any part f the magnetic system. Effect of switching must be noted during adjustment of compass.

Navigation Lamps.—Each navigation lamp is to be separately wired and controlled by a eparate switch and fuses, and to have an automatic indicator in circuit to give warning of the ailure of the light. Metal filament bayonet cap vacuum lamps fixed vertically of not less than 0 watts to be employed.

Storage Batteries.—The cells shall be so constructed that the electrolyte cannot be spilled, ith strong containers (not celluloid). They should be in a single tier and mounted on oil nsulators. The deck must be lined with lead or other acid-resisting material, and all exposed netal protected with acid-resisting paint. The battery compartment must be well ventilated. witches and fuses must be fixed outside the battery room. All connections in the battery room re to be of bare metal or lead-covered cables.

Fittings.—Fittings are to be so designed and fixed that dust and moisture cannot accumulate ithin them, and are not to be mounted on surfaces liable to become damp. In exposed positions hey are to be weatherproof and waterproof; open type fittings must not be used near inflam-nable goods or where inflammable dust or gases can occur. Switches, etc., must not be installed n bunkers or where inflammable gases may be present. Weatherproof portable lamp fittings ith metal frames must have all metal parts connected to earth by a third conductor in the flexible ord, and must be provided with hooks to hang them up with. Lampholders in weatherproof ortable fittings must be earthed, and in open type fittings they must be insulated and pro-ected with insulating shields. Plugs and sockets must be so constructed that they cannot be eadily short-circuited or earthed or allow an arc to be maintained. Plugs must be provided ith hand-shields or interlocked with switches in the sockets. Weatherproof plugs and sockets nust be employed in exposed positions. See B.E.S.A. Specifications Nos. 97, 98, 67, 73.

Lamps.—Arc lamps must have the whole of their live parts insulated from the frame, and mus be provided with wired globes or other protection; they must not be fitted near combustibl goods or where gases can accumulate, and each circuit must be controlled by a switch and fus on each insulated pole.

Motors.—May be of any type enumerated in B.E.S.A. Specification No. 168, or of submersibl type. When larger than 1 b.h.p. they must strictly conform. Working parts must be accessible and construction must allow of dismantling in space where fitted, unless readily removable. Th carbon brush gear must be adjustable. For brushes see p. 2290 and B.E.S.A. Specificatio No. 96 for standard terminals. Lubrication must be automatic. Motors should be placed i well-ventilated compartments, with axis of rotation in a fore and aft direction and clear of in flammable material: otherwise they must be of flame-proof or forced-draught type with pipe taken outside compartment. Where temperature exceeds 120° F. motors to be pipe-ventilatec induced- or forced-draught type connected to inlet air at less than 120° F. Motor starters abov 3 b.h.p. must have no volt-release and replaceable resistance elements.

Control Gear.—Regulators and controllers are to be of incombustible materials and guarde or enclosed in incombustible cases; contacts shall be renewable, and all live parts enclosed b metal covers, and so designed that they cannot be touched by the operator. Resistances sha not rise to an excessive temperature, and no accessible part of the apparatus may rise abov 130° F. Internal connections shall not be soldered. Control gear shall not be placed wher inflammable gases can accumulate, unless it is flameproof; in exposed situations it shall b totally enclosed. Resistances shall be placed in well-ventilated compartments and away fror combustible material.

Heating and Cooking Apparatus.—Appliances shall be so constructed that parts which ar handled cannot exceed a temperature of 130° F. The elements shall be readily replaceable live and highly heated parts shall be guarded. Connections between the elements and switche or external leads shall be made without solder, and their temperature shall not exceed 200° F All appliances for pressures exceeding 150 volts shall be efficiently earthed. Whether portabl or fixed, appliances shall be controlled by fixed switches; portable appliances shall have at leas one section of the elements controlled only on the live side of the wall plug or other connectio with the fixed portion of the circuit.

Internal Communications.—Transforming apparatus and batteries shall conform with the rule for lighting and power plant. If the working pressure exceeds 25 volts, all parts of the apparatu shall be made and fitted in accordance with the rules for lighting and power circuits. Com munication cables shall be made and fixed in accordance with the rules for light and powe cables, and shall be kept as far as possible separate from the latter, with separate groove when run in wood casing. Fuses need not be fitted in branch circuits for pressures not exceedin 25 volts, or in circuits supplied from primary batteries.

Lightning Conductors.—Conductors shall be fitted to all vessels having wooden masts, c copper tape or rope having not less than 0·15 sq. in. sectional area. When in dry dock, ship lightning conductors shall be connected to an efficient earth on shore.

Oil ships.—On oil ships the pressure for all purposes shall not exceed 110 volts with a.c. with d.c., for power 220 volts, for lighting and heating 110 volts. No part of the system sha be earthed, and double-pole linked switches shall be used on every circuit or sub-circuit. A cables shall be lead-covered, with or without armour. Distribution shall be on the two-wir two-conductor system. No wiring shall be taken into oil-holds or coffer-dams, which must b lighted by lamps entirely outside the space and separated from it by an airtight glass bow Lamps in dangerous spaces shall be in gas-tight fittings, and the switches shall be outside th spaces; no portable lamps other than self-contained battery-fed lamps (mining type) may b used in dangerous spaces.

Constant-current Series System.—Special requirements include automatic circuit closer fc short-circuiting generator in the event of an open circuit anywhere in the system, and forbid th use of open-type machines. All bare conductors (including heating elements) to be totall enclosed in metal cases with conductors accessible only when disconnected, and no part of th system shall be earthed.

Trials.—The insulation of the whole system, with all lamps and fuses in place, is to be teste before putting into service with direct current at twice the working pressure between the syster of conductors and earth, and shall not be less in megohms than 10 divided by the number of lamp (on lighting circuits), but the insulation resistance of any final lighting sub-circuit need not exceed one megohm. The insulation resistance of every piece of apparatus, with switch or contrc gear, etc., shall not be less than half a megohm. The installation shall be run for six hours an all the apparatus operated, not necessarily simultaneously.

Wall Plugs and Sockets.

British Standard Specification for 5-, 15-, and 30-ampere, 2-pin wall plugs and sockets for lomestic purposes (without earthing connection), No. 73—1927, gives details of materials to be used, sizes and spacing of all insulating, current-carrying, protecting, and fixing parts, toegther vith gauges and tables of dimensions.

Directions for Making Joints in Electric-Light Conductors.

(*Silvertown Instructions.*)

Preparing Ends and Making Metal Joints.

The braiding should first be removed, the tapes unlapped, and the conductor exposed for a ength of not less than eight to ten times its diameter (for small wires the length should not in ny case be less than 2 ins.). With vulcanised or similar cables the rubber should then be cut ff at a right angle, care being taken not to nick the wires. With pure rubber cables the pure ubber should be unwrapped, not cut.

In making all joints resin should be used, either raw, or a little powdered resin dissolved in pirits of wine to a thin paste.

The soldering-bit should always be kept clean. This is best done by dipping it into a satu- ated solution of sal ammoniac and water.

The copper conductor to be jointed should always be carefully cleaned ; and when the joint is inished, all rough points should be removed by means of a file so that the surface may be smooth or insulating.

For a Single-conductor Wire.—The ends of the copper should be filed to a long bevel—i.e. carfed—and the two ends so filed laid one on the other, the object being to get a long surface of ontact. The scarf should then be carefully soldered and whipped with small binding-wire, and he whole again soldered and cleaned up with emery cloth or a file ; the finished diameter should ow not greatly exceed the original diameter of the conductor.

For a 7-Strand Cable.—The whole of the strand should first be soldered up solid ; then scarfed nd jointed as a solid wire, in the same way as above.

For a 19-Strand Cable.—The conductor should be bared to a suitable length, and a small binder ied round the ends next to the rubber to keep the strand in place. The 12 outside wires should hen be unstranded and turned back. The central 7-strand should then be soldered up and ointed as a solid conductor. To joint the 12 wires over this, every alternate wire should be cut ff short, and the two sets of 12 married—that is, the long wire from the one end jointed to the hort wire on the other, and so on round the central strand ; thus half the joints on the single wires vill be on the one side of the joint in the central strand, the other half being on the other side. The joints in these single wires need not be scarfed, but only butted together at each end of the oint, where the long and short wires are soldered together. A narrow whipping of binding-wire hould be put on at each end and soldered, the whole being then filed down smooth.

For a 37-strand Cable.—If flexibility is required, the same method is followed out, with the ddition that the 18 wires surrounding the 19-strand joint are married in the same way.

If flexibility is not essential, the 19-strand should be scarfed and jointed in the same way as he 7-strand, and the 18 remaining wires only are to be married.

For a 61-strand Cable.—The joint should be made the same as the 37-strand, with the addition hat the remaining 24 wires surrounding the 37-strand should be married in the way previously lescribed.

Directions for Making T-Joints in Conductors.

To Joint a Single Wire to another Single Wire.—The smaller wire should be scarfed and laid long the surface of the other wire, and then whipped with binding-wire and soldered and finished mooth ; the binding should, however, not be continued up to the point where the smaller wire is ent.

To Joint a Single Wire to a Strand.—The surfaces should be carefully cleaned, and the single vire wound spirally round the strand at the end, but lying flat with the strand at the point of unction ; this flat part should be whipped, and the whole soldered.

To Joint a 7-strand on to a larger Cable.—The 7-strand should be unstranded, and, after clean ing the wires separately, the wires should be twisted round the larger cable, three being twiste parallel in the one direction and four in the reverse direction, and on the other side of the T, an a light whipping of copper wire round each end ; and the whole should then be carefully soldere together.

For Large T-Joints.—Each conductor should be soldered up solid. The smaller one shoul then be scarfed and a recess filled in the other, about halfway through, the shape of the scarf the whole should then be soldered together, and whipped with binding-wire, and soldered again Where the joints are heavy strong binding-wire should be used.

Directions for Insulating Joints.

Vulcanised Rubber Joints.—When the conductor joint is finished the rubber should be care fully trimmed and cut with as long a bevel as possible, according to the thickness of the rubber the copper conductor and the bevelled ends should then be rubbed with pure benzol and slightl heated with a spirit lamp. The conductor and the bevelled edges of the rubber should then b lapped with a pure rubber strip laid on as tightly as possible in one or two layers according t size : this pure rubber should then be covered with special rubber solution, rubbed in so as t exclude air as much as possible ; the joint should then stand until thoroughly dry. When th solution is sufficiently dry, and will not adhere to the fingers, a special rubber strip should b lapped on spirally, forming a uniform covering over the first coat of pure rubber, care bein taken, by lapping tightly and evenly, to exclude all air. This rubber should be put on in two o more layers, until the diameter is equal to that of the original insulation, and over this a layer c proofed tape should then be applied, the whole joint so made slightly exceeding in diameter tha of the original insulation. When so completed the next process is that of vulcanisation. To d this it is necessary to cover the joint with special sheeting cut to the whole width of the join and firmly rolled round it, making a longitudinal seam, binding the sheeting over all by a stron cotton selvedge tape applied spirally, and as tightly as possible by hand. The sheeting thus wi serve as a mould to keep the joint together during the process. The joint should then be fixed i the 'cure' (a cast-iron box) and the cover bolted on ; and, to prevent damage to the origina insulation and to make the box tight, the insulation on each side of the joint, for the proper dis tance to fit the cure, should be lapped with two or more coats of tape, to cover the original in sulation down to the point of junction. When the cure has thus been made tight molten sulphu compound, previously melted in a suitable pot, should be poured into the cure round the join through the small hole in the top of the cure, and a suitable thermometer afterwards inserted i this hole, to enable the temperature of the sulphur compound to be noted. This temperatur should be kept as constant as possible between 290° and 300° F. by means of spirit lamps.

After the joint has been kept at the full temperature for about half an hour the molten sulphu is run out and the cure-cover unbolted. The joint should then be taken out, the wrapping stripped off, and it will then be found to be vulcanised. A rough test of the degree of vulcanisa tion may be made by trying with the thumb nail (when the joint is cool) to indent it. If th mark of the nail remains in the rubber, or if the rubber is too hard, the joint is a failure, an should be cut out and remade. If the joint thus examined is found to be in good order, it shoul be finished off by lapping over all special tapes, extending, say, over about 2 ins. each side c the braiding ; this taping to be then painted with shellac varnish.

When insulating with rubber the hands should be kept dry and perfectly clean. When solu tion is used, it should only be used in small quantities, and the spirit allowed to evaporate befor the whole is again covered up. The spirit used should be of the best quality, so that it evaporate quickly and leaves little or no residue behind. Special care should be taken that the rubbe applied be brought into immediate contact with the prepared ends, and that no tapes of th original insulation, or foreign material which would conduct moisture, should intervene betwee the two surfaces to be joined. Unless everything used is perfectly clean, and all air exclude by careful and tight lapping, the joint may be found to have blown, even though the rubber i properly vulcanised. Special attention, therefore, is required to these points.

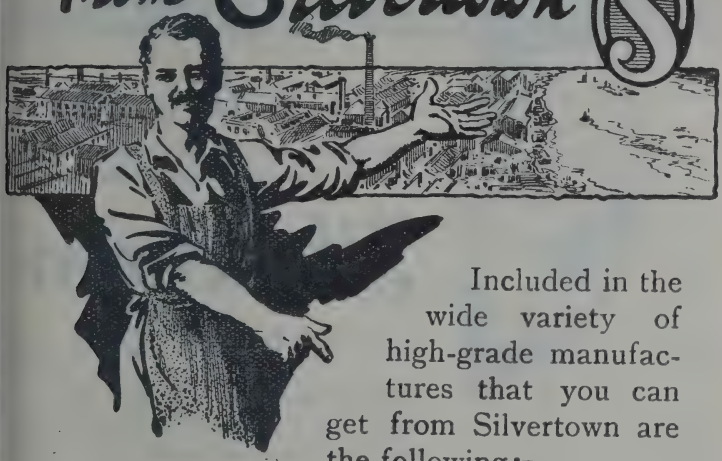
If, during vulcanisation, the temperature should drop below 290°, the heat will require to b maintained for a longer time ; say, if at 280°, the cure would last for about three-quarters of a hour instead of thirty minutes ; but it is important that the temperature should be kept a constant as possible between the limits of 290° and 300° F.

If the pure rubber appears hard and brittle it should be slightly warmed before using. Shoul the compound tape become dirty or too hard, it can be softened by wiping with benzoline.

The Electrical Testing of Electric-Supply Mains.

The accurate testing of electric-light mains before and after laying, and periodically durin use, is a matter of great importance if the efficient working of a system is to be obtained an maintained. For the purpose of accurate testing each station should be provided with a sensitiv

From Silvertown



Included in the wide variety of high-grade manufactures that you can get from Silvertown are the following:—

Rubber Insulated Cables and Wires of the highest possible standard of quality; all types of Primary Batteries; Instruments; Wireless Accessories; Insulating Tapes and Jointing Materials; Ebonite Sheet, Rod, Tube, etc. Belting, Hose, Gloves and other Rubber Goods.

Write for copy of List No. 16 which gives the complete range of Silvertown products.

LECLANCHÉ CELLS

Efficient working and durability is assured, and every cell may be put into use with the utmost confidence.

Extended tests preclude any risk of faulty cells leaving our Works.

We introduced Leclanché cells into Great Britain more than 50 years ago, and ever since have kept well to the forefront.

Order Silvertown Leclanché cells to meet your next requirement.

We make all types of Primary Batteries. Write for List No. 31.

F. 2231

gh-resistance mirror galvanometer, a shunt box, a resistance coil of not less than 10,000 ohms f possible, a megohm), a condenser, keys, and a battery of not less than 100 Leclanché cells. or tests during laying this battery should consist of 400 to 600 cells. It is often possible, how- ver, to use the current from the mains at the normal supply voltage on a direct-current system.

The shunt boxes usually supplied with the mirror galvanometers are fitted with shunts having r that particular galvanometer multiplying powers of 10, 100, and 1,000. For the varying insu- tion resistances which have to be measured in electric-light testing a resistance box having oils of units, tens, hundreds, and thousands is most convenient for use as a galvanometer shunt ox, as it enables work to be done between very wide limits, and the obtaining of the deflection pon any part of the galvanometer scale. The Ayrton-Mather 'Universal' shunt-box can be sed with advantage, as the multiplying powers are independent of the resistance of the

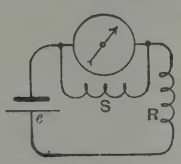

FIG. 2.

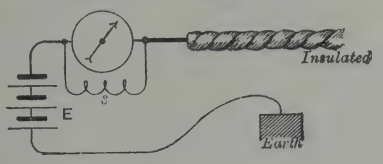

FIG. 3.

alvanometer. The instruments should be erected and adjusted before the work of laying or alling is commenced, so that tests may be taken on the arrival of the drums of cable and the pecified insulation resistance assured.

The test should be taken with the drums of cable immersed in water wherever possible; but here this cannot be done they must be well wetted, except in the case of lead-sheathed cable.

The preparation of both ends of the cable is of the utmost importance if the real insulation esistance of the dielectric is to be obtained, the difference in the results given with properly and mproperly prepared ends being very great. For vulcanised rubber cables the tapes, braiding, or ther covering should be removed for at least 6 inches from the ends. The tape next the rubber hould then be carefully removed, the surface of the rubber washed with naphtha, and well scraped o remove any fragments of the tape. The rubber should be tapered off with a pair of clean, bent cissors, the length of the taper being 1 to 2 inches. Next the whole of the prepared end is horoughly dried by means of a spirit lamp, allowing the flame to play round the rubber, but aking care not to burn it. If the test cannot be taken immediately, the prepared end should e well warmed and lapped with clean, warm, pure indiarubber tape, well stretched.

The most accurate method of obtaining the insulation resistance of a highly insulated cable the direct deflection method—i.e. by a comparison of the deflection of the galvanometer needle roduced by a given battery power working through a known high resistance with the deflection roduced by the same battery power working through the insulation of the cable. This method is s follows :—

A small battery (usually 1 cell) is first connected up, as shown by fig. 2, with the galvano- eter and with a resistance, R. of 10,000 ohms, the galvanometer being shunted by a shunt, S sually the $\frac{1}{1000}$th shunt), so that a convenient deflection, D, is obtained; this is called taking the onstant. The connections are then altered as shown by fig. 3, a large battery, E (about 100 more cells), being used, and the wire whose insulation is to be measured being joined up as nown. Let the deflection be d, and the shunt s on the galvanometer be the $\frac{1}{n}$th (usually $\frac{1}{10}$th, $\frac{1}{100}$th or $\frac{1}{1000}$th—i.e. $n = 10$, 100, or 1,000); also let the shunt used when the constant is taken e the $\frac{1}{N}$th shunt; then

$$\text{Insulation resistance of wire in megohms} = \left(\frac{D \times N}{n} + K \times R\right) \div \left(d \times 10^{s}\right),$$

here K is the ratio between the number of cells used in taking D and in taking the constant; us, if d is given by 100 cells and D by 1 cell, then K = 100. When great accuracy is required the xact ratio of the electromotive force of the large to the small battery has to be determined, for it is ldom that 100 cells have exactly 100 times the E.M.F. of 1 cell, though in a large number of cases is sufficient to consider it as such, care being taken that the cells are all in good condition. If a egohm resistance (1,000,000 ohms) is available, the constant may be taken with the same battery s is used for testing the insulated wire, the megohm being used in the place of the 10,000 ohms; this case K=1. A short-circuit key must be connected across the galvanometer terminals, nd must always be closed so as to short-circuit the galvanometer at the beginning of each test, therwise the rush of current from a high battery power will probably demagnetise the needle. or testing short lengths of highly insulated cable a battery of at least 400 Leclanché cells should

by used. If the battery is kept on for fifteen minutes, during which readings are taken eve minute, it will be noted that the deflection falls rapidly the first two or three minutes, the fa per minute becoming gradually less, till, at the end of fifteen minutes, the deflection is falling ver slowly. It would thus appear as if the insulation resistance rises during the test; but the chi reason is, that when the battery is first connected, and after the first rush of current, the dielectr

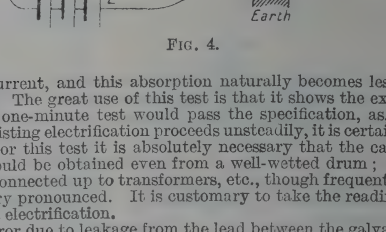

FIG. 4.

electrifies or absorbs current, and this absorption naturally becomes less and less as the cab becomes fully charged. The great use of this test is that it shows the existence of minute faul in a cable which on a one-minute test would pass the specification, as, if there is little or r electrification, or the existing electrification proceeds unsteadily, it is certain the dielectric contai undeveloped faults. For this test it is absolutely necessary that the cable should be in wate as no reliable results could be obtained even from a well-wetted drum; and of course it cann be taken on a system connected up to transformers, etc., though frequently before connecting u the electrification is very pronounced. It is customary to take the reading of the deflection *d* a the end of one minute's electrification.

In order to avoid error due to leakage from the lead between the galvanometer and the cabl the galvanometer key should be depressed before the lead is connected to the cable; any deflectic that may be observed is to be deducted from the deflection *d* before calculating the insulatic resistance. The leads should also be tested for continuity. Further, to prevent error due t leakage over the surface of the insulating covering of the cable, which is often of considerab importance, especially when the length of cable under test is short and the insulation resistanc very high, a 'guard wire' should be connected at one end to the junction between the batter and the galvanometer, the other end being wrapped round the prepared insulating surface at eac end of the cable (if both ends are accessible): this device (fig. 4) by-passes round the galvan meter any current due to surface leakage, and greatly improves the conditions of testing.

All insulated conductors should be tested after at least twenty-four hours' immersion in wat and none but those giving the specified insulation resistance should be accepted. When laid drawn in, but before jointing, the section having one end in the station should have its en prepared, the distant end being well warmed and lapped, and a careful test taken; if all righ prepare section 2, and having by means of a short piece of fine wire connected it to section test both sections together. If the insulation resistance per mile is found to be correct, the tw sections may be jointed, after which they should be again tested, and if not up to the previo tests the joint must be remade. Sections 1 and 2 being jointed and passed, section 3 may b temporarily connected and tested, jointed, and the three sections tested, and so on till the enti system is jointed and the final test taken. If this method is carried out the engineer in charg will have a record of tests—1st, upon each section in water; 2nd, upon each section after laying 3rd, upon the system as each length is jointed on—and he will feel satisfied that the cables ar up to the specification, that they have not been damaged in laying, and that the joints are a well made.

With vulcanised indiarubber joints in a vulcanised indiarubber insulated cable there is n difficulty in keeping th completed system up to the specified insulation resistance per mile c the cable. It is manifestly absurd to lay down high-class mains and, by means of inferior joint reduce the insulation resistance to a few thousand ohms. If a section cannot be tested from th station, or if the jointing cannot be commenced at the station end of the mains, a portable testin set should be employed; and when all the sections are jointed up a final test should be taken wit the station instruments.

With portable testing apparatus it is not possible to attain the same degree of accuracy a by the method outlined above; but, on the other hand, the insulation resistance of cables an wires when laid or installed in position is usually very much lower than in the former case, an therefore does not call for equally refined methods of testing. The most convenient portabl instrument for testing insulation resistance is the 'Ohm-meter,' of which several patterns ar obtainable, each combined with a generator which gives the necessary testing pressure withou the aid of a battery. These instruments are capable of applying a testing pressure of 500 c even 1,000 volts, and of measuring to a sufficient degree of accuracy insulation resistances up t 2,000 megohms.

Testing sets are also made for carrying out tests of insulation resistance by the direct de flection method, using a galvanometer of the pivoted type, and a battery; these instrument in some cases are so designed as to be capable of being applied also to the measurement of direc currents and pressures, low resistances, etc., and for localising faults on cable network. Th Evershed ohm-meters are described on p. 2310.

Earth Detectors.

Earth Detectors are required in mining work in stations covered by the following extract om the Home Office Rules :—

> ' In every completely insulated circuit, earth or ground detectors shall be kept connected up in every generating and transforming station, to show immediately any defect in the insulating of the system.'

Generally Earth Detectors are either one or other of two kinds, depending upon the pressure the circuit on which they are used :—

(a) For circuits not exceeding 750 volts a milli-ammeter is used. This consists of a voltmeter, e scale of which is calibrated to read milli-amperes. This instrument is used in conjunction ith resistances which are so proportioned that in the case of a bad fault giving full line voltage earth, the needle would indicate the maximum reading marked on the scale.

For three-phase circuits one instrument with resistance is used as shown in fig. 5, illustrating Westinghouse Earth Detectors.' One pole of the instrument is connected to earth, the other ole being connected to the centre point of a special three-way key switch. Under normal orking conditions the instrument is connected through the three-way key switch and the three sistances shown on the diagram to the three phases, the three keys being locked in the closed osition, thus ensuring that the leakage detector is kept in circuit permanently.

If a fault occurs on one of the mains, a deflection is obtained on the milli-ammeter, and to termine upon which phase the fault exists it is only necessary first to release all three keys and

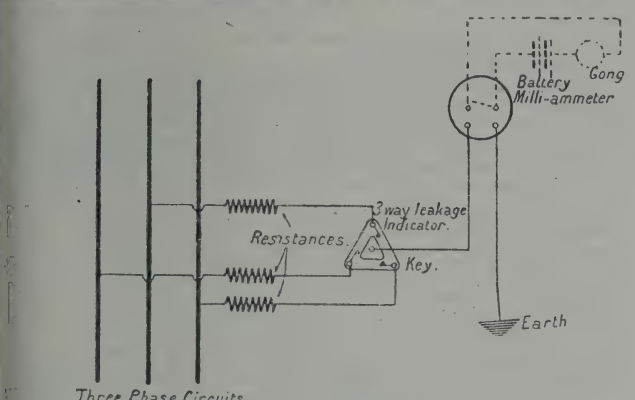

FIG. 5.

en to depress them one at a time. The faulty phase will give the smallest deflection. As dicated in the diagram, a bell and battery can be included and the milli-ammeter can be prooded with special contacts so that in the event of a serious fault occurring on the mains the ell would sound an alarm.

(b) For circuits having pressures greater than 750 volts, it is customary to use a Static Earth etector. In this instrument, the indicating pointer carries a large black disc, which under ormal conditions appears in the centre of the scale. This disc and pointer are electrically conected to the case of the instrument, which in turn is earthed. The live portion of the instrument onsists of two metal plates embedded in the porcelain base of the instrument to the right and ft respectively of the central position normally taken up by the black disc on the pointer. When he condition of the system is healthy, the pointer retains the central position, since the ull between the disc and each one of the live pieces of metal is equal. As soon as a fault occurs n one main, however, the attraction between the centre disc and the particular stem to which he faulty main is connected becomes less and the disc is consequently attracted towards the ther stem. The scale is calibrated so that the deflection is an approximate measure of the actual onditions. Since the two stems must be connected one to each phase in the case of a three-phase ircuit it is necessary to employ two instruments.

Electrostatic Earth Detectors can only be used on circuits having an insulated neutral. In he case of systems where the neutral is earthed, it is customary for an ammeter to be placed in he earthed connection.

Cable Soldering Sockets.

Specification No. 91—1926 of the British Engineering Standards Association gives the standa dimensions of cast and wrought lug sockets, clamp sockets, and clamps, for cables from 0·0 to 1·000 sq. in. sectional area. Cast lug sockets are of brass containing 70 per cent. of copp and tubular lug sockets are of solid-drawn copper tubing; clamp sockets are of brass or oth suitable non-ferrous metal. Sweating surfaces are to be drilled and tinned, and contact surfac machined.

Cables for Installation Work.

As far as electrical installation work, and particularly conduit work, is concerned, the type cable with which the contractor has mostly to deal is that known as a rubber insulated cable. T real properties of rubber insulated cables are more or less obscure, and the question as to wh constitutes a good cable is almost impossible to answer with any degree of accuracy. To gi some indication as to the quality of the rubber compound covering, a careful chemical test required, and this combined with a stretching test will give a distinct clue as to the possible du bility of the material.

Government Department Specification for Rubber-Covered Cables J, K and L Class for Power and Light.

Designation.—Cables shall be designated by the nominal sectional area of the conductor a a letter prefix as follows: 'J Low' and 'J Low Twin,' 'J Medium' and 'J Medium Twin' f 250-volt and 660-volt respectively for V.I.R. taped and braided. 'K' and 'K Twin' for V.I. taped, and lead sheathed (660-volt) and 'L' and 'L Twin' for V.I.R. taped, lead-sheathed a armoured (660 volts).

Material.—The conductor shall comply in all respects with B.E.S.A. specification No. 7 (s p. 2196), and be free from all mechanical defects.

Tinning.—Each wire shall be tinned uniformly with pure tin free from lead in a bath free fr contamination with copper. Before stranding, a sample shall be bent into a loop of radius n less than 12 and not more than 15 times its diameter, cleaned to remove grease and immers for 1 minute in hydrochloric acid specific gravity 1·088 at 60° F., washed and examined unde lens for blackening. Average number of times of immersion to produce visible blackening sh not be less than 8 times for wire 0·029 to 0·048 inches diameter, 7 times for diameters abo 0·048 up to 0·0808, and 5 times for diameters over 0·0808 inches. A further sample to wrapped round a rod of diameter four times that of the wire and submitted to the above for o cycle.

Jointing.—Not more than one joint to be allowed in any wire forming 1000 yards of conduct nor a joint to be within 12 inches of another in same layer, nor in conductor after strandi Joints shall be brazed, silver soldered or electrically welded.

Stranding.—To be uniform throughout length. 3-stranded wires to have a left-hand heli lay, 7 strand to have straight centre wire with six left-hand helically laid wires, the strandi for other numbers of wires to have alternate left-hand and right-hand lays.

Resistance of Conductors.—To conform to B.E.S.A. specification No. 7. Compensation the laying up of twisted twin cables to be agreed between contractor and inspector.

Dielectric.—Conductor shall be covered with one layer of British plantation pure rubb applied helically or longitudinally, then a covering and jacket of vulcanised rubber consisting of pu rubber mixed with sulphur, non-hydroscopic mineral matter and wax if required. The dielect shall contain not less than 45 per cent. by weight of pure rubber. After vulcanisation the aceto extract shall not exceed 5 per cent. by weight, of which rubber-resins are not greater than 2 p cent. and free sulphur 0·75 per cent. Maximum amount of organic matter in residue after aceto extraction not to exceed 1·0 per cent. of total dielectric. Sulphur content in rubber not to less than 1·25 or greater than 1·75 per cent. of total dielectric. No re-manufactured rubb or rubber substitutes to be used. Cable to be rejected if blackening is shown on pure rubb or tin, or if pure rubber adheres to conductor.

Thickness.—To be in accordance with B.E.S.A. specification No. 7.

Taping and Vulcanising.—To consist of helical binding of fine cotton tape (red and black blue for twin cables) of specified thickness, rubber proofed. The whole to be vulcanised in homogeneous body, after which rubber layers shall be inseparable but tape removable witho tearing rubber.

Mechanical Tests.—After removal of the conductor, an outer covering a length of 2 inch marked on the dielectric shall be maintained stretched to 6 inches for 24 hours at an ordin temperature not exceeding 65° F. After release, the length shall not be greater than 2½ inch no signs having been shown of the rubber cracking or elongating irregularly. Tensile streng not to be less than 800 lb. per sq. in.

Heat Tests.—Separate samples after removal of conductor shall withstand without mater deterioration a dry heat of 270° F. for 1 hr. and a moist heat of 320° F. for 3 hrs. After th days interval samples to be stretched as above from 2 ins. to 5 ins. for 6 hrs., the distance becom not greater than 2½ ins. on release.

Electrical Tests.—(*a*) High voltage test as B.E.S.A. Specification No. 7 after vulcanising a before outer protective coverings are put on. (*b*) Insulation resistance shall not be less than th given in tables and to be measured immediately after test (*a*). Cable to be immersed in wa

ıd measurement made with not less than 500-volt direct current after 1 minute negative electrifi-
ıtion. The electrification must proceed regularly.

Twinning.—For circular twin, the complete cores shall be twisted with a right-hand lay,
ɔrmed with tanned jute and wrapped to approximate circular section with rubber-proofed
ttton tape. For flat twin, the two cores side by side are tape-wrapped to form symmetrical
ble.

Mechanical Protection.—The specification gives particulars for braiding, identification cotton,
ad sheathing, bedding and serving, galvanised steel wire and steel tape armouring, tests on
ıished cables and packing, together with tabulated data and a temperature correction table
r insulation resistance.

The foregoing details give some indication of the main features which are to be looked for in
high-class rubber insulated cable. As regards the conductors, the conductivity question is
ıe of considerable importance, but it should be mentioned that trouble in this direction very
ldom arises, because there is little difficulty in maintaining a standard purity in electrolytically
fined copper. The phrase 'to show no sign of sulphide of copper after vulcanising' refers to
ıe appearance of the wire when it is stripped of its insulating covering. It should then present
clean, bright appearance, free from blackening.

The building up of the rubber dielectric in three layers represents the usual English practice,
ıd the wording of the specification is designed to exclude the use of adulterants and deleterious
ıbstances, these being practically synonymous so far as the life of the rubber insulation is
ɔncerned.

The specifying of a minimum percentage of rubber in addition practically leaves no room for
ıything but legitimate compounding ingredients, the choice of which is left to the experience
ıd skill of the cable manufacturer.

There is, perhaps, no industry so greatly dependent on detailed experience and skill in apply-
g that experience as that of the manufacture of rubber, and when electrical conditions are
.volved this is doubly true.

Generally speaking, therefore, where considerations of quality and durability are paramount
will always be best to purchase rubber-insulated cables, either to a specification such as that
stanced above, or to agreed standards such as those of the Cable Makers' Association.

The provision of suitable outer coverings for rubber-insulated wires and cables which are
ɔposed to abnormal conditions is a point which should not be overlooked. Conversely, in a
ven situation, a certain method of installing may be unsuitable. For instance, condensation
fects, which occur in tubes and pipes, are notoriously bad for rubber cables, and in such situa-
ons either the method of installing should be varied or special coverings, such as a bitumen
eath, should be applied to the cables. Many cable makers are prepared to advise as to the
ɛst type of covering and method of running or fixing cables under abnormal surrounding
ɔnditions.

A second quality of vulcanised rubber cable has been placed on the market to meet the demand
those users who are satisfied with a cheaper grade of cable. Such cable, known as 'non-
ɛsociation' cable, is quite satisfactory when properly manufactured, and may be safely used in
ıses where only a moderate length of life combined with good mechanical properties, is required,
ıd where the conditions do not require a permanent maintenance of high elasticity of the di-
ectric.

Revised Specification for Cab Tyre Sheathed Cable.*

The following specification for this class of cable is based on the British Admiralty Specifica-
on Tests for Cab Tyre Sheathing :—

The cab tyre sheathing shall contain not less than 35 per cent. and not more than 40 per
ınt. of first-grade plantation rubber or other rubber of not less good quality.

The surface of the sheathing shall not be treated or dressed without the consent of the
dmiralty Overseer.

The acetone extract of the vulcanised sheathing shall not exceed 5 per cent. calculated on the
eight of the complete sheathing as manufactured.

Bending Test.—A test length of the complete cable containing the conductor shall be bent
ınd a hard rod having the same diameter as the external diameter of the cable to form a loop.
he unbent portions of the test piece shall be bound together so that the two parts touch one
ıother closely throughout their length from their ends up to the beginning of the loop.

In cables of large size when this method is not practicable the test piece shall be bent in a
·op so that the maximum extension of the external surface at the curvature at the bend
ɛaches 50 per cent.

The sample in either case shall be left untouched for a period of 48 hours and at the termina-
on of this time shall show no signs of cracking.

Immersion Tests. (*a*) *Chemical.*—Test pieces 6 ins. long shall be prepared, and after the
ɔnductor and dielectric have been removed they shall be dried at a temperature of 100° C. for
ne hour in an air oven; they shall then be cooled in a desiccator for two hours, and at the end
f this period shall be weighed. The ends of the test pieces shall be plugged with rubber bungs
ıd sealed with paraffin wax for a length of half an inch from each end. The test pieces thus
repared shall be completely immersed in a vertical position in the following solutions for a

* Referred to in I.E.E. Rules under 'Tough Rubber Compound' Covering, p. 2221.

period of 48 hours at normal temperature; they shall then be removed and washed in runnin water for a period of two hours, afterwards being wiped dry and the wax and plugs remove The samples shall then be dried in an air oven for one hour at a temperature of 100° C. and sha be cooled for two hours in a desiccator; they shall then be reweighed. The difference i weights before and after immersion shall be calculated as grammes per 100 sq. ins. of surfa exposed to the solution.

(1) *Acid Test.*—The solution shall be hydrochloric acid having a specific gravity of 1·04 The figure calculated as stated above shall not exceed 1·0.

(2) *Alkali Test.*—The solution shall be sodium hydrate having a specific gravity of 1·11 The figure calculated as stated above shall not exceed 1·5.

(*b*) *Oil Test.*—A test piece shall be prepared 6 ins. long; one end shall be sealed so efficiently to prevent access of oil to the interior. The test pieces shall be immersed in pure ra oil of the best quality to such a depth that not less than 2 ins. of sheathing is exposed to t action of the oil. The immersion shall be continued for six hours, the oil during that time bei maintained at a temperature of 100° C. After immersion the sample shall be removed and roll dry between blotting paper; the seal shall then be removed and the sample re-weighed.

The difference in weights shall be calculated as grammes per 100 sq. ins. of surface expose and the figures so obtained shall not exceed 15.

The cable should be generally in accordance with *St. Helens Cable & Rubber Company's* origin Patent No. 3996/1911.

Cab Tyre Sheathed Cables are now made in C.M.A. 'Nonazo' (non-Association) quality, well as in C.M.A. Association grade.

WIRING SYSTEMS.

Conduits and Fittings for Electrical Installations.

Conduits, with the exception of the seamless or drawn varieties, are generally made fro specially selected steel strip, varying in gauge according to the diameter of the tube. T strips are rolled to a circular section of exact external and internal diameter, by a method whi ensures freedom from internal roughness and an even surface to facilitate the drawing of t wires into the conduit, thus preventing injury to their insulation. Exact sizes are essential order to obtain a tight junction between the conduit and fittings with both socket and screw junctions.

The conduits are made in two different types, viz. Light Gauge, for socket and continuit junctions, and Heavy Gauge for screwed junctions.

Conduits are usually supplied in two standard finishes, as follows:—

(1) Stove enamelled (black); (2) Galvanised.

For all ordinary installation work in the interior of buildings, enamelled conduits will found satisfactory in working.

The enamel employed should be flexible, acid-resisting, insulating, and durable.

The conduits must be well cleaned before being enamelled, and subsequently stored at even temperature until the enamel is set, so that it is not liable to flake or break away wh the conduit is bent. The enamel should resist any chemical action which is likely to be found the plaster of buildings.

Where conduits are subjected to excessive chemical action, especially when buried in cind fill concrete, quick-drying chemical plasters, and the like, a more efficient protection is require and this is afforded by galvanising.

BRITISH STANDARD SPECIFICATION FOR STEEL CONDUITS FOR ELECTRICAL WIRING.*

(No. 31—1923.) (*Abstract.*)

Steel conduits shall be either close-joint, brazed, welded or solid drawn as ordered, and sh be of mild steel and free from burrs and internal roughness. The conduit fittings shall be ma of steel or malleable iron. All steel shall have a tensile strength of not less than 18 tons nor mo than 24 tons per square inch of section, and an elongation of not less than 15 per cent. in a leng of 8 inches. Malleable castings shall be well annealed and free from internal projections.

The conduit shall be manufactured in straight lengths of ten to fifteen feet.

For all fittings made out of *tube*, the minimum thickness of the fittings shall be equal to th of the corresponding conduit with which they are used. In no case shall 'close joint' tube used for these fittings.

Two classes of steel conduit for electrical wiring are recognised as Standard:

Class A.—Plain.
Class B.—Screwed.

Class A consists of light gauge conduit of the thickness and dimensions given in the Ta (p. 2237). Class A conduit is either close-joint, brazed, welded or solid drawn. The coup joining the lengths of tubing is a sleeve, and neither the ends of the conduit nor the coupler screwed.

* By permission of the British Engineering Standards Association.

The Henley Wiring System.

(W. T. Henley's Telegraph Works Co., Ltd.)

In this system the cables carry their own metallic protection, which is of a flexible nature it is consequently very easily and speedily erected. The wires and cables are of very small dimensions, and when painted, distempered, or stained and varnished to match existing decorations they are to all intents and purposes indistinguishable. If desired, the cables may be buried in plaster and concealed generally. The cables may be run under floorboards, in lofts or cupboards and dropped down between the faces of lath-and-plaster partition walls. The chasing of walls or cutting away of joists is very much less than is required with tubing.

The cables employed are of flat section of one, two, or three conductors, each conductor composed of tinned copper wires, insulated with pure and vulcanised rubber, taped with proofed tape of a distinctive colour for each core, the whole then vulcanised together, cores laid side by side, sheathed with a solid drawn tube of special alloy to protect the cores from mechanical damage. These cables may be used on either direct or alternating current.

TABLE OF SINGLE-CORE, TWIN, AND TRIPLE CABLES.

0·002	3/·029	1,250	7·8	0·274 × 0·574	10·00
0·003	1/·064	2,000	12·9	0·276 × 0·580	10·36
0·003	3/·036	1,250	12·0	0·294 × 0·634	11·43

Test Pressure.—1,000 volts alternating for 15 minutes after 24 hours' immersion in water at 60° F. (15·5° C.).

For the purpose of bonding the sheathing at switch and light points the Universal Bonding Clamp is provided. This clamp, fig. 7, has been designed so that one clamp only, instead of several, may be used at any point, thereby reducing to a minimum the necessity for stocking various sizes of clamps for various numbers and sizes of wires, etc.

When erecting it will be found more economical in many instances to run both switch and light feeds to a three-plate ceiling rose, looping from there to the next light. In the case of electroliers controlled by two switches, in many instances it will be found economical to use a four-plate ceiling rose, taking both switch and light feeds to this rose, the switches being connected by means of a triple cable. This three-core cable can be used to advantage in many other instances which will be readily apparent when the work is planned out.

Straight through and tee joints, etc., are made by means of the boxes provided under ne system.

For fixing the cables, the 'Link' clip, fig 8, is specially convenient. These clips are ade from tinned brass, and may be fixed either with nails or countersunk-headed screws.

Fig. shows a form of Tee Joint Box for ne twin system. These Boxes are manu- actured from brass heavily tinned; the ternal connectors are of the porcelain type, nd are made in various forms according o requirements. The continuity of the metal neathing of the cables is preserved by means f mechanical clamps that bond the lugs on ne boxes to the cables.

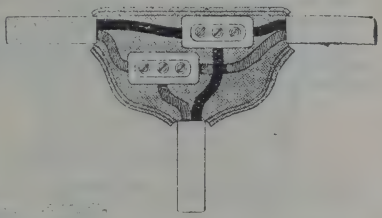

FIG. 6.

Another form of Tee Box—the 'Super' ox—is shown by fig. 9, p. 2241. In this Box ne loose bonding clamps used with the box lustrated in fig. 6 are dispensed with; the over is held in position by one unlosable self- entring nut which is fixed in the cover, and ne porcelain connectors are substituted by a ouded terminal block.

The latest addition to the system is a Box of the 'Universal' type, which is illustrated in g. 10, p. 2241. This Box works on the same principle as the Universal Bonding Clamp illustrated fig. 7, and can be used as a straight through, tee, or four-way box as required. As with the Super' Box, the cover is secured by one unlosable nut. The joint is made by means of porcelain onnectors.

The fixing of link clips, saddles, protective covering, or other articles, to plaster, brick, arble, slate, stone, etc., is best effected by the use of "Rawlplugs" (see p. 521).

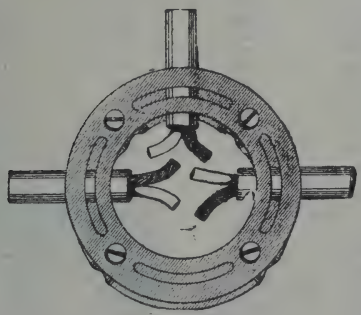

FIG. 7.

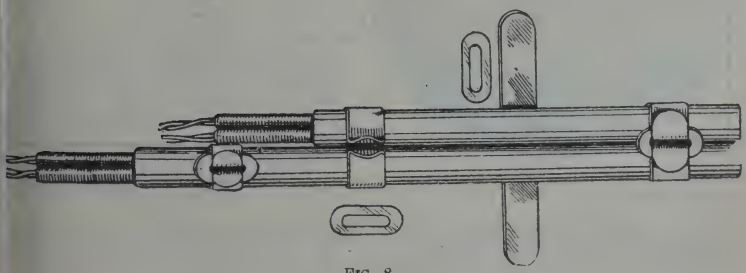

FIG. 8.

The Henley 'Nomet' (Regd.) Wiring System.

This system, whilst not new, employs Henley C.T.S. cables, and has been developed:

(*a*) To meet the wishes of customers who prefer a non-metal covered system.

(*b*) For use in abnormal situations where metal-covered wiring may be undesirable.

It is strongly recommended that, wherever possible, a metal-covered system be used, this being an economical and efficient means of electric wiring, and also a relatively safer method than any non-metal covered system.

Table of Single-Core, Twin, and Triple Cables.

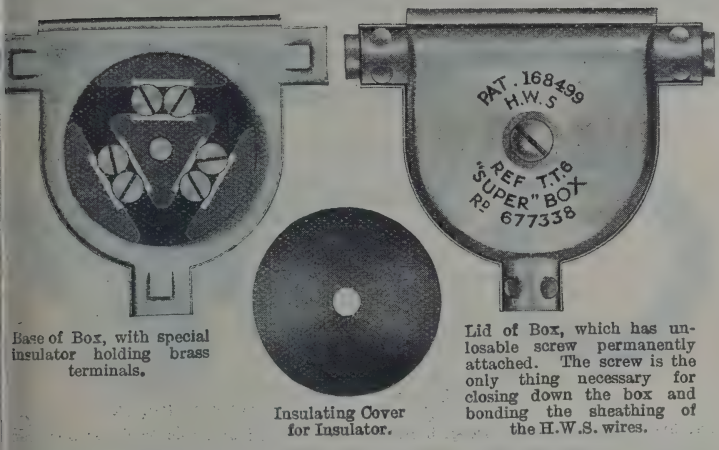
0·003	3/·036	1,250	12·0	0·274 × 0·582	3·30

Test Pressure.—1,000 volts alternating for 15 minutes after 24 hours' immersion in water at 60° F. (15·6° C.).

The 'Nomet' Wiring System cables, like the Henley Wiring System cables, are small in dimensions and carry their own mechanical protection. The cables can be easily erected, painted or otherwise treated, and the complete range of accessories (which are stocked) facilitate the wireman's work and enable a neat and satisfactory installation to be made.

THE HENLEY WIRING SYSTEM.



Base of Box, with special insulator holding brass terminals.

Insulating Cover for Insulator.

Lid of Box, which has unlosable screw permanently attached. The screw is the only thing necessary for closing down the box and bonding the sheathing of the H.W.S. wires.

FIG. 9.

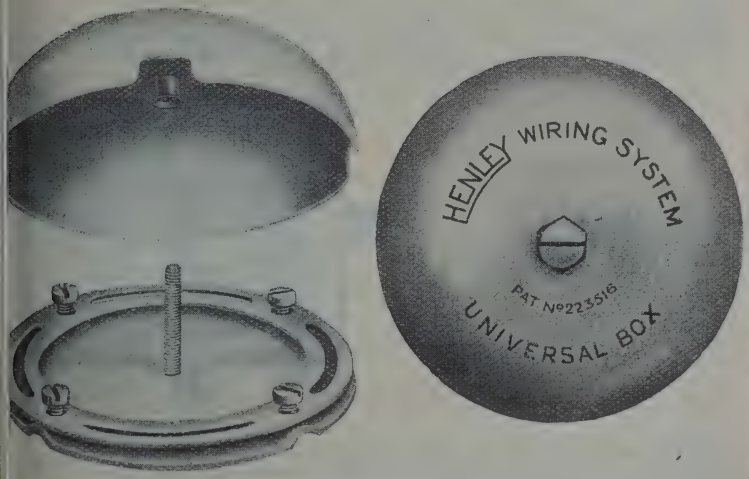


FIG. 10.

The J. and P. Wiring System.

(Johnson and Phillips Ltd.)

This system consists of single, twin (fig. 11), or three-core (fig. 12) rubber-insulated cal protected by a metallic sheathing of a special lead alloy. The cables are of flat section, and a intended for the wiring of domestic and other building interiors without further protecti

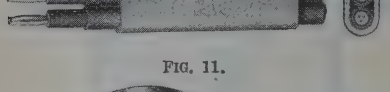

FIG. 11.

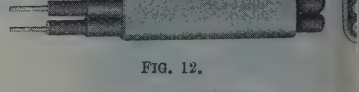

FIG. 12.

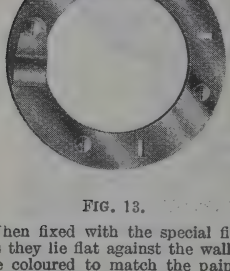

FIG. 13.

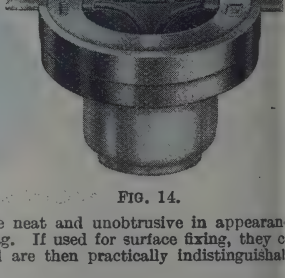

FIG. 14.

When fixed with the special fittings provided, they are neat and unobtrusive in appearan as they lie flat against the wall or ceiling and do not sag. If used for surface fixing, they c be coloured to match the paintwork or distemper, and are then practically indistinguishal from their surroundings.

The system fully complies with the I.E.E. Wiring Rules, and with the requirements of f insurance companies and electricity supply authorities.

The bonding fixtures are a special feature of the J. & P. wiring system. By means bonding and bonding clips a perfect bond can be secured with the greatest ease.

The bonding ring (fig. 13) is fixed behind a wooden pattrass (fig. 14), where connectio are made to switch points, etc. The ring is supplied with four ways, one or more of which m be used as required, suitable for cables up to 3/·036 twin core.

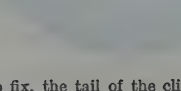

FIG. 15.

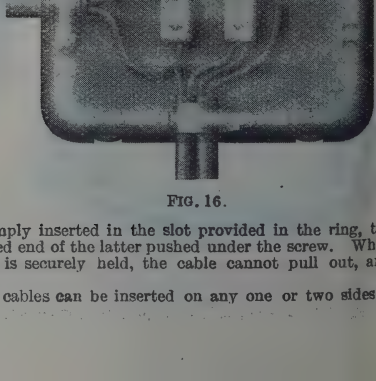

FIG. 16.

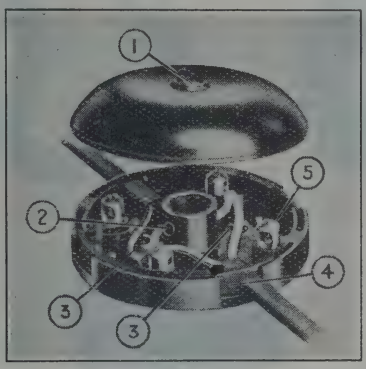
To fix, the tail of the clip, fig. 15, is simply inserted in the slot provided in the ring, t cable is placed under the clip and the notched end of the latter pushed under the screw. Wh this is tightened up, the metal cable sheath is securely held, the cable cannot pull out, a absolute electrical continuity is attained.

Fig. 16 shows a joint box in which twin cables can be inserted on any one or two sides it is desired to do so.

The J. and P. 'Non-Metal Sheathed System,' designed to supplement the Metal Sheathed system scribed, uses C.T.S. cables which are of the same overall size as the corresponding metal-sheathed bles, and the same fixing clips and saddles, protective steel covering, etc., can be employed. T.S. cable is more flexible than the metal sheathed cable, and although this extra flexibility luces the risk of kinking the cable during installation, a little more care is needed to avoid gging on long straight runs. An ornamental wood moulding, designed to cover the cable and ps, and shaped so that it cannot be misused as a picture rail, is available for use where the pearance of a moulding would harmonise better with the decorations.



1. Blanked hole for flex.
2. Hole in pillar for flex.
3. Blanked holes for back entry cable.
4. Sliding Shutter.
5. Terminal post.

FIG. 17.

Only one size and type of Joint Box (fig. 17) is used with this system. It is hot moulded in kelite, and has a very fine finish. Four apertures are provided for side entry cables, the apertures ng reduced in size to fit any cable used for domestic installations, or closed completely by means sliding shutters. Two blanked holes in the base can be knocked out cleanly and easily to accom- date back entry cables, and by knocking out another blanked hole in the cover the box can be ed as a neat ceiling rose. The flex is passed through the central pillar, and is gripped firmly en the cover is screwed down. Loose connectors are not required with this box, four terminal lars being moulded into the base.

The 'Kaleeco' Wiring System.

(Callender's Cable and Construction Co., Ltd.)

The conductors for this system, which are supplied either single, twin, or three-core, consist of h conductivity tinned copper wires, insulated with two layers of vulcanised india-rubber, then ed with a proofed tape of a distinctive colour, the whole being vulcanised into a homogeneous ly. The cores are sheathed under heavy hydraulic pressure with a tube of metal possessing siderable strength and flexibility, thus ensuring an effective mechanical protection for the lectric.

Before despatch from the works, each length of insulated core is immersed in water for at least hours, then subjected for a period of 15 minutes to a pressure test of 1,000 volts alternating, erwards being tested for insulation resistance with a battery having a pressure of not less than) volts.

'Kaleeco' metal sheathed wires, although stiff enough to prevent sagging between fixing clips perly spaced, are easily bent round mouldings and cornices, and being of small dimensions have articularly neat appearance when in position.

By the use of 'braided' 'Kaleeco' wire, which is made in various styles of decoration, a arrangement of the electrical equipment of a room may be made at any time without spoiling effect of an artistic scheme of decoration, or losing the wiring efficiency.

A special feature of the system is the 'C-B" Kaleeco" Universal Junction Box,' fig. 18, which designed on engineering principles and is of sound and substantial construction. It consists of ir component parts, accurately finished, neat in appearance and easily assembled. The box is ple to erect, accommodating without special adjustment any width and thickness of meta - ered wire and any direction of entry. It is universal throughout, and alterations can be made h perfect ease, without dismantling the box or employing additional component parts. By

the introduction of a lamina of tinned copper strip, which is termed the bonding ring, the effectiv ness of the continuity is ensured. The wires can be brought into the junction box at any positio and provision is made for bonding up to eight cables. All the jointing of the wires is effected l porcelain sheathed connectors.

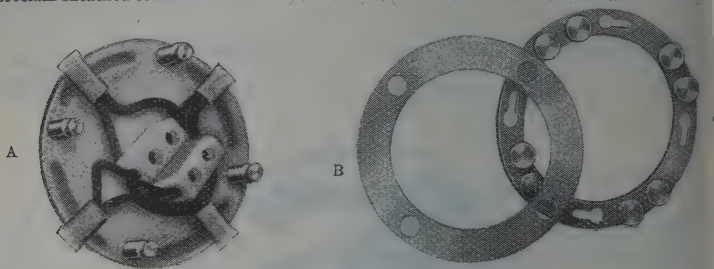


FIG. 18.

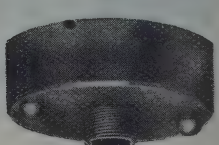

FIG. 19.

The fig. shows—(A) backplate of tinned brass on which the connection is made; (B) bo ing ring of tinned copper strip; (C) underside view of tinned steel bridge ring showing br mushroom tailed bonding screws.

Fig. 19 shows the special cord grip cover of a C-B 'Kaleeco' loop-in box. The box l been designed to obviate the use of ceiling roses mounted separately on wood blocks; t arrangement is a particularly desirable one in situations where head room is limited. The co is provided with a screwed nipple which will take either cord grip or standard $\frac{3}{8}$-in. lamp holde the whole fitting being fixed to the loop-in box by means of two screws.

The C.T.S. Wiring System.

This well-known type of protected cable was originated by The St. Helen's Cable & Rub Co. Ltd., Slough. It is generally known as C.T.S. It was designed for use in positions wh ordinary protected cables often give trouble, principally as trailing or portable cables, and since been found of value in all kinds of dangerous situations.

The conductors are usually insulated in accordance with the standards of the C.M.A., whole then being sheathed with the same tough rubber material as is used in the manufact of cab tyres. The principal characteristics of this rubber are durability, non-corrodibil and non-absorbence. This type of cable is, therefore, now used in the numerous places wh corrosion, moisture, hard wear, climatic or temperature changes are likely to be met with.

An advantage for some classes of work is that the elastic flexibility of the material preve it from being kinked.

This class of cable is being largely used for general wiring. Being a portable solid syst not needing any further protection, it is easily and cheaply run.

The use of C.T.S. without further protection of any kind is authorised by the Wiring R of the Institution of Electrical Engineers (see p. 2221, *re* 'Tough Rubber Compou Protection).

The Macintosh Wiring System.

(The Macintosh Cable Co., Ltd.)

The highly flexible properties, tough nature, and high permanent dielectric strength of this sulating material, known as ' Maconite,' have led to its adoption for nearly all classes of electrical nductors. The fact that twin cables of the now well-known 8 section can be mounted on the rfaces of walls, ceilings, etc., (either with or without the special wood fillet supplied) without ing conspicuous, and at low cost, renders it particularly suitable for the wiring of small houses, ats, and working-class dwellings. Many housing schemes have utilised it for this purpose. Its sulation resistance is equal to high quality vulcanised rubber, but in the case of ' Maconite ' it more constant and is unaffected by prolonged immersion in water or in a saturated solution of ustic soda. Resistance to breakdown pressure is also stated to be very high.

The following are details of tests to which Maconite has been satisfactorily subjected. Except here specifically mentioned, no tests of less duration than some thousands of hours are given :—

Extremes of temperature.—

(1) Freezing Maconite Cable in a block of ice for several days, and testing at 1,000 volts a.c. for 30 minutes. Then thawing out in running water and again testing at 1,000 volts a.c.

(2) Boiling in water and for 3 hours in a weak solution of caustic soda.

(3) Exposure for several months in temperature of 100° F. above boilers and brass furnaces.

In all these cases, not only did the cable withstand the tests, but its flexibility was found be absolutely unimpaired at the end.

Exposure to Chemical Action.—

(1) Immersion in dilute uric acid.
(2) ,, copper pickling acid.
(3) ,, 50 per cent. solution of sulphuric acid.
(4) ,, 5 per cent. solution of nitric acid.
(5) ,, 50 per cent. solution of hydrochloric acid.
(6) ,, slaked slag water.
(7) ,, two samples of corrosive pit waters.
(8) Immersion in saturated solution of caustic soda.
(9) ,, saturated solution of common soda.
(10) ,, 10 per cent. solution of ammonia.
(11) ,, saturated solution of common salt.
(12) ,, sea water.

In all cases the cables withstood the tests, the cables carrying direct current at 250 volts, vo cables being on test in each solution, and being connected to the positive and negative oles of the system respectively. This was done in order to be certain that the material would ithstand osmotic action.

The general results of the tests indicate that cables insulated with ' Maconite ' are particularly ited for installation in chemical works, steel works, dye works, long railway tunnels, etc., etc., here corrosive fumes or liquids are always present.

The material may prove to be suitable as a sheath for cables in the place of lead alloys or itumen. It is already being used as a sheath for a surface wiring system which requires no onding or earthing.

Failures only occur at the points where it is jointed to other apparatus, such as junction boxes, witches, lamp fittings, and distribution boards. *The Macintosh Cable Company* have therefore roduced a complete system embodying gas-tight fittings of the above nature, using patented Maconite ' glands which will ensure that no destructive gases or elements reach the metal fittings ecessary for junction purposes.

A further use for which ' Maconite ' has proved highly efficacious is in the construction of multi- ore cables for telephone and signalling purposes: its resilience and flexibility prevent destruction y the mechanical strains to which the cores of such cables are subjected. The same feature is lso leading to its adoption for trailing and similar cables for colliery work, etc.

Electro-chemistry.

A current of I amperes will, in T units of time, deposit from a solution of any salt of a metal under suitable conditions, ITa grammes of the metal (if time is reckoned in seconds), or IT grammes (if time is measured in hours), where a and b have the values given below, due account being taken of the valency of the metal in solution. One 'gramme-equivalent' of any substance is dissolved, deposited, or decomposed by the passage of 96,494 ampere-seconds (coulombs) or 26·80 ampere-hours; this quantity of electricity is known as the 'faraday.'

Element.	Atomic Weight.	Valency.	a Gm. per coulomb.	b Gm. per amp.-hr.	Element.	Atomic Weight.	Valency.	a Gm. per coulomb.	b Gm. per amp.-hr

(*Kohlrausch & Holborn.*)

PRIMARY BATTERIES.

'Siemens' Dry Cells.

These cells (*Siemens Bros. & Co. Ltd.*), originally known as the 'Obach,' have the exciting agent in the form of a damp paste. The following table gives the details of a few

he rectangular sizes. The outputs in ampere-hours are for continuous discharges through an xternal resistance of 10 ohms, until the P.D. across the terminals of the closed circuit has fallen o 0·75 volt.

Size.	Approximate Overall Dimensions (including terminal).	Approximate Weight.		E.M.F.	Initial Internal Resistance.	Output.
		Lb.	Oz.	about	about	Amp. Hours.
M	$4\frac{7}{16}$ ins. × $4\frac{7}{16}$ ins. × $8\frac{1}{8}$ ins. high	10	0	1·5 volt	0·15 ohm.	260
N	$3\frac{5}{16}$ „ × $3\frac{5}{16}$ „ × $7\frac{1}{2}$ „	5	4	1·5 „	0·15 „	110
O	$2\frac{15}{16}$ „ × $2\frac{15}{16}$ „ × $6\frac{5}{8}$ „	3	0	1·5 „	0·20 „	40
P	$2\frac{1}{4}$ „ × $2\frac{1}{4}$ „ × $6\frac{1}{8}$ „	1	14	1·5 „	0·25 „	25

An improved form of high-tension dry battery comprises large cells capable of giving satisfactory service with multi-valve wireless receiving apparatus at a normal anode current not exceeding 10 milliamperes. Three sizes only are standardized, viz., 18 volts, 36 volts, and 72 volts. Spring clip terminals are fitted and tappings provided at suitable intermediate voltages.

Siemens Inert Cells.

These cells, originally known as the 'Dura' cells, have the exciting agent in the form of an inert powder, which by the addition of ordinary clean drinking water becomes a paste, thereby giving a cell all the characteristics of a 'dry' cell, as described above.

Batteries and single cells are made up in this form, and the special utility of the construction is that the cells before being charged keep for an unlimited time in any climate, without deterioration, and may be converted at any time, as required, into a newly-made, so-called, 'dry' cell, with equivalent E.M.F. and output. This form is particularly suitable for use in those countries where it is essential to keep considerable stocks and where deterioration would be serious.

Siemens 'Sack' Leclanché Cells.

These cells are wet cells using sal-ammoniac as the exciting agent, and are modifications of the porous-pot form, the depolarising material being enclosed in fabric instead of a porous-pot. This enables a lower internal resistance and higher output in ampere-hours to be obtained.

Improved results can also be obtained by using Siemens 'Siebrosal' as the exciting agent in place of sal-ammoniac crystals.

G.E.C. 'Extra Sec' dry Cells.

The cell only requires to be filled with water, without any exciting element, and the excess of water emptied out. Specially suitable for use in tropical climates as the cell can be stocked for considerable periods without deteriorating, and only becomes active when charged with water.

G.E.C. 'Porous Pot' Leclanché Cells.

Specification.—Porous pot of high porosity, thoroughly tested and filled with a mixture of best selected peroxide of manganese and crushed carbon; positive plate of carbon throughout; without lead cap; well-amalgamated, solid drawn zinc rod of 98 per cent. purity; E.M.F., 1·5 volts.

Directions.—Place porous pot and zinc in glass jar and fill two-thirds full with solution of sal ammoniac, 2 ozs. to the pint of water.

G.E.C. 'Carsak' Leclanché Cells.

Specification.—Positive element consists of a porous sack which surrounds the carefully selected granules of carbon and manganese peroxide, which are very tightly packed. The 'pot' is practically unbreakable and its cylindrical form is maintained by a cap and base of hard material. The zinc is a semi-circular plate of ample dimensions, well amalgamated. 'Carsak' cells have a very low resistance, are thoroughly reliable and constant, and have a long life. They are particularly suited for telegraph, telephone, bell and signal circuits and for all positions where a low resistance Leclanché cell is required.

The 'Carsak' cell is designed to withstand severe transit conditions, and is therefore particularly suitable for export.

ACCUMULATORS.

Compiled from information supplied by the Hart Accumulator Co. and the Chloride Electrical Storage Co.

Storage cells should be placed in a well-ventilated room, preferably with louvres at the top to allow of the free escape of the gases evolved during charging; and the room should also be well lighted, both naturally and artificially, provision being always made for a hand inspection lamp to enable cells to be examined individually. The best working temperature is 50° to 80° F. Windows should face north to avoid direct sun rays. The room should not be exposed to undue draughts, as this promotes evaporation of the electrolyte, and it then becomes necessary to add an abnormal amount of water to keep the plates well covered with electrolyte.

Insulation.

Good insulation is essential. The cells should be mounted on insulators unless the boxes, if glass, are provided with feet. Above 100 volts the stands should be mounted on insulators also.

Assembly.

Cells with a capacity of less than 1,000 ampere-hours are assembled in glass boxes. The smaller sizes may be provided with feet or are mounted on separate insulators with lead discs, indiarubber washers or wood strips intervening. The larger sizes are mounted on wooden trays filled with sawdust. Above 1,000 ampere-hours capacity, cells are assembled in lead-lined wooden boxes.

The battery should be mounted on strong wooden racks or stillage protected with acid-proof paint with sufficient space between each cell to allow for insulation and cleaning.

The cells should be placed with the edges of the plates to view (if in glass boxes) and should only be arranged in double rows when they are accessible from each side.

Polarity.

The positive pole is painted red and is that to which the brown plates are connected: the negative pole is painted black and is that to which the grey plates are connected. The positive pole of each cell must be connected to the negative pole of the next cell throughout the battery, so that there will be a disconnected positive terminal at one end and a disconnected negative terminal at the other end of the battery. These are the battery terminals, which are connected to the dynamo as indicated in the diagram of connections in fig. 20. Cells should never be connected in parallel so as to form single cells of larger capacity; but if necessary they may be formed into batteries, and the batteries connected in parallel by coupling their ends.

Regulating cells should be at the negative end of the battery.

An automatic switch should be provided in the charging circuit.

Dynamo.

The dynamo used for charging should be shunt-wound, and the electromotive force required will be 2·6 volts for each cell in series. Before connecting up the dynamo it should be tested for polarity, which may be done as follows: Place two clean strips of sheet lead in a stone jar filled

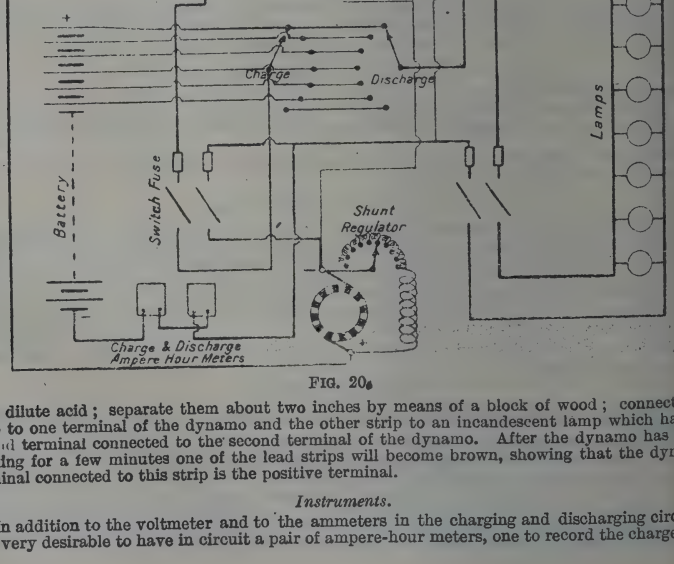

FIG. 20.

with dilute acid; separate them about two inches by means of a block of wood; connect one strip to one terminal of the dynamo and the other strip to an incandescent lamp which has its second terminal connected to the second terminal of the dynamo. After the dynamo has been running for a few minutes one of the lead strips will become brown, showing that the dynamo terminal connected to this strip is the positive terminal.

Instruments.

In addition to the voltmeter and to the ammeters in the charging and discharging circuits it is very desirable to have in circuit a pair of ampere-hour meters, one to record the charge and

the other the discharge. These may be connected in series as shown in the diagram of connections, and fitted with pawls which will prevent backward running, so that there will be a continuous record of both charge and discharge.

Water.

The water used for the cells should be distilled, as this avoids any danger of impurities entering the cell.

Acid.

The electrolyte in all storage batteries—lead-acid type—is dilute sulphuric acid with a specific gravity of 1·200/1·215. The method of manufacture is immaterial provided the finished article when diluted does not contain more than 0·001 grammes per 100 c.c. of chlorine or copper, twice that amount of iron, or one-third that amount of arsenic.

On the continent, sulphuric acid prepared by the catalytic process is largely used, but as this acid is usually prepared from iron pyrites the iron contents are higher than that made from natural brimstone. In this country *Messrs. F. W. Berk & Co., Ltd.*, the manufacturers of the well-known B.A.A. Accumulator Acid, prepare it from distilled water and the best brimstone, producing thereby an acid of the highest purity and best quality.

Preparing Electrolyte.

To dilute concentrated sulphuric acid it must be mixed with about 4½ times its volume in a suitable acid-proof vessel. The acid must be added to the water, never the water to the acid on account of the heat generated. Careful stirring is necessary. Correction for temperature must be made when testing the specific gravity to the extent of one point added to the hydrometer reading for every 2·7° F. above 60° F. The mixture must be allowed to cool before using it.

Filling up.

When everything is ready for charging, the acid must be put into the cells to a height of not less than one inch above the plates. Charging must proceed as soon as possible afterwards.

Charging.

Before the battery is switched into circuit with the dynamo care should be taken that the field-magnets are properly excited and the proper E.M.F. generated. The initial charge should be continued for not less than 36-40 hours at the normal charge rate specified by the makers for the battery in use. It has been recommended that the first 12 hours' run be continuous. Some makers, *e.g.*, The Chloride Electrical Storage Company Limited, now supply their batteries in a short first charged condition, which entails only 15 hours' initial charge at a prescribed rate, or alternatively two runs of 8 hours each. During the early portion of the initial charge the specific gravity will drop 20 to 50 points, and the charge cannot be considered complete until the specific gravity has maintained a maximum stationary value for at least two hours in the case of short first charge batteries, or five hours in the case of ordinary batteries. As the plates absorb the acid slowly, the level of the electrolyte will fall at first, and to compensate for this, more acid should be added, but any subsequent evaporation should be made good by the addition of water only.

Discharge.

The permissible rate of discharge depends upon the number of hours for which the discharge is required—the longer the time the smaller the rate. The product of rate into time is, however, not constant, but is greater with low rates of discharge than with high. Thus in the Hart Accumulator, 25-plate Lighting Type, the rates of discharge for 5, 7 and 10 hours are 126, 99 and 75·6 amperes respectively, giving discharge capacities of 630, 693 and 756 ampere-hours. The discharge rates for different times are always given by the makers, and should never be exceeded, the ampere-hours taken out being recorded on the discharge ampere-hour meter. The accompanying tables have been prepared for users of batteries supplied by The Chloride Electrical Storage Company Limited, and may be considered applicable to all Planté batteries.

CAPACITIES OF PLANTÉ TYPE STATIONARY BATTERIES AT VARIOUS RATES OF DISCHARGE.

Capacity in Ampere-Hours (expressed as a percentage of the ampere-hours available at the 5-hour rate) When Discharging in

7·5	6·0	5·91	5·82	5·61	5·35	5·10	4·47	3·58	3·0

Recharging.

To obtain longest life from a battery it should be recharged whenever the cells are about two-thirds discharged, determined by specific gravity and voltage, also by ampere-hours used (where ampere-hour meters are installed). A battery may be charged at any convenient rate between the conventional 'normal' specified by the maker, and half that value. In any case the charge should be completed at the lower rate. The ampere-hours put in should exceed the number taken out by about 10 per cent. ordinarily, but at least once a fortnight the battery should be brought up to a thorough healthy condition regardless of ampere-hour meter readings—all cells uniform and the extent of gassing, the specific gravity of the acid, the voltage, and the colour of the plates. Records should be kept on suitable forms of the individual voltage and specific gravity of each cell periodically and details of each charge and discharge.

Level of Electrolyte.

The level of the electrolyte must never be allowed to fall to less than half an inch above the top of the plates. Any loss due to evaporation must be made up by adding pure distilled water as above explained. Evaporation will be greatly retarded by the use of glass spray arresters covering the top of the plates or by an anti-spray oil film. Spray arresters must be so placed as to be easily removable for the purpose of examining the cells. Acid should not be added, except under the maker's advice.

Specific Gravity.

The specific gravity of each cell should be taken and recorded at least once a week, and if the consecutive readings so obtained are carefully compared, it is possible at once to detect a backward cell and take steps to remedy what is amiss. The hydrometer should be long enough to float in about two-thirds of the total depth of the electrolyte. The specific gravity varies to some extent with the temperature, and during the summer months will be rather lower than during the winter. The standard is taken at 60 deg. Fahr.; for every 2·7 degrees above this 1 degree of specific gravity may be added; for every 2·7 degrees below 1 degree of specific gravity may be deducted.

Weak Cells.

The indications of weak cells are bad colour of the plates, irregularity of gassing, or failure to gas, and a fall of specific gravity of electrolyte (obtained by the hydrometer), or voltage (obtained

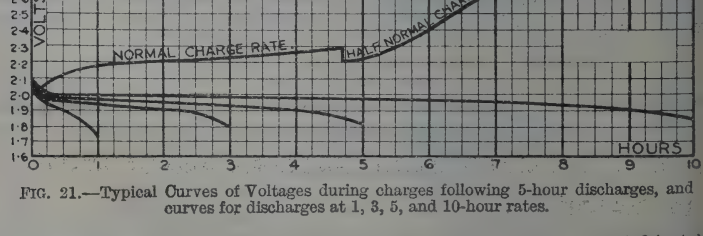

FIG. 21.—Typical Curves of Voltages during charges following 5-hour discharges, and curves for discharges at 1, 3, 5, and 10-hour rates.

by a cell-testing voltmeter) below that of other cells. Weak cells should be inspected for 'short circuits.' These may be caused by the lodgment of material between the plates or by the positive and negative plates touching each other. After removing the short circuit the weak cell should be cut out of circuit for a few discharges and put into circuit again for the following charge. Care must be taken not to allow the negative plates to dry out or heat by exposure to the atmosphere

Voltage Characteristics.

Fig. 21 indicates the characteristic rise in voltage on charge, and fall in voltage during discharge ording to the rate of discharge in amperes. The curves are applicable to any modern Planté ttery.

Buckled Plates.

Buckled plates should be removed and straightened by pressing between thick boards. e positive plates are most easily straightened when fully charged, as they are then softer and t so liable to crack. The negative plates should be kept in dilute acid while the positives are ing overhauled, as otherwise they may get heated by oxidisation with the air.

Battery Rooms.

SIZE OF BATTERY ROOMS REQUIRED FOR 25, 50 AND 100-VOLT 'HART' BATTERIES.

apacity n Amp. Hours.	25 Volt.		50 Volt.		100 Volt.	
	Single Tier.	Two Tier.	Single Tier.	Two Tier.	Single Tier.	Two Tier.
	′ ′ ′ ′	′ ′ ′ ′	′ ′ ′ ′	′ ′ ′ ′	′ ′ ′ ′	′ ′ ′ ′
140	6 6×3 9	3 6×4 3	6 9×5 0	7 0×4 3	13 3× 5 0	13 3× 4 3
280	9 3×3 9	5 0×4 3	10 0×5 0	10 0×4 3	12 9× 8 9	9 9× 6 0
420	6 9×5 0	6 9×4 3	13 0×5 0	13 0×4 3	16 6× 8 9	12 6× 6 0
630	9 0×5 0	9 0×4 6	11 6×8 9	9 0×6 6	16 9×12 6	16 9× 6 6
770	10 6×5 0	10 6×4 6	13 3×8 9	10 6×6 6	19 6×12 6	13 3×11 0
1,050	13 3×5 0	13 3×4 6	17 0×8 9	13 3×6 6	25 3×12 6	17 0×11 0

In preparing this Schedule the number of cells is as follows: 25-volt circuit, 13 cells; 50-volt cuit, 27 cells; 100-volt circuit, 54 cells. The height of room in each case should not be less an 8 feet.

Idle Batteries.

When a battery is not required for several weeks it should be thoroughly charged and the ates well covered with electrolyte. The cables should then be disconnected at the ends of ch row to avoid any possibility of electrical leakage. Cells will remain in this condition for veral months. If a charge can be given once every six or eight weeks it is best to do so; this ould be given at 75 per cent. of the normal rate and continued until the full charge is com-ted, and the plates gas freely. If a battery is to be used at infrequent intervals, it should given an extended charge once every two weeks.

CARE OF STORAGE BATTERIES.

The essential instructions in condensed form are:—

(1) add nothing but pure distilled water to the cells, and do this often enough to keep the ates always covered.
(2) Give ordinary charges as frequently as the service demands, and extended charges periodi-ly.
(3) Avoid high temperatures at all times.
(4) Avoid excessive gassing at end of charge.
(5) Record readings of voltage and specific gravity of each cell at the end of extended charges.
(6) Attend to weak cells without delay.
(7) Keep the battery and surroundings dry and clean.
(8) Take voltage while normal charge or discharge current is flowing.
(9) Never discharge below 1·8 volts per cell.

TESTS FOR IMPURITIES.

Hydrochloric Acid (Chlorine).—To a small quantity of dilute electrolyte add a few drops of ric acid, then add 3 drops of silver nitrate. The formation of a white, cloudy precipitate icates the presence of chlorine in some form.

Nitric Acid.—Mix a solution of diphenylamine in concentrated sulphuric acid, and add it the sample under test. Nitric acid will be indicated by a blue colour.

Iron.—Fill a test-tube with dilute electrolyte and heat to boiling point; add several drops concentrated nitric acid and boil again. Repeat two or three times. When solution is cold d a few drops of potassium sulphocyanide, which will colour a deep red if iron is present.

Copper.—Add common ammonia until the resultant mixture gives an alkaline reaction; a p blue indicates the presence of copper.

Arsenic.—Add an equal quantity of hydrogen sulphide solution; a yellow precipitate indicates enic.

Chloride Sealed-in Batteries.

The most recent development in the lead-acid storage battery is the Chloride Company's sealed-in battery. The positives have a large surface area for rated capacity, the negatives have armoured frames enclosing adhesive, porous, and homogeneous active material. The plates are assembled in moulded glass containers with isolating ribs between each pair of plate lugs. The containers have fully sealed lids minimising evaporation and acid spray and enabling cells to be transported in a fully charged condition. Between the plates are fitted treated wood separators forming a complete diaphragm entirely preventing internal short circuits. The cells only require to be coupled up on site and be given a short freshening charge and they are then ready for service.

Signalling and Wireless Batteries.

Special lines of batteries are designed for wireless batteries, electric bells, telephones, fire alarms, clocks, and signalling circuits. The two types have a capacity of 20 and 45 amp.-hr. respectively. Each cell consists of one positive and one negative plate of unusual thickness and incorporating an extremely large mass of active material in proportion to the grid or frame. The plates are kept correctly spaced by grooves in the side and bottom of the moulded glass box, which is fitted with a sealed-in ebonite lid. These cells are supplied in a dry charged condition and only require the addition of acid to render them ready for service at any time within six months from date of manufacture.

Edison Nickel-Iron Accumulator.

The Edison storage cell, which is largely used for propelling vehicles, has a positive plate of iron and a negative plate of nickel, immersed in a solution of potassium hydrate. The E.M.F. when fully charged is 1·5 volts, falling to 1·0 volt, or less, at the end of discharge. The output is 14 to 16 watt-hours per lb. of complete cell.

Standardisation Rules for Electrical Machinery, issued by the British Engineering Standards Association.

The following eight specifications of the B.E.S.A. are devoted to the electrical performance of electric machinery :—

No. 170—1926 applies to fractional horse-power motors of any continuous rating less than 1 h.p. per 1,000 revs. per minute, but not to 'universal' motors (*i.e.* motors capable of operating on both a.c. or d.c. circuits).

No. 168—1926 applies to industrial motors and generators having rated outputs larger than in Spec. No. 170 and smaller than those in Spec. No. 169, and wound for voltages not exceeding 7,000 volts.

No. 169—1925 applies to large generators and motors permitting overloads and of such size that the rated load plus the sustained overload of 25 per cent. for 2 hours does not exceed 2·5 k.w. 2·5 k.v.a., or 2·5 h.p. per revolution per minute.

No. 226—1925 applies to large generators and motors with continuous maximum rating of sizes not exceeding 2·5 k.w., 2·5 k.v.a., or 2·5 h.p. per revolution per minute.

No. 225—1925 applies to steam-turbine driven alternators (turbo-alternators) and to alternators not steam-turbine driven if of similar high-speed construction.

No. 172—1927 applies to rotary converters (to be ready shortly).

No. 173—1923 applies to traction motors (see p. 2275), and is now under revision.

Sizes of Bare Copper Wire for Electrical Machinery.

The British Engineering Standards Association's Specification No. 128 (1922) gives the dimensions and resistances of bare annealed copper wires for winding electrical machinery and apparatus. The standards for resistance fixed by the International Electrotechnical Commission have been adopted (see p. 2193). The dimensions are expressed in decimals of an inch, and the sizes are divided into three classes : 29 sizes identical with the even numbers of the Standard Wire Gauge are classed as *primary* standards ; the remainder of the S.W.G. sizes are classed as *secondary* standards, and intermediate sizes are given but not recommended for general use. The total number of sizes for which data are tabulated is 110.

GENERATORS.

DIRECT-CURRENT GENERATORS.

The Metropolitan-Vickers Direct-Coupled Generator.

(The Metropolitan-Vickers Electrical Co., Ltd.)

A circular field yoke carries inwardly-projecting pole pieces of laminated soft steel. The field ring is divided horizontally or vertically to suit variable conditions of service. When the machine is coupled at one end of a high-speed engine, and there is sufficient overhead room, the

izontal position is adopted. But when overhead room is restricted or if the machine be ced between the cranks of a cross-compound engine, the field ring is split vertically, the two ves being set on a guide plate. This vertical division of the field affords facility for inspection removal of armature or field coils without the necessity of removing the outboard bearing or mantling the engine. The opening of the field in a horizontal direction is of convenience where id room is limited and cranes or other devices for handling heavy castings are not available.

The armature core consists of punchings of carefully annealed steel held together between d-plates. This core is built upon an iron spider, which also carries the commutator. The der is pressed and keyed upon the extended engine-shaft, and may be drawn off at will should at ever be necessary, without in any way interfering with the permanent arrangement of the mmutator and winding. Ventilating spaces through the spider and armature core are so anged as to give a constant circulation of air through the commutator and winding.

The generator field is over-compounded to compensate for drop of potential in the line. By ans of a shunt on the series coils, the compounding may be adjusted for different degrees of er-compounding. The shunt and series coils are separately wound and removable at will. e series coils are composed of forged copper conductors of rectangular section.

The periphery of the armature is slotted. The armature winding of all machines of 50 kw. d over is made from bars of drawn copper, forged into proper shape on cast-iron formers. ter being thus shaped, the bars are thoroughly insulated and baked to remove all moisture. e coils are held in slots by means of retaining wedges of hard fibre driven into notches near e top of the slots, parallel to the shaft. These fibre wedges may be pressed out should it become cessary to remove any armature coil.

The brush-holder mechanism is carried by brackets projecting from a ring concentric with, d supported by, the field. A hand-wheel rocker arrangement accomplishes the adjustment of the brushes simultaneously. The ring carrying the brush-holder brackets does not project er the commutator face ; the commutator face and brushes are therefore clear of obstructions, d may easily be inspected at any point. Carbon brushes are used in connection with all these achines.

A feature of importance in the Metropolitan-Vickers engine-type generators is that all brushes the same polarity are maintained at the same potential. Trouble has frequently been experi- ced in working with large multipolar direct-current machines owing to the difficulty of securing e same magnetic strength in all the poles ; the E.M.F. generated in conductors under one pole fered from that generated in conductors similarly situated under another pole of the same larity, the result being a slight difference of potential between brushes of similar polarity. is caused currents to flow from one brush to another, and from one section of the armature nding to another, an occurrence attended by wasteful heating and the sparking of brushes. ie difficulty is obviated in these generators by a particular method of electrical balancing. By e use of this method, the armature could be considerably out of centre and no injurious results cur, as the balancing currents flow, not through the brushes, but through specially provided nnections. The pull exerted by one side of the field on a large armature out of centre by even e small fraction of an inch may become as high as several tons ; this method of balancing events such an increased pull.

DIRECT-CURRENT GENERATORS DRIVEN THROUGH GEARING.

The Mather & Platt Direct-Current Geared Generator.

(Mather & Platt, Ltd.)

One of the latest phases of electrical engineering is the driving of large D.C. slow-speed nerators, through gearing, by steam turbines, and a considerable number of these plants ve been installed up and down the United Kingdom by Messrs. Mather & Platt, Ltd., of Park orks, Manchester.

A typical generator is shown in fig. 22. This machine is installed at the works of the lectro Bleach and By-Products, Ltd., Middlewich, Cheshire, and is driven by a steam turbine, the ' Howden-Zoelly ' Multi-Stage Impulse type, running at 3,000 r.p.m., manufactured by essrs. James Howden & Co., Ltd., Glasgow. The generator is driven through double helical aring and runs at a speed of 250 r.p.m. The substantial character and satisfactory operation the plant—which runs day and night—cannot be better exemplified than by the fact that a rther set of 1,000 kw., consisting of two 500 kw. machines in tandem, and a 1,250 kw. set ve recently been installed, and set to work.

The details of construction of this machine is as follows :—

Carcase.—The frame is a plain ring of high permeability cast steel ; the main poles consist steel stampings accurately punched and assembled, and are bolted to the frame. Magnetic mmetry is thus ensured.

Bearings.—The bearings are of the self-lubricating, parallel bush, pedestal type ; the bushes e of cast iron with white-metal lining, and all bushes and pedestals are split horizontally. ach bearing is lubricated automatically by means of two oil rings running in an oil well of rge capacity.

Commutator.—The commutator is designed with a very high factor of safety. The segments of hard-drawn copper, are insulated by megohmit, mounted on a strong cast-iron hub, and clamped between steel end rings. Before connection to the armature every commutator is subjected to an insulation flash test of 3,000 volts.

Armature Core.—The armature is built of thin steel slotted laminations of the highest electrical and magnetic quality, insulated from each other and clamped together under pressure on a strong cast-iron hub, an extension of which carries the commutator hub.

Armature Winding.—All wires and strips are thoroughly impregnated before winding, and the main insulation consists of mica sheet mechanically protected by leatheroid. The complete armature is finally dried and impregnated with varnish.

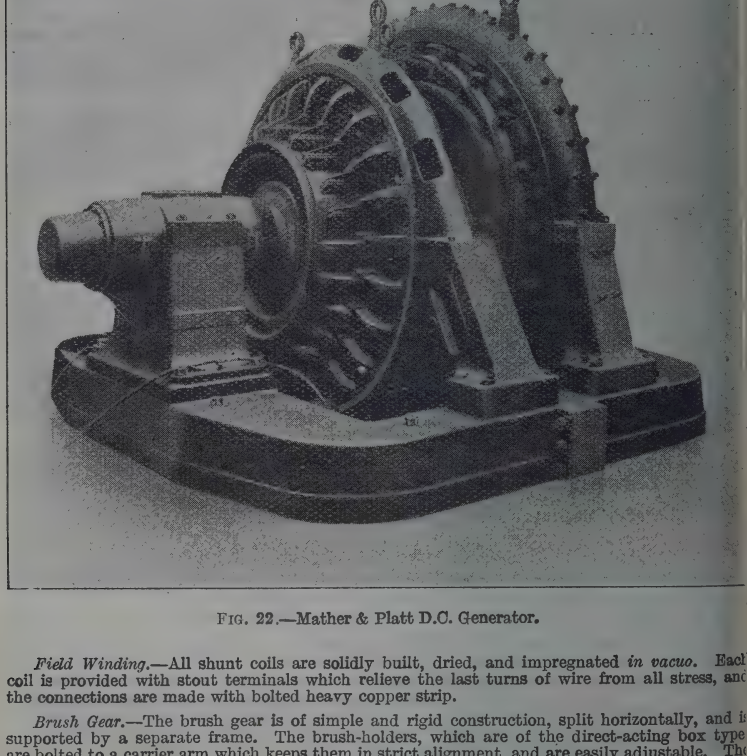

FIG. 22.—Mather & Platt D.C. Generator.

Field Winding.—All shunt coils are solidly built, dried, and impregnated *in vacuo*. Each coil is provided with stout terminals which relieve the last turns of wire from all stress, and the connections are made with bolted heavy copper strip.

Brush Gear.—The brush gear is of simple and rigid construction, split horizontally, and is supported by a separate frame. The brush-holders, which are of the direct-acting box type are bolted to a carrier arm which keeps them in strict alignment, and are easily adjustable. The insulation is micanite throughout. When the brush rocker has been once set in the working position, it remains fixed for all loads up to the maximum permissible overload.

G.E.C. 'WITTON' DIRECT-CURRENT GEARED GENERATOR.

(The General Electric Co., Ltd.)

Fig. 23 shows a 1,000 kw. direct-current generator, driven through gearing by a Fraser & Chalmers turbine, in a Scotch iron and steel works. This set delivers direct current at a pressure

240 volts, and runs at a speed of 600 r.p.m. with the turbine operating at 3,000 r.p.m. The aring is employed to enable the speed of the generator to be reduced to such a point that the

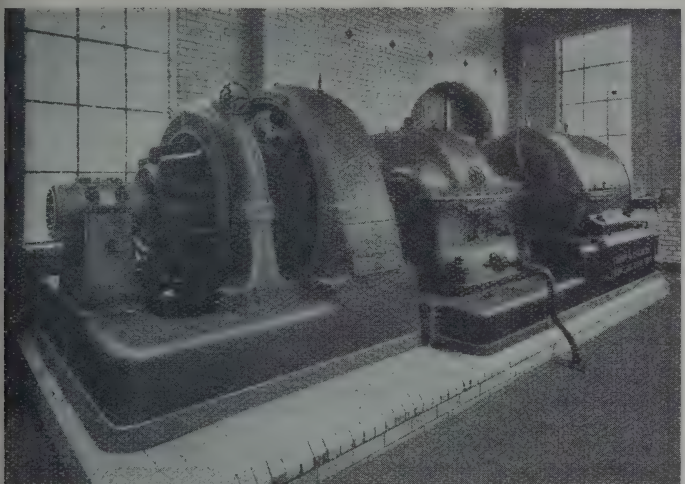

FIG. 23.—1,000 kw. G.E.C. 'Witton' Direct-Current Generator; 240 volts, 600 r.p.m.; turbine driven through gearing by Fraser & Chalmers turbine—3,000 r.p.m.

st commutation is obtained, and to enable the turbine speed to be raised to the point of highest ciency.

Care of Direct-Current Generators.

Steadiness.—It is important that the machine be firmly fixed to a good foundation. A machine y be run successfully on an upper floor, if supported on solid joists either of timber or iron. e machine will spark and the brushes and commutators wear unduly if there is vibration.

Commutator and Brushes.—These will always repay careful attention. If the brushes are t to wear unequally, and the commutator is not cleaned, the machine will soon commence spark badly, and both brushes and commutator will wear rapidly. If, however, these parts attended to in accordance with the following instructions, the wear and tear will be very small.

Adjustment of Brushes.—The brushes must be set truly on a diameter so that the point of is diametrically opposite the point of the other. Gauze and metal brushes as they wear must advanced to maintain the same distance, and consequently to bear the same angle on the face of the commutator. They must be advanced frequently, even though the wear may be y small, otherwise the brush will not bed properly on the surfaces of the commutator when vanced. Each brush must always bed equally well at the point, or toe, and at the heel. If ushes are allowed to wear too much before advancing (but this should not be), they must be ten out and filed to fit truly. In filing a brush, clamp it firmly, and file by taking long strokes th a file always in one direction. If it is the toe that requires filing, after filing to fit take the sharp edge, leaving the toe always $\frac{1}{16}$ inch thick. One brush often wears faster than fellow (or fellows), and must be set up accordingly. Moreover, sometimes a whole set of ushes on one side of the commutator will wear faster than those on the other side, and this ust be allowed for, or the brushes will cease to be on a diameter, and sparking and flatting of the mmutator may result.

Carbon Brushes are usually set radially to the commutator and therefore require no diagonal justment. They require periodical inspection, adjustment and cleaning, as the toes or heels ually burn away and a new surface giving the full contact area of the brush must be again tained. The best results with carbon brushes of ample contact area and good designs fitted th flexible tails are obtained by keeping the brushes absolutely clean and free from dust and e commutator true and polished with polishing paste.

Flats.—The most common source of the formation of little 'flats' upon the surface of the mmutator is the brushes being out of adjustment. Another cause is vibration of the brushes, e primarily to vibration of the machine, owing to improper foundations or a badly-jointed

belt. Flats are sometimes caused by the pressure of the brushes being reduced to too low limit.

Pressure.—It is well to have the pressure as light as possible, so long as no sparking and n vibration takes place at the brushes.

Oiling and Cleaning the Commutator.—In the case of metal brushes use a little good miner oil or vaseline, applied with a piece of rag. Do not on any account apply oil with a feeder, or o a piece of waste. A commutator well looked after will acquire in time a dark-coloured, smoot polish. When this takes place run a piece of No. 0 0 emery cloth on the commutator occasion ally before starting to work. In flour-mills and dusty places it is necessary to clean the com mutator with a little benzoline every day before starting, or, if run continuously, during the run taking care not to drench the commutator ; also to apply emery cloth about once a week as jus directed.

Belting.—Where practicable, the drive should be arranged so that the under side of the belt the tight or driving side. A flexible belt should always be used. Leather-linked belting, arche on the face next the pulleys and flat on the outside, is very suitable. Such a belt should *not* t taken off after working. Single belting with double edges makes a good cheap belt for ordinar use, and may be jointed with a butt joint, secured by belt fasteners. If an ordinary single be is used, it should be straight and of good quality. It should be jointed with a laced butt join until it has stretched, and then a proper spliced and cemented joint made. A dynamo belt mu run evenly. A belt which lashes either up and down, or from side to side, should not t tolerated.

Oiling the Bearings.—Adjust the sight-feed lubricator to give about 3 to 10 drops per minut The amount required varies with the quality of the oil used and the load on the machine. If th machine has been standing, give it a few extra drops before starting. It is well to use an o feeder made entirely of copper. Keep the machine clean—free from copper dust and waste oil.

Should the commutator wear out of truth or become very uneven (scored), take out th armature and turn up the commutator in a lathe, being careful to use a fine-pointed tool and no to take heavy cuts ; afterwards polish with emery cloth. If the commutator should be onl scored, it may be dressed in the machine with coarse, and afterwards fine, emery cloth, finishin with No. 0. Slight 'ringing' does not matter.

ALTERNATING-CURRENT GENERATORS.

ernators are supplied for mounting direct on the engine crankshaft, for coupling direct, or for t or rope driving. They are of the stationary armature type, with open parallel slots or semi-losed slots depending on the general design of the machine and the duty required. The coils held in position by hard wood or fibre wedges. The magnets are of the rotating radial pole e, with the poles and shoes laminated or cast solid, according to the design. The field coils und on insulated formers are held in position by the pole shoes.

When driven by slow-speed gas or oil engines, amortisseur or damping coils are often fitted.

The ventilation is a special feature of these machines. The armature coils are protected with tal covers, which assist in directing the air currents from the revolving field of the machine ially through the armature end windings to the back of the armature stampings, and thence ough the ventilating holes in the cast-iron frame of the machine.

In the larger size machines the stationary armature is divided on the horizontal centre to ilitate transport and erection.

The exciter is of the usual standard construction for direct-current machines, and is ally direct coupled to an extension of the alternator shaft, fitted with an outer bearing and unted on an extension of the alternator bed plate.

ALTERNATING-CURRENT GEARED GENERATORS.

While many D.C. machines nowadays are driven by steam turbines through gearing, a similar angement is adopted with alternators in spite of the fact that it is not very difficult, either n an electrical or a mechanical point of view, to construct medium-size high-speed turbo rnator sets. The geared alternator is adopted from motives of economy, as the steam turbine then be designed for speeds of over 3,000 r.p.m.

The Mather & Platt Geared Alternator.

(*Mather & Platt, Ltd.*)

Fig. 25 shows a 1,250 k.v.a. alternator, 2,200 volts, suitable for a speed of 500 r.p.m. and

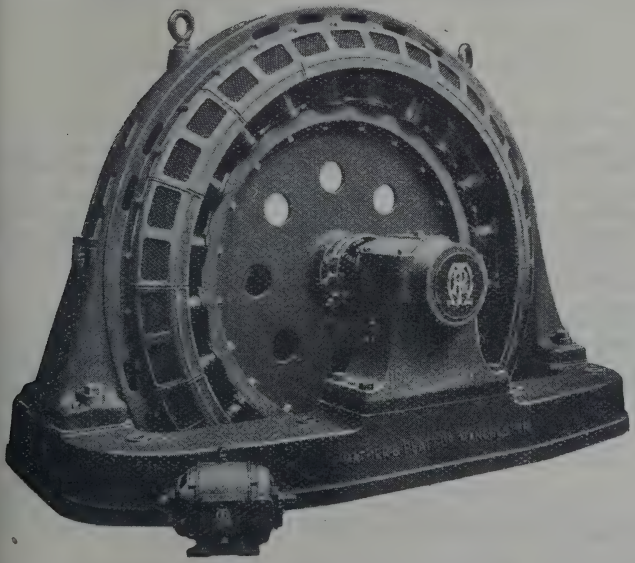

Fig. 25.—Mather & Platt 1,250 k.v.a. Alternator.

nged for gear driving from a steam turbine of over, say, 4,000 r.p.m. Such a machine is structed on the following lines:—

The stator consists of a cylindrical core, built up of thin steel laminations of the highest

electrical and magnetic quality, insulated from each other, and firmly clamped together in rigid cast-iron frame.

The windings are fully insulated before insertion in the slots, the latter being usually of th open type. High-tension coils are insulated with moulded mica, and low-tension coils wit standard mica sheet mechanically protected by leatheroid. In all cases the insulatio forms a complete sealed tube completely enclosing the straight part of each coil, and extendin for a considerable distance beyond the stator core at each end. The coils are held in positio by hard wood wedges.

In normal machines, the poles are completely laminated, the core and tip being stampe in one piece. The built-up poles are usually bolted to the rim of a cast-steel hub. In speci cases, however, the above construction may be modified.

For small machines with few poles, the field coils consist of cotton-covered wire or stri Each coil is provided with terminals which relieve the last turns of wire from all stress. Th coils are thoroughly dried and impregnated in vacuo with an oil- and moisture-resisting varnis For larger machines copper strip bend on edge is used in all cases where it is practicable.

The shaft is of mild steel of ample size and stiffness. Each bearing is of the pedestal typ with a cast-iron bush of large diameter and length, lined with white metal, and lubricated aut matically by two oil rings running in an oil well of large capacity. The oil channels and esca grooves are carefully designed to eliminate oil-flinging and creeping, and the overflow is arranged that frothing or churning of oil in the oil well does not cause any drip. The pedest and bearing bush are split horizontally.

The slip rings are of bronze, insulated entirely by mica. The brush-holders are of the direc acting box type, and the whole brush gear is simple and strong.

ALTERNATING-CURRENT TURBO-GENERATORS.

The G.E.C. Turbo-Alternator

(with combined axial and tangential ventilation).

(The General Electric Co., Ltd.)

The following is the specification of a G.E.C. turbo-alternator of the standard type :—

The alternator is of the enclosed type, with drum-type rotor and forced ventilation. Sh and exciter are included, but no bearings or coupling, excepting where this is specifically stat

Stator Frame.—The stator frame is a massive casting of box section, accurately bored accommodate and clamp tightly the laminations. Stout end-plates are used for this purpo and are secured in such a way that no bolts pass through the stampings, thereby avoidin considerable amount of iron loss. All longitudinal ribs are fitted with dovetailed keys to wh the stampings are secured. The casing rests on two feet, which are connected to the main bo by strong ribs to avoid flexure or vibration.

Laminations.—The laminations are accurate stampings of special low-loss iron, punched of large plates with carefully ground tools to avoid burrs. They are re-annealed after punchi and insulated as a last operation. No filing or scraping takes place after the laminations assembled, as this causes much higher iron losses due to eddies than in ordinary machines. the same reason, the insulation between plates is increased by sheets of strong paper placed suitable intervals.

Stator Winding.—The stator winding consists of a lap winding of the diamond coil type.

The coils are completely insulated before insertion in the slots, which are of the open ty The insulation of the coils is entirely class ' B ' insulation and consists of mica and micanite.

The insulation of the slot portion consists of a micanite tube carefully moulded on to coil by a special process, which eliminates the possibility of air spaces. The end turns are sulated by a suitable number of layers of mica silk tape wrapped round the coil, and the coi finally finished off with a layer of protective tape.

Clamping of Stator Windings.—The end windings are suitably braced, which prevents a possible movement of the coil under the severe stresses which accrue should a sudden sh circuit take place.

Ventilation of Stator.—Fans are arranged at both ends of the rotor, to draw air throu channels in the end shields from ducts in the foundations and force it into the space enclo

F. 2259

by the guards of the stator winding. From there, after cooling the overhanging parts of the stator coils, the air is pressed into pockets in the stator casing, and through the vent ducts of the stator core. It enters these vent ducts on the outer periphery of the core, and is guided by suitably shaped spacing pieces first inwards to the teeth and stator coils and then outwards to the outer periphery. The air escapes from the ducts through the stator casing to the outlet opening, a funnel-shaped orifice, through which the cooling air finally leaves the machine. This orifice can be arranged either at the top or below the machine, according to local requirements. The employment of an air-cooler is recommended, but a decision as to the type can only be arrived at in each particular case with a knowledge of the local conditions.

Rotor Winding.—The winding consists of coils which are completely shaped before they are embedded in the slots. Strong and ample insulation is provided between the winding and the rotor, as well as between the conductors themselves, particular care being taken to avoid crushing action due to centrifugal force. The insulation used is practically incombustible.

Clamping of Rotor.—The rotor windings are held in the slots by metal wedges. The overhanging end-connections are enclosed by steel shrouds of ample strength to withstand with safety the centrifugal stresses at maximum speed. These are put on with a moderate shrinkage. The shrouds are located at one end on a spigot provided in the core, at the other end on strong steel end plates carried from the shaft. Balancing grooves are provided at both ends of the rotor. The windings are entirely boxed in and protected from injury.

Ventilation of Rotor.—The cooling air enters the rotor at both ends through channels underneath the stator fans and passes under the rotor end winding into axial ducts arranged below the rotor coils. It escapes from these ducts through radial vent spaces, provided at intervals in the rotor core, into the air gap of the alternator, and leaves the machines through the stator core and casing.

Slip Rings.—The current is supplied to the winding through two steel slip rings shrunk on to an iron sleeve, and insulated therefrom by a moulded-on mica bush. Any danger of distortion or of getting out of truth of the rings is thereby avoided. Particular attention is paid to the leads connecting the rings to the windings. They are sunk into a groove in the shaft and protected by a key-shaped cover.

Terminals.—The terminals are usually arranged at the bottom of the shell, the cables being brought up to them from the basement. They are thus in a naturally protected position without necessitating unsightly boxes in the engine-room. The neutral point of each phase is brought out separately.

Rotor Construction.—The rotor is of the drum type, the winding being distributed in slots all round the periphery. The rotor body and shaft are one solid forging. This design has been adopted because a solid forging gives the strongest possible mechanical construction. The slots are milled out of the solid.

Journals.—The journals are of ample dimensions to run without overheating. They are finished off after the whole of the rotor is completed to ensure a true surface. Ample oil flirts are left at both sides, working in rings supplied with the bearings by the makers of the turbine.

Exciter.—The exciter is carried from the bearings at the slip-ring end. It is specially built for high speeds, and is usually compound wound.

Tests.—Numerous tests are carried out during the process of construction to see that the materials are satisfactory at all stages. Amongst these tests are the following :—

(*a*) Breakdown test for tubes after inserting them in the core.

(*b*) Test between adjacent conductors in a slot, not less than ten times the working voltage between conductors.

(*c*) Between finished coils and between any coil and earth, twice working voltage plus 1,000 volts, but in any case not less than 2,000 volts.

(*d*) Rotor winding tested to earth with 2,500 volts when all connections are made to the slip-rings and after balancing test.

(*e*) Static balancing on flat rails.

(*f*) Dynamic balancing at full-speed.

(*g*) Synchronous run at full speed to measure iron, windage and excitation losses. During this test the open-circuit curve and the short-circuit curve are obtained.

(*h*) Overspeed test at 15 per cent. above running speed.

(*i*) Oscillograph of wave-form on open circuit.

The G.E.C. Fraser & Chalmers Turbo-Alternator Set.

(The General Electric Co., Ltd.)

In fig. 26 is shown a G.E.C. Fraser & Chalmers Turbo-Alternator set for 6,000 k.v.a. a 6,600–7,200 volts, 50 cycles, 3,000 r.p.m.

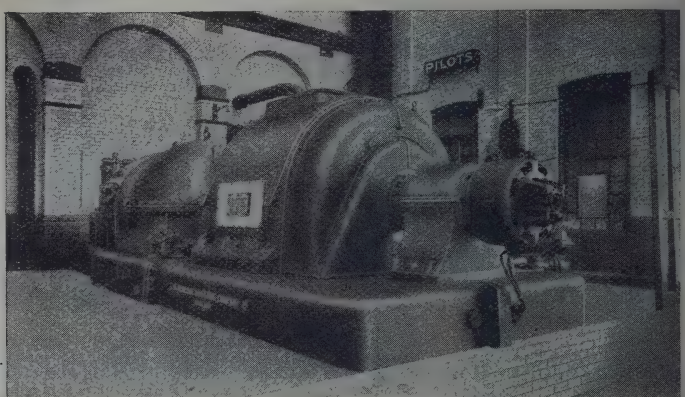

Fig. 26.—Fraser and Chalmers Turbo-Alternator Set.

The Tirrill Automatic Voltage Regulator.

(Messrs. British Thomson-Houston Co. Ltd.)

Fluctuation loads, and the time-lag inseparable from manual control of generator voltage, ma cause serious variation in a generating station voltage. This regulator (fig. 26A) automaticall

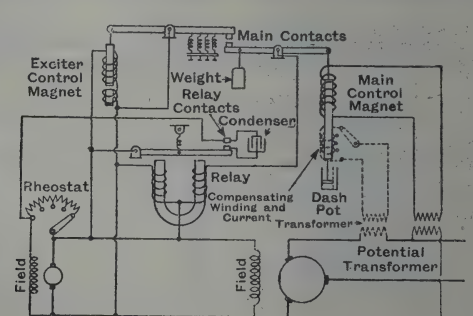

Fig. 26A.—Elementary Diagram of Type T A Regulator, connected to Three-Phase Alternator, showing (in dotted lines) Compensating Coil and Current Transformer.

and instantaneously regulates the voltage of either alternating- or direct-current generators In fig. 26A, the rheostat in the field circuit of the exciter results in the alternator generating onl about 60 per cent. of its normal P.D.; when it is short-circuited, the P.D. of the alternator greatl

xceeds the normal value. The action of the Tirrill regulator is to vary the duration of the periods f open- and of short-circuit of this exciter field resistance. In the diagram, the two main or float- ng contacts are fixed respectively to two pivoted levers. The top contact lever tends to be kept epressed by springs, which are opposed by the downward pull of the exciter control magnet. 'he bottom contact lever has a counterweight balancing a core which is acted upon by the main ontrol magnet energised from the alternator terminals. The pivoted armature of the relay carries ne of the rheostat short-circuiting contacts which the spring tends to keep closed. The middle oint of the relay winding is connected to an exciter terminal, one end to the other exciter terminal ermanently, and the other end intermittently through the main contacts. When these contacts re closed there is no magnetic effect in the relay, because the two portions of the winding eutralise each other and the exciter rheostat remains short-circuited. The rising generator oltage then increases the current in the main control magnet sufficiently for the core to rise and pen the main contacts. The relay magnet now becomes strongly excited, and, its armature being ttracted, opens the short-circuiting contacts across the exciter field rheostat terminals, the ondenser reducing sparking. The regulator is thus in a constant state of vibration and responds nstantaneously to changes in alternator P.D. The function of the compensating winding on the ontrol magnet (energised through a current transformer) is to eliminate circulating currents etween alternators in parallel by reducing the excitation of an over-excited generator and *vice ersa*.

Air Coolers.

The 'Heenan' Air Filter.

(*Heenan & Froude, Ltd.*)

The overload capacity of turbo-alternators and generators is dependent to a considerable xtent upon the supply of suitable volumes of cool air for carrying away the heat generated by lectrical loss. The usual method is to mount fans on the rotor shaft, arranged to extract air hrough a supply system in which a combined air filter and cooler is inserted.

The 'Heenan' Air Filter receives ordinary unfiltered air from the neighbourhood of the enerating station and brings it into very thorough and intimate contact with wet scrubbing urfaces. The arrangement of these surfaces has undergone a complete transformation ince the machine was last described in The Engineer's Year-Book. The rotary principle as been given up in favour of stationary air screens, the surfaces of which are kept horoughly wetted by water issuing from jets. After cleansing the scrubbing surfaces the water ravitates to a tank, from which it passes through strainers to a centrifugal circulating pump and hence to the distributing jets. The atomisation of water, forming part of certain air-filtering ystems, is entirely avoided. The air leaves the filter in an entirely natural condition, containing o trace of loose moisture.

The filtering efficiency of this apparatus is extremely high, both heavy and fine dust being liminated. The cooling effect in hot summer weather in temperate climates is often as high s 20° or 30° F. In tropical climates the latter figure is sometimes exceeded. The consequent eduction in air temperature is of great value in permitting the generation plant to run on heavy verloads without overheating.

The 'Heenan' Closed Circuit Air Cooler.

(*Heenan & Froude, Ltd.*)

This cooler, fig. 27, which is designed for the ventilation of turbo-alternators, comprises a tubular air cooler built generally on the lines of a surface condenser arranged in the alternator foundations and coupled up to the bottom discharge of the alternator by suitable ducting.

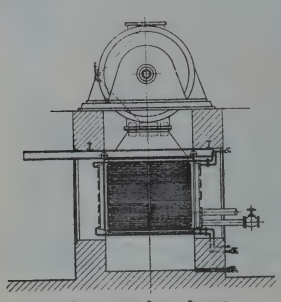
After passing through the cooler the air returns to the alternator *via* the end shields, the fans circulating the air being carried on the rotor.

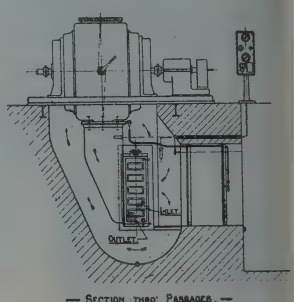
With this system the same air is continually recirculated through the windings of the alternator, so that the only dirt that can be deposited is that contained in the initial volume of air, thus the necessity for air filtration is obviated.

With an unfailing and clean supply of water the circuit can always remain a closed one, but under actual working conditions it has been found necessary to provide for cooling in the event of a failure of the water supply or other eventuality, and the arrangement, therefore, embodies a system of dampers and emergency air doors which cut out the air cooler and permit external air to enter the foundations, the hot air in this case being discharged direct to atmosphere from the top of the alternator.

Dampers are fitted to the top and bottom discharges of the alternator, which are inte connected and operated by one lever, and arranged so that if one set is closed the other set open. Connected to the same lever is the trip gear for the emergency air doors, which ar balanced and which open automatically, due to the difference in pressure, immediately the cate is released. As soon as the trouble has been diagnosed and rectified the emergency doors ar closed and the alternator dampers changed over for closed circuit running.

A thermostatic alarm device is fitted in conjunction with the system, which gives visib and audible warning to the attendant should the temperature of the air leaving the cooler reac a pre-determined figure. This alarm device consists of a dial type thermometer with a klaxo horn, red lamp and relay, arranged on a panel either for wall or floor fixing. The thermomete is connected to a bulb in the foundations, and as soon as the dial hand reaches a certain poin the relay brings into operation the klaxon horn and lights up the red lamp, so warning th attendant that the air temperature is rising.





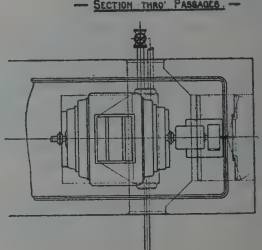


FIG. 27.—Arrangement of 'Heenan' Enclosed Circuit Air Cooler.

The arrows show the direction of the air.

In regard to the construction of the coolers, this follows condenser practice in as far as they consist of a nest of tubes held between tube plates, the joints being formed by screwed ferrule and packing. The water headers fitted with division plates and branches for inlet and outle water connections are also in line with condenser practice, but the tubes in these coolers ar gilled at close pitch, the gills being soldered to the tubes in one operation for each length of tube this construction giving the highest heat transference efficiency, which has, of course, been ascer tained chiefly by experimental work.

Another departure from an ordinary condenser is the addition of secondary tube plates i front of the main tube plates, so that a dead air chamber is formed at either end of the coole into which any leakage from the main tube plates would drain instead of being carried over wit the air into the windings. Rubber bushes are used in these secondary tube plates to form an air and water-tight joint with the tubes.

Air cocks are fitted to the top of the water headers and drain pipes to the dead air chambers

The tubes are of brass (Admiralty mixture), solid drawn and tested to an internal pressur of 2 tons per sq. in.

The tube plates are also brass, of ample thickness to allow for a suitable stuffing box an screwed gland. The water headers are of cast iron of ample thickness to withstand any pressur

ıey are likely to be subjected to, and are fitted with small inspection doors, so that the tubes ıd tube plates can be inspected from time to time without breaking the joints of the main ;ader.

The gills are of thin copper, and both gills and tubes are tinned in the process of soldering the lls to the tubes, so that the danger of corrosion is well catered for.

Fig. 27 shows the arrangement of a cooler in the foundation, from which it will be noted that ıe cooler itself is carried on rollers, which bear on the flanges of a steel joist, the latter being :tended and supported outside the foundations, so that the complete cooler unit can be removed r overhaul or cleaning when necessary, with a minimum amount of trouble.

Inspection doors are provided on either side of the foundations to permit the removal of the ›oler and also to give access to the foundations.

Portable Electric Blower.

(The Consolidated Pneumatic Tool Co., Ltd.)

This blower, fig. 28, is largely used for keeping the windings of motors and dynamos free from ıst. Weighing, complete, about 15 lbs., and suitable for use on either a direct or alternating

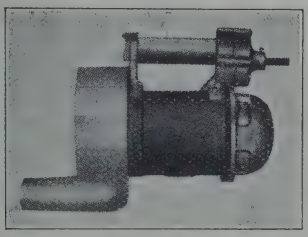

Fig. 28.

ırrent circuit, it will maintain a steady air blast through a 1¼-in. orifice, with a pressure of ›out 12 ins. of water. It is very convenient to handle, and can be attached to any ordinary mp socket.

Visco Air Filter.

(The Visco Engineering Co., Ltd.)

The Visco Air Filter (devised in 1916) is used in conjunction with turbo alternators, pipe ntilated motors, and general ventilating plants. It works on the principle that the air volume divided into a large number of thin streams which are passed through a layer of specially pre- ıred filter bodies, the surfaces placed irregularly to each other, so that the direction of the r flow is changed suddenly and a great number of times. The filter bodies are thin copper- ated steel rings $\frac{7}{16}$ in. diameter and $\frac{7}{16}$ in. long, coated with a thin film of viscinol, which is specially prepared blend of highly viscous mineral oils. When the direction of the air flow is ıanged, the dust particles continue in the original direction and are thrown against and retained ; the viscinol-coated surfaces.

The filter is standardised in units 20 by 20 ins. square and 3½ ins. deep, consisting of frame and ıll, which latter is simply hooked on the frame. The capacity per unit is 600 cu. ft. per minute. ressure loss is practically steady at $\frac{3}{8}$ in. water gauge. Average consumption of oil, 1 gallon per uit per annum. Cleaning is done by rinsing in hot soda water on the average every eight weeks epending on the original dust content and length of daily run. There are practically no other ınning costs.

The filter units are assembled in a convenient shape to make up any capacity, and are p ferably built into the alternator foundations (thus taking up no valuable space) or as self-contai units in any position.

The *advantages* claimed are: No moving or wearing parts, all metal, fireproof, no attenti foolproof, small space.

SYNCHRONOUS OR ROTARY CONVERTERS.

The G.E.C. Synchronous Converter.

(The General Electric Co., Ltd.)

The following is a specification of a Synchronous Converter of standard type:—

Frame.—The frame is constructed of cast iron or steel of high magnetic permeability. I split horizontally and bolted together by strong steel bolts. The construction permits the half to be readily removed for inspection or repair.

Main Pole-Pieces.—The main pole-pieces, which are bolted to the frame from the outsi are built up of laminations in order to reduce eddy-current losses in the pole faces to a minimu The design is such as to permit the removal of a field coil without disturbing the armature or yo In exceptional cases cast steel poles with laminated shoes may be employed.

Armature.—The armature is built up of best quality stampings of high permeability and l iron loss. They are mounted on a cast iron spider and held tightly in position by heavy en plates. The laminations are accurately punched before assembling and are covered with a spec insulating compound which is effective in reducing eddy-currents to a minimum. The core held together between the end-plates by means of bolts which, however, do not pass throu the active portion of the core and therefore introduce no local circuit for eddy-currents. Ven lating ducts, adequate in number and ample in dimensions, are provided at frequent interva Similar ducts are included at the two ends between the core and end-plates. The general c struction of the armature is such as to afford a current of air to the field coils for ventilation a cooling. The armature winding is composed of former wound coils, taped, varnished, and bak before assembly. The slots are lined with several layers of non-hygroscopic insulating mater Special care is taken to make the leakage surfaces as large as possible. The aperture at the of the slot is filled by strong wooden wedges driven in tightly. There are no binding bands the armature core itself, that part of the winding being retained in position by the wooden wedg The end windings are so shaped that the surface exposed for cooling is as large as possible. large number of equalising connections is provided. Prior to assembling in the frame the armat is balanced statically, and the final balancing is obtained dynamically.

Commutator.—The commutator is built up of hard-drawn copper segments, insulated by b mica insulation and held tightly between two V-shaped clamping rings in such a manner that inevitable expansion of the copper and iron on account of temperature rise may take pl without in any way affecting the commutator surface. During its construction the commuta is subjected to several baking processes, with the result that no binding varnish remains in mica insulation. When completed, the whole commutator gives a true ring, which indica that the entire mass has been formed into one rigid body. In addition, the construction is su that 'breathing' is reduced to a minimum and the possibility of moisture permeating the insu tion is eliminated. A considerable distance to the iron parts is allowed at the front and ba of the commutator in order to secure a high insulation resistance to earth, and to prevent a leakage to the iron. The radial depth of the segments is ample for the size of the commutat and varies somewhat with the size of the machines. Before leaving the works, the mica betw the segments is grooved to a suitable depth to promote good commutation. To assist in cooli the commutator lugs which connect the segments to the armature windings are given a consid able width, and thus provide a large cooling surface.

Field Coils.—Shunt field coils are wound upon spools composed of a material with h insulating properties, a former larger than the poles being employed in the winding proces ensure that no undue stresses are imposed upon the spool when in position. The wires insulated with a double cotton covering and after being wound are put into a heated impregnat chamber where they are dried for several hours under vacuum. Afterwards they are floo (while still under vacuum) with a heavy insulating compound. They are then subjected heavy pressure at the same temperature, the insulating compound being forced right thro the layers of the coils. Series coils are wound with bare copper strip and treated with an insulat compound. Ample leakage surfaces to the frame are provided.

Commutating Poles.—G.E.C. synchronous converters are fitted with commutating poles c design which permits sparkless collection of current at all loads with fixed brush position. coils are wound with bare copper strip and treated with an insulating compound. The m spools are moulded direct on the poles and ample leakage surfaces are provided.

Damping Winding.—A substantial damping winding is fitted to the field poles. This is instrumental in strongly opposing any tendency to hunt, whether from changes in load or from any low frequency oscillations originating in the generating plant. It consists of a pair of heavy copper rings bolted together by copper bolts between the poles and connected up by drawn copper rods passing through the pole faces and fixed at each end of the rings. In order that any pole winding may be removed, the rings are divided up between the poles and jointed in a manner which permits the joint to be readily unmade for the removal of the pole or winding, and at the same time in no way impairs the mechanical strength or the electrical conductivity of the rings. A damping winding of high conductivity and great rigidity is thus obtained which completely damps out all oscillations. The damping winding is also necessary for improving the starting characteristics of the converter when started from the alternating current side, from transformer tappings.

Booster.—When a booster is specified it takes the form of an alternating-current generator, with a stationary field. The booster armature is mounted on the main shaft side by side with the armature of the synchronous converter, and is constructed on the same principle as the latter. The current passes from the converter slip rings through the booster armature to the armature of the rotary. The booster field frame is split horizontally into two parts, and mounted on the bedplate by the side of the main frame. The booster field may be excited either by shunt or series windings, or both.

Six-phase and Four-phase Connections.—Synchronous converters intended to work on a three-phase supply are usually wound as six-phase machines, drawing a six-phase supply from three-phase transformers in order to take advantage of the greater output and more even heating of a six-phase armature as compared with a three-phase one. Similarly converters for operating on a two-phase supply are wound either four-phase or six-phase, the latter being made possible by the use of a double Scott-connected transformer.

D.C. Brush Gear.—The direct-current brush-holders are fixed to a strong cast-iron arm projecting radially from the brush rocker. The rocker is carried in a spigot in the yoke, or carried by a separate frame from the bedplate. The rocker is split across the horizontal diameter, so that the halves can be readily removed for inspection or repair. The rings connecting the brush sets of the same polarity are carried from the brush rocker on insulating supports; they are well insulated from the rocker and have ample clearances and cooling surfaces. Provision is made for separating the halves of the rings should it be desired to remove one-half of the brush gear for any reason. Each brush carbon is contained in a separate box-type holder to avoid rubbing, and a spiral clock spring exerts radial pressure on the brush. The pressure on the brush is adjustable by means of a steel lever, which engages in one of a large number of slots in a quadrant. The design of the brush holder is such that each brush mechanism is self-contained; the pressure of the brushes can therefore be adjusted when running, and one brush can be removed without in any way disturbing the others. The brush gear is of compact design, giving a maximum distance between adjacent brush sets, thereby assisting in the prevention of flashing-over.

A.-C. Brush Gear.—The alternating current brush holders are mounted on semi-circular arms which are carried on, and insulated from, two strong brackets projecting from the pedestal bearing on the slip-ring end of the converter. Each brush is contained in a separate box-type holder and a helical spring exerts radial pressure on the brush. This pressure is maintained by means of a lever terminating in a special pawl which wedges against corrugations on the inside of a brass tube. The pressure is adjusted by slightly canting the lever, moving it up or down the brass tube and releasing it, when the pawl will automatically engage in other corrugations. The terminals for the incoming cables are provided and are fixed direct on to the arms.

Slip-rings.—The slip-rings are of Admiralty gun-metal, and are so designed as to ensure efficient cooling. Each ring is so cast that the portion between the contact face and the internal diameter takes the form of a fan. A cast-iron sleeve which is securely keyed to the shaft forms the base for the slip-ring structure. This sleeve is insulated throughout its length with micanite wound to size, the slip-rings being shrunk on to it. The connections from the armature to the slip-rings consist of copper rods strongly bolted into the slip-rings at one end and supported at the other by a steel ring shrunk on to the sleeve, similarly to the slip-rings. These connecting bars are covered with insulating material and are efficiently protected from breakdown to the other slip-rings through which they have to pass. Ample clearances are provided for cleaning. Wherever possible, each tapping of the armature winding is brought to the rings separately in order to avoid unbalanced current. Thus the slip-rings themselves act as balancing rings.

Shaft.—The shaft is of such strength that it will carry the armature without undue flexure or vibration. It is supported by two main bearings lined with white metal and split in halves.

Bearings.—The bearings are of the self-oiling type, and have rings which dip into oil chambers of large dimensions. The bushes are of cast-iron lined with best quality white metal and are split horizontally. The length of the bearing is 2·5 times the diameter of the shaft in the bearing. A glass level gauge with draw-off tap is fitted to each bearing. The general design of the bearing is such as to preclude any oil flinging.

Bedplate.—A strong bedplate of box section is provided, having heavy ribs connecting sides at various points. Its general construction is substantial and ensures complete freed from vibration. The bedplate is fixed to the foundations by strong bolts and plates suppl with the machine.

Speed-Limiting Device.—All large G.E.C. Synchronous Converters (and small ones if desir are equipped with a speed-limiting device which will shut down the machine if by any chance normal speed should be exceeded by a predetermined amount. A weight, which tends to m under the action of centrifugal force, is mounted on a shaft and revolves with it. Under action of centrifugal force it tends to run outwards, against the compressive resistance of a spri At a predetermined speed the arm, to which the weight is attached, flies out and closes contact in a tripping circuit, thereby opening the direct-current circuit breaker. This devic usually fixed at the direct-current end of the shaft.

Oscillating Gear.—When specially ordered, an oscillating device can be supplied for mov the armature to and fro longitudinally while it is running. As the armature rotates, it is alt nately pushed out of the magnetic centre and then released, thus causing a smooth oscillatio

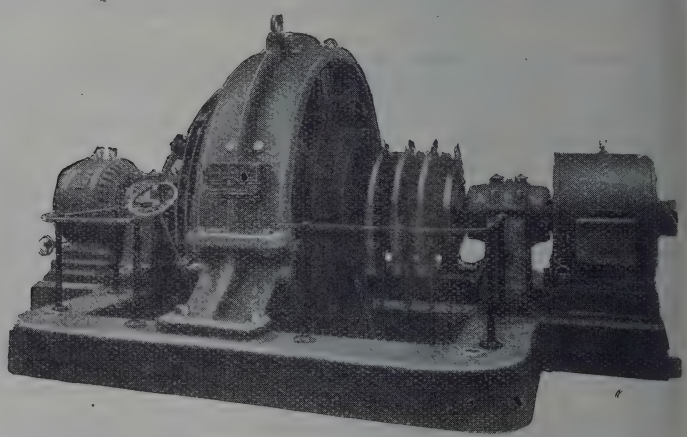

FIG. 29.—1,000 k.w. G.E.C. Synchronous Converter; 550–570 volts, 50 cycles, 750 r.p.m.

Temperature Rise.—The synchronous converter is capable of developing its full rated l continuously with a rise in temperature of 40° C. (72° F.).

Overload Capacity.—The synchronous converter will give an overload of 25 per cent. for t hours, and 50 per cent. for 15 minutes. It will also withstand overloads of 100 per ce momentarily.

Starting Motor.—If the synchronous converter be supplied with a starting motor, the latte mounted on an extension of the bedplate. The motor is of large capacity and is adequate in siz run the converter up to speed in a short time. The motor is either of the solid rotor or slip-r type, as circumstances demand. The starting torque is sufficient to permit rapid acceleration the first moments of starting, even though the supply voltage is below normal, as may be case after a shut-down at the main power station.

Tests.—All material is subjected to tests at various stages of its manufacture to ensure t no faults exist in the completed machine. Tests for static and dynamic balance are also carr out before the machine leaves the works. Excellence in this respect is assured. Standard fi tests on rotaries for 650 volts direct current or under include a 2,000 volt flash test with altern ing current for five minutes, and six hours run on full load to ascertain the efficiency and te perature rise.

A 1,000 k.w. G.E.C. Converter is shown in fig. 29. This machine is for 50 cycles, and 550– volts, D.C., at 750 r.p.m.

Starting, Self-Synchronising, and Controlling Rotary Converters.

G.E.C. Methods of Starting, Self-Synchronising and Controlling Synchronous Converters.

It is usually required that synchronous converters shall be of the self-synchronising type, as the ning of sub-stations is thereby facilitated. The practice can be considered standard. In the E.C. patented method of starting and self-synchronising, the starting current is not allowed to ss into the armature until the field is excited. Consequently, when the armature is switched through the choking coils, the current is not strong enough to reverse the field, so that the larity of the converter is always correct.

Fig. 30 shows the scheme of connections. The essential features are the synchronising switch d the choking coils. The rotary converter is provided with a starting motor, which is started closing the triple-pole circuit-breaker shown at the right of the figure. This brings the set to approximately synchronous speed. Meanwhile the switch shown in the figure is closed in starting position, where the blades make contact on the long synchronising contacts. Under ese conditions the slip-rings of the rotary are connected to the source of alternating-current pply through the choking coils, which limit the current taken by the machine. This current, wever, is sufficient to pull the set into synchronism. When this has happened, the synchronis- switch is pushed right home, so that the blades go into the full-on contacts. Mechanism is ovided which prevents the synchronising switch being pushed at once into its fully-closed sition. The device is so arranged that on slightly pulling the switch towards the ' off ' position pin releases a slotted bar, which falls under its own weight, allowing the pin to pass along the t and permitting the synchronising switch to be pushed right home. When this happens, an

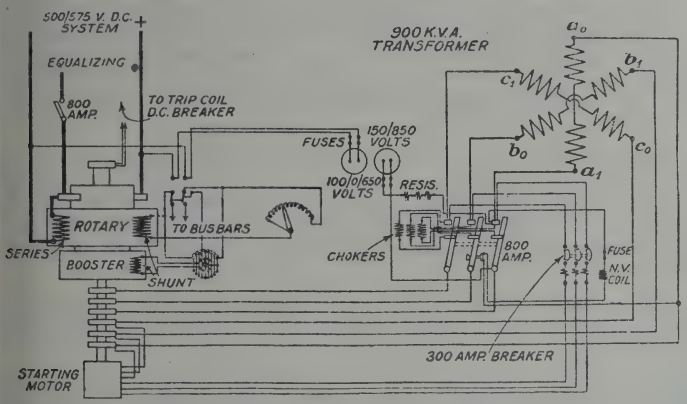

FIG. 30.—Diagram of Connections for Self-Synchronising Synchronous Converter.

erlocking contact is operated, which opens the no-volt coil of the starting-motor circuit-breaker pping the latter, so that the converter set is left in synchronism with the starting motor connected.

The standard starting motor used is provided with a solid rotor. The stator windings are justed once for all when the set is first put into use so as to give the best value of slip to the rting motor and so as to necessitate the minimum value of synchronising current.

MOTOR CONVERTERS.

The Motor Converter represents a compromise between the motor generator and the synchr nous converter, combining the best features of each type of converting plant. It consists of a se starting a.c. motor, the rotor of which is coupled both electrically and mechanically to the arm ture of a d.c. generator, about half the power supplied to the motor being transmitted to t generator by way of the shaft, and half by the electrical connections. The motor fulfils the du functions of a transformer and a motor, while the generator similarly acts both as a rotary co verter and a dynamo. The rotating parts—the rotor of the motor and the armature of t generator—run at half the speed corresponding to the frequency of supply. The motor convert is used to supply direct current when fed with alternating current, and *vice versa*, the ratio the a.c. and d.c. voltages being determined by the design.

Comparing the three methods of conversions, the motor-generator is more expensive, tak up more floor-space, and is much less efficient than its rivals, whilst it possesses no advantag comparable with these drawbacks, except under special circumstances, such as supplyi wide d.c. voltage regulation or an a.c. load at low power factor. The chief advantage of t rotary converter is that, including transformer losses, it is slightly more efficient than the mot converter at full load—about 1½ per cent. for 1,000 kilowatts. On the other hand, the mot converter has a high efficiency at half and quarter load, is not easily thrown out of step wi the generating plant by a heavy drop in voltage, and is practically immune from liability flash over on a short circuit occurring, while it can carry heavy overloads without sparkin The motor converter is very easily started up from the a.c. side and synchronised with the supp frequency, without risk of reversal of the d.c. polarity—a drawback to which the rotary convert is very subject ; it can equally well be started from the d.c. side, and it works with unity or les ing power factor, which varies very little when the d.c. voltage is varied over a wide range. T rotor of the motor converter is usually wound for 12 phases, conferring upon it very high sy chronising power and stability of running. The generator can be shunt or compound woun according to requirements, being capable of a variation of d.c. voltage of 40 per cent. ; th it can be used alternatively for supplying a light and power system at, say, 400 volts, or a tracti system at 550 volts, and like a rotary converter, it can be arranged for use in connection wi a three-wire system, automatically balancing the load. As the motor and generator togeth have the same total number of poles as the equivalent rotary converter, a 50-cycle motor co verter operates under as favourable conditions as a 25-cycle rotary converter, with correspondi advantages in respect of the wider spacing of poles (entailing less magnetic leakage) and brushes (with consequent freedom from flash-over). As the slip-rings of the motor-conver are only used for starting up, or for balancing a three-wire system, their maintenance is l onerous than that of the six slip-rings and brushes which carry the whole of the a.c. load ir rotary converter.

Owing to the stator of the motor being wound for the full supply pressure (up to 10,000 vol no transformers are necessary, and thus the floor-space occupied is a minimum ; the switch-g also is simple and compact. The air-gap on the a.c. side may be larger than in a correspondi induction motor, the advantage of this naturally being more apparent in the larger sizes. Wh exceptionally wide variations of d.c. voltage are required, the motor converter can be provid with a 'booster,' as in the case of a rotary converter, but as the booster carries only half t load, it is much smaller. The starting current is from 25 to 35 per cent. of the normal full-lo current.

Whilst the machine is usually required for converting from three-phase or two-phase curre it is also suitable for use on a single-phase supply, and in this case it offers special advantag its synchronising power being practically as good as on a polyphase supply, and its efficie being but little lower.

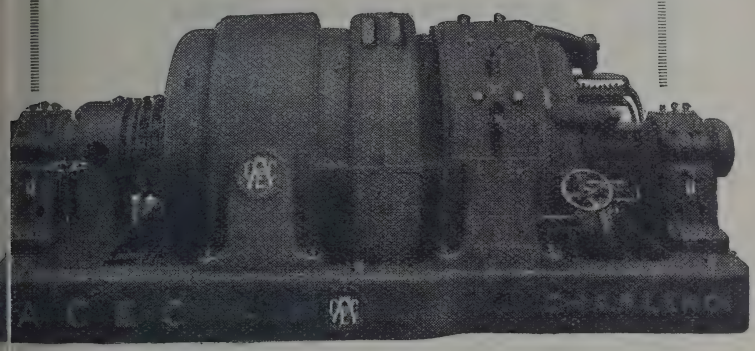
Motor converters run perfectly in parallel at either or both ends, and are not subject to hunti Whilst their good d.c. regulation is highly appreciated on lighting systems, their ability to co with heavy overloads and violent load fluctuations renders them particularly well suited supplying d.c. tramway and railway systems.

Power-factor correction can be obtained at a certain predetermined load and voltage ra The set can also be run with the d.c. side open, and the a.c excitation increased until the side supplies leading wattless current to the main.

Action of Motor Converter.

The motor converter consists of an induction motor directly coupled mechanically and e trically to a direct-current generator, and is a synchronous machine. Fig. 31 is a diagram connections of a three-phase motor converter.

A·C·E·C



1000 k.w. A.C.E.C. La Cour Motor Converter.

A.C.E.C. LA COUR MOTOR CONVERTERS.

Among many other advantages, A.C.E.C. La Cour Motor Converters are provided with patent automatic starting and self-synchronising gear which enables them to be started and synchronised with perfect safety by an unskilled operator.

There is no High-tension current on any revolving part, and the machines automatically balance the two sides of a three-wire system within fine limits.

The obsolete three-bearing design has of course been abandoned, and all A.C.E.C. La Cour Motor Converters are of the latest two-bearing type.

We shall be glad to send an instructive booklet descriptive of these machines to anyone who is interested.

A·C·E·C

FOR CONVERTING FROM A.C. TO D.C. OR D.C. TO A.C.

Three types of machines are available:—

(1) La Cour Motor Converters.

(2) Rotary Converters with Transformers.

(3) Motor Generators.

The most suitable type of machine to adopt is determined by the conditions which obtain in each case.

As manufacturers of all three types we shall be glad to place our extensive experience at your disposal.

We not only manufacture the particular types of plant mentioned above, but also everything which is required for the complete electrical equipment of all kinds of works and factories, central and sub-stations, tramways and railways.

We also specialise in the manufacture of all types of paper and rubber insulated cables, centrifugal pumps, turbo alternators, electric winders, rolling-mill motors, electric cranes, transformers, etc. We shall be glad to supply full particulars of any or all of our products on request.

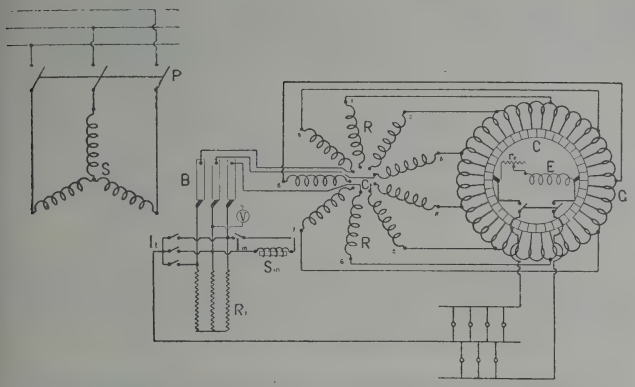

FIG. 31.—Diagram of Connections of Motor Converter.

The following gives the explanation of the letters used in the diagram:—

P Main three-pole high-tension switch.
S Stator winding of the a.c. machine, which is supplied with current direct from the three-phase system.
R Rotor winding, which is connected at symmetrically arranged points with the armature winding of the direct-current machine.
Rt Fixed three-phase starting resistance, which is connected with the rotor through the slip rings *B*.
B Rotor slip rings.
G Direct-current machine.
C Commutator of the direct-current machine.
E Field winding of the direct-current machine.
re Field rheostat of the direct-current machine.
Sm Self-synchronising coil.
Im Switch for self-synchronising coil.
V Synchronising voltmeter.
It Three-pole short-circuiting switch.
Ct Slip-ring short-circuiting device.

Assuming, for the sake of simplicity, that both machines have the same number of poles, the mber of revolutions of the set will be half of the number which corresponds to the synchronous eed of the motor. The primary current produces a rotating field, the speed of which, in relation the rotor, is equal to half the synchronous speed. This field induces, in the rotor windings, series of E.M.F.'s, the frequency of which is half the frequency of the primary current. These M.F.'s induce polyphase currents, which circulate through the direct-current armature windings, d produce in turn a rotating field, the speed of which, in relation to the shaft, is equal to half e speed of the primary field. The phases of the armature of the direct-current machine being nnected in such a way that the field tends to revolve in a direction opposite to that of the shaft, is field remains stationary and the machine runs as a synchronous set.

The alternating current side operates partly as a motor and partly as a transformer, while e direct-current side operates partly as a generator and partly as a rotary converter.

Both parts of the machine are smaller than corresponding induction-motors or d.c. generators d the slower speed is beneficial to commutation.

In cases where the alternating and direct current sides have different numbers of poles, e motor converter runs at a speed which is inversely proportional to the sum of the number poles.

With a view to obtaining the highest possible efficiency, in accordance with the theory the rotary converter, the number of phases in the a.c. rotor is increased, twelve phases bei commonly adopted. No difficulty is caused by this arrangement, since the connections betwe the rotor and armature are made direct, and without the use of slip rings. In most cases, on three phases are used for starting, and only three slip rings are therefore required.

The A.C.E.C. Motor Converters.

The A.C.E.C. la Cour motor converters, fig. 32, follow the general design described. Starti and self-synchronising are obtained by a patented device. The A.C.E.C. is the sole licens for Belgium of the la Cour and Arnold patents relating to motor converters, and, now that t British master-patent has expired, is supplying these machines for use in Great Britain and t colonies.

Starting of Motor Converters.

The A.C.E.C. supplies its own patented devices by the use of which the starting a synchronising of a motor converter are effected simply by closing the main switch; the machi runs up to speed and automatically comes into synchronism with the high-tension supp In the operation of the A.C.E.C. patent devices the following general points relating to t starting of motor converters should be taken into consideration.

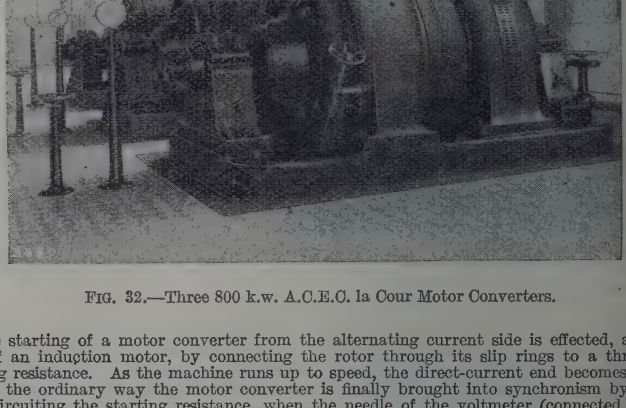

Fig. 32.—Three 800 k.w. A.C.E.C. la Cour Motor Converters.

The starting of a motor converter from the alternating current side is effected, as in t case of an induction motor, by connecting the rotor through its slip rings to a three-pha starting resistance. As the machine runs up to speed, the direct-current end becomes excit and in the ordinary way the motor converter is finally brought into synchronism by quick short-circuiting the starting resistance, when the needle of the voltmeter (connected betwe two of the rotor slip rings) is seen to pass or approach the zero point. It will be readily und stood that the short-circuiting process just described is one of some nicety, requiring the attenti of a skilled and experienced operator, and it is to obviate this difficulty and uncertainty that t A.C.E.C. patented devices have been developed.

These devices are based on the well-known fact that machines of the multiphase stator a single-phase rotor type have a second synchronous speed at half that of the primary field. F starting and synchronising a motor converter in which the alternating and direct-curre ends have the same number of poles, an additional resistance, or, better, a single-phase reactan coil, is connected between two of the slip rings. When the number of poles is different in t two machines, either a single-phase or a three-phase reactance coil is used. The effect of th reactances is to produce a resultant retarding torque when the E.M.F. in the rotor is in advan of the E.M.F. in the armature, and an accelerating torque in the contrary case, so that or the motor converter has attained synchronous speed, it remains in step at that speed.

With the A.C.E.C. patent devices, which embody these principles, the starting and synchron ing operations are as follows:—The rotor circuit being closed on three phases by means of t starting resistance, and on a single phase by a suitable reactance coil, the field rheostat also be

approximately in its normal position, the main switch is closed. The machine at once starts d automatically runs up to synchronous speed, when the needle of the synchronising volt- ter comes back to zero. The rotor slip rings are then short-circuited by means of a three-pole itch, and the short-circuiting device for all the phases of the rotor closed. It will be seen at the whole operation is simplicity itself, and one which can be performed without difficulty risk by an unskilled person.

The fixed starting resistance and the self-synchronising coil, since they are never touched, n be placed in any convenient position, the usual practice being to fix them in the pit below e machine so that no floor space is required for their accommodation. The synchronising ltmeter is generally mounted on the main switchboard.

General Design and Construction.

The practice of building motor converters with three bearings has been abandoned favour of the two-bearing design, except in the case of very large machines. The advantages the two-bearing type are economy in floor space, a simple, strong, and easily accessible arrange- ent of the electrical connections between the rotor and the armature, and the ease with which e set can be erected and dismantled on account of the fact that the rotor and armature are ch mounted on separate shafts provided with massive couplings bolted together at the centre.

The modern design with two bearings entirely avoids the inherent source of weakness and nsequent liability to break down, which is involved by the use of a hollow shaft for the connec- ons between the rotor and armature of three-bearing machines.

Mercury Vapour Rectifiers.

The necessity of converting alternating to direct current in many cases, and the desirability dispensing with running machinery in sub-stations, etc., has led to the development of the ctifying properties of the mercury vapour lamp for this purpose. Essentially the rectifier nsists of an arc *in vacuo* between iron anodes and a mercury cathode, which allows the current pass in one direction only, namely, from the anodes to the cathode, as the names imply. In der to enable the rectifier to deal with large amounts of power, the original glass bulb has en replaced by an iron container, the difficulty of making stanch joints having been overcome. Whereas in rectifying single-phase current the resulting unidirectional current pulsates between ro and a maximum value, in the case of three-phase current the pulsations are reduced in nplitude by using three anodes connected to the three phases; or better still, by connecting the ansformer to give six-phase current and using six anodes, the fluctuation can be still further ppressed. Rectifiers of this type can now be made for outputs of 1,000 amperes per cylinder, id being characterised by small depreciation and maintenance, and high efficiency, besides quiring very little attention, are rapidly coming into use. They work well in parallel with ie another and with a battery; the average overall efficiency is about 90 per cent., the power ctor on full load about 94 per cent. The rectifier is practically independent of frequency and ave-form. As there is a constant drop of 15 to 20 volts through the rectifier, the higher the oltage the higher the efficiency—hence their suitability for high-voltage d.c. traction.

The rectifier consists of an iron cylinder, exhausted to at least 0·1 mm. of mercury, with ie mercury cathode at the bottom and six iron anodes suspended from the cover, suitably sulated. Auxiliary anodes, one for starting the rectifier and two for excitation (to keep the ctifier in operation if the load temporarily falls to zero), are provided. The rectifier chamber water-cooled, as the temperature in the interior must not exceed 70° C., and a cooled chamber n the top of the main cylinder condenses the vaporised mercury, which returns to the cathode y gravitation. A vacuum pump is necessary to maintain the high vacuum, but after the esidual gases are all removed the pump need not be used regularly. Choking coils or induction gulators ensure stability of operation and provide means of regulating the d.c. voltage. The ansformer used in conjunction with the rectifier is specially wound, and is practically equivalent o an ordinary transformer of a k.v.a. rating about 40 or 50 per cent. larger than the d.c. output. . 750-kw. rectifier occupies about the same space as a rotary converter of 100 kw., and weighs ,100 kilograms.

The 'Tungar' rectifier, which is suitable for charging small storage batteries, is more closely llied to the 'valves' used in wireless telegraphy, the cathode being an incandescent filament.

MOTORS.

DIRECT-CURRENT MOTORS.

Shunt-wound Motors.

The shunt is the most common type of field winding, and is generally applied to motors lesigned for operating at constant speed under constant or varying loads. Nearly all com- nercial applications, particularly those of large capacity, require this type of motor. When ecessary, considerable speed variation can usually be secured by means of a rheostat in the ield circuit, increased resistance resulting in an increased speed.

On many shunt-wound commutating-pole motors a stability winding is used on the field fo the purpose of insuring stability under all conditions of operation. This is, in effect, a ligh series winding, which, however, does not change the speed-torque characteristics from those o an ordinary shunt-wound motor.

Series-wound Motors.

These are variable-speed machines particularly adapted to such uses as railway and cran service. The characteristic features of a series-wound motor are its great torque at startin and low running speeds possible.

Compound-wound Motors.

For some special classes of service, in which it is necessary to start under heavy loa and later operate at approximately constant speed, a series winding is added to assist th shunt field at the low-speed points. A compound-wound motor combines the characteristi of both shunt and series-wound motors. In most cases, however, the series winding has com paratively little effect except during the starting period, and may be short-circuited, if desire at higher speeds.

Starting Motors.

Except very small machines, all direct-current shunt and compound-wound motors ar started by first giving the shunt field full excitation and then connecting the armature, with starting resistance in series, to the circuit. The resistance is then cut out in steps as the moto accelerates, the time required to attain full speed varying from about 15 seconds for small, t one minute for large motors. These limits should be used with discretion, since more time required to start with heavy load than with light load.

After all connections are made according to instructions and all mechanical preparation are complete, see that all the field adjusting resistance (if used) is cut out and that the startin resistance is all in circuit. Close the circuit-breaker (if used), then the line switch, and lastl cut out the starting resistance step by step, allowing enough time for smooth speed acceleration Too rapid starting results in excessive starting current and possibly flashing at the brushes. Th motor should generally start when the armature circuit is first closed through the startin resistance, and failure to start when the second or third step of resistance is cut out is a signa to open the line switch or circuit-breaker at once and find the cause of the failure.

Stopping Motors.

Never move a starter or controller handle to the off position under any circumstances by doing so the shunt-field circuit of the motor is opened. The high inductance of th motor field may generate voltage enough to puncture the insulation. If it is necessary to open shunt-field circuit it should be done very slowly, allowing the field current to die out, throug the resistance of the arc across the switch terminals. If a field circuit must be opened in th manner often, a field switch should be installed, so that a local circuit is closed through the fiel before the latter is disconnected from the line. Starting rheostats are usually so arranged tha the field circuit is always closed through the motor armature. If the starter or controller is pro vided with a low-voltage release, the line switch or circuit-breaker should always be opened firs for stopping; the motor speed will then decrease until the starting resistance is automaticall cut into circuit.

Brushholder Adjustments.

The correct position for the brushes in either direction is clearly marked before th machine is shipped, and before starting up the position should be checked. Sparkin at the brushes when the machine is operating with load can frequently be entirely remove by shifting the brushes slowly from or towards the neutral point. In any case the correc distance of the brushes from the neutral point is very slight, and the movement should be mad with great care, for shifting the brushes too much will cause violent sparking.

Care of Commutator and Brushes.

Carbon brushes are used on all direct-current machines nowadays. The chief considera tions in caring for such machines are to keep the commutators clean, the brushes properl adjusted, and the contact surface of the brushes good. The last condition, once fulfille will usually take care of itself until the brushes are worn out, provided the other condition are complied with. At intervals depending on the service and the location, the commutato contact surface and end should be thoroughly wiped with clean cloth that is free from lin

few drops of oil on the cloth or a piece of paraffin rubbed lightly across the commutator surface will give all the lubrication necessary. Lubricant should be used very sparingly on a commutator, and no grease, oil, or dirt should be allowed to accumulate on the commutator or the brushes.

The ideal appearance of a commutator surface is polished dark brown or chocolate colour. Such a commutator needs no attention other than cleaning when necessary. If the surface has a raw copper colour with gradual roughening, it should be smoothed with sandpaper or, if very rough, with a piece of sandstone; emery paper or cloth should not be used for this purpose. The sandpaper should be held against the commutator by means of a block having the same curvature as the commutator. The sandstone likewise should be curved to fit the commutator. The brushes should be lifted from the commutator surface when using sandpaper or stone, and should not be placed in contact again until the commutator surface is thoroughly cleaned of all gritty particles.

Bedding the Brushes.

When making proper contact with the commutator, the face of the brush is glazed. The glazed portion does not extend over very nearly all the brush face the brushes should be ground in by wrapping a long strip of fine sandpaper closely around the commutator with the rough side toward the brushes and then rotating the commutator and the sandpaper slowly through perhaps one revolution. Shorter pieces of sandpaper held close to the commutator surface and drawn a few times back and forth under each brush or set of brushes will answer the same purpose. The commutator surface should be wiped clean after the brushes have been ground in, and lubricated with a few drops of fresh oil on a clean cloth.

Field Coils.

An open-circuited shunt field coil can be detected by touching the terminals of a voltmeter to the terminals of the individual coils while full voltage is applied to the field circuit. The voltmeter will show no deflection until the defective coil is reached and will then indicate the full voltage.

A short-circuited shunt field can be found by the same test, the voltmeter deflection being least in the defective coil. The short-circuiting of one field coil may result in burning out one or more of the others if full voltage is applied to the circuit.

In replacing a field coil make sure that the polarity of the pole differs from that of either adjacent pole. The polarity can be tested with a small bar magnet or a piece of steel wire suspended from its centre by a string. In holding the magnet near the poles successively it should reverse at each pole, i.e. no two successive poles should attract the same end of the magnet.

Cautions.

Never allow the load to be entirely removed from a series-wound direct-current motor while operating, or to be reduced enough to cause a dangerously high speed. A series motor should not be belted, on account of the possibility of the belt running off, thus permitting the motor to race.

Never open the shunt-field circuit of a motor in operation, otherwise the motor may race and produce serious damage.

When the shunt-field circuit of a motor or a generator is excited, never open it quickly unless a path for the inductive discharge is provided. The circuit can be opened slowly, if desired, the arc at the opening serving to reduce the field current gradually. *Do not permit any part of the body to bridge this opening*, or a serious shock will be received.

Always follow a fixed regular order in closing and opening switches, unless there are special reasons for departing from this order. A routine method will aid in avoiding mistakes. Keep all switches open when the motors are idle. Close switches carefully, keeping firm hold of the handle until completely closed.

A routine method of making inspections, replenishing lubricants, etc., will also prevent oversights and possible damage.

Specification for Direct-current Motors.

(The English Electric Co. Ltd.)

These machines are of the two end-shield type, and are supplied with standard shaft extensio but without pulley, coupling, sliding base, or foundation bolts, unless otherwise ordered.

Commutation poles are fitted as standard on all sizes from C.B. 7 upwards.

C.B. machines are usually supplied in the Protected or in the Enclosed-ventilated type but they are also made as Pipe-ventilated, Drip-proof, or Totally-enclosed machines.

The *Protected type* motor is so designed that the internal rotating parts and live parts ar protected mechanically from accidental or careless contact, a perforated metal cover bein fitted to the cylindrical opening over the armature fan.

The *Enclosed ventilated* type is similar to the Protected type, but a perforated metal cove is fitted over both cylindrical openings in the frame.

The frame is circular, of cast steel. The four main poles are bolted to the frame and ar laminated except in the smallest sizes, C.B. 5 and C.B. 6, which have solid poles. Commutatio poles, when fitted, are of solid wrought iron.

End shields are in the form of end plates bolted to facings on the magnet frame, and form substantial supports for the bearings.

Ball or roller bearings, or in certain cases a combination of both, are used, and are of ampl proportions. On the larger machines a ball-thrust bearing is fitted.

The bearings are enclosed in dust-proof housings.

This type of bearing has stood the test of lengthy experience in practical use. It requir practically no attention. As the bearings will work equally well in any position, provide the shaft is horizontal, the motor may be fixed to wall or ceiling without altering the position o bearings or end shields, as is necessary with ring-lubricated oil bearings.

The field coils of all sizes are former wound, thoroughly impregnated and taped al over. All coils are heavily insulated from the poles and the frame, to safeguard agains earthing.

The armature is slotted and drum wound, and is specially designed to give thorough ventil tion of the windings, core, and field coils. The core plates are keyed directly to the shaft, an are held in position by two end flanges. The windings are carefully impregnated.

The commutator is built up of segments of hard-drawn copper which are held in positio by end flanges fitting into deep V grooves in the segments.

The brush rocker which carries the brush spindles is mounted on a turned seating on th end-shield. The brush holders are substantial castings, and the brushes are easily replaceabl

A terminal box is arranged on the magnet frame, and is provided with a cast-iron cover. flange is provided on the terminal box to receive screwed conduit.

The standard direction of rotation is counter-clockwise when viewed from the commutato end; if the opposite direction of rotation is required, this must be stated on the order.

The following accessories are supplied as extras, if required :—

Pulley for rope or belt (standard or otherwise) or half-coupling or flexible coupling.

Sliding base with adjusting screws and four bolts for fixing the machine to the base.

Foundation bolts.

Speed Regulation of Direct-current Shunt-wound Motors.

There are three commercial methods of varying the speed of direct-current shunt-woun motors: (1) by altering the terminal voltage; (2) by a resistance in series with the machine (3) by a resistance in series with the shunt circuit. The first method is not employed as a ru with the ordinary industrial motor, but is only used in connection with self-contained plants suc as winding, and certain printing press control equipments. The second method is sometim adopted where a small speed reduction is required. With it, fine regulation is difficult to obtai while the power consumption of the motor remains practically the same throughout the whol range of speed, an amount of the power proportional to the speed reduction being dissipated i the resistance. The method is convenient where it is desired to regulate the speed down t about half for very short periods, such as for crane and haulage work. The third method control is one which has received a good deal of attention during the last few years, and moto have been developed which are capable of speed regulation by field resistance up to 4 : 1, and i certain cases up to 6 : 1, the torque being maintained constant over the whole range.

Such large variations of speed generally require some special device to compensate for t cross magnetisation of the armature due to armature reaction, and for this purpose inte poles or auxiliary poles are employed. The poles are placed mid-way between the main fie poles and carry either the full armature current or a percentage of it. The interpole flux therefo varies directly as the load and as the armature reaction, and as the tendency of the motor spark increases as the load, so the compensating flux increases proportionately.

The size of motors with shunt regulation is determined by the minimum speed and t maximum b.h.p., although it may be necessary for the motor to give a much lower output the minimum speed. This is clear when it is considered that minimum speed requires maximu

and maximum speed requires minimum flux, that the magnetic circuit must be large enough arry the full flux, and that the dimensions of the armature are also determined by the number size of the armature conductors. The only variable, therefore, is the field flux. The efficiency s not largely vary throughout the range of speed at a given load, owing to the fact that at the imum speed the electrical losses are a maximum, whereas the friction and windage losses are

APPROXIMATE COMMERCIAL EFFICIENCY OF DIRECT-CURRENT MOTORS PLOTTED AS A FUNCTION OF THE BRAKE H.P.

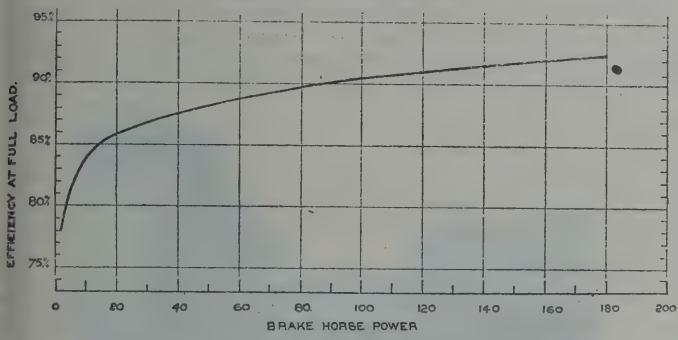

FIG. 33.

nimum ; but at the maximum speed the electrical losses are a minimum and the friction and wage losses a maximum. The curve shown in fig. 33, giving the full-load commercial efficiency as function of the brake horse-power, is typical of constant speed motors running at the normal ds recommended by the British Engineering Standards Association. Motors with series tance regulation have their sizes determined by the maximum speed and maximum out, and although the torque can remain constant throughout yet the output or power will educed in proportion to the speed.

Direct-Current Traction Motors.

DIRECT-CURRENT, SERIES-WOUND TRACTION MOTORS.

*British Standard Specification for Traction Motors (Direct-Current, Series-wound.) No. 173—1923.**

Types of enclosure are : (1) Open traction motor with no unnecessary restriction to ventilation ; protected type in which only rotating and live parts are shielded from accidental contact ; totally enclosed, there being no air circulation between inside and outside of case ; (4) ven- ed, having free circulation between the sides of the case ; (5) grid ventilated, which has orated covers over frame openings and no special provision for air circulation ; (6) self- ilated, having air-fan ; and (7) forced ventilated (draught) type, in which air is forced ugh by external means.

Classes of Rating.—(1) Nominal one-hour rating to be the h.p. output at vehicle axle, at the rated age and constant current, which the motor can produce for one hour, the limit of temperature measured by thermometer being 70° C. on any accessible part of winding and 90° C. on commu- r. (2) Continuous rating is defined as the input in amperes at which motor can be worked at and full rated voltage respectively, the temperature rise measured by thermometer not to ed 85° C. on commutator, and on insulated windings and their imbedding cores 65° C. and . for Class A and Class B insulation respectively. Class A includes enamelled wire and cotton, paper, etc., when impregnated or oil immersed. Class B, asbestos and built-up and cemented insulation.

he motor must run sparklessly in both directions with fixed brush position from no oad to one hour rated load, and without injurious sparking at 30 per cent. excess current input ied for two minutes. The statement of efficiency to be made on result of direct measurement

* By permission of the British Engineering Standards Association.

at 75° C. and not on the basis of addition of losses. The new machine must withstand, at t conclusion of the one-hour test, an alternating voltage, at 25 to 100 frequency, of 1,000 plus tw the line voltage (minimum 2,000 volts R.M.S.), applied for one minute, between the windings a frame. The insulation resistance in megohms, when the high voltage test is applied, to be r less than line volts (1,000 + Rated B.H.P.). The specification lays down methods of carryi out performance and voltage tests, and the information as regards type, voltage, speeds, weig and characteristics, to be supplied by the maker.

The Metropolitan-Vickers Electrical Co. Direct-current Traction Motor.

(The Metropolitan-Vickers Electrical Co., Ltd.)

Fig. 34 is a view of a standard direct-current series-wound motor made by the Metropolit Vickers Electrical Co., Ltd., for tramway service.* This motor is of 45 b.h.p.; the field fram

of cast-steel divided into an upper and lower half, the two parts being hinged together on the opposite to the axle. The figure shows the lower half hanging open, exposing the arma the bearings of which are bolted to the upper half of the frame. The pole pieces are buil of annealed soft-steel punchings riveted together between wrought-iron end-plates. The

* For 'Electric Traction' see Section XIV., p. 757.

s shown in the figure are held in place by a brass support resting on the projecting pole tip. armature is of the slotted drum type, the core being built up of annealed soft-steel punch- . Ventilation is provided by six axial and one radial air-duct. The armature coils are pletely formed before being put in place and are held by steel wire bands sunk in the ace of the armature, so that in the event of the armature bearings being worn the bands do touch the pole pieces. The winding is of the two-circuit type designed to give a balance rmature circuits should the armature get out of centre owing to wear of bearings. The mutator consists of 117 hard-drawn segments pressed on and keyed to the armature spider. bearings are of cast iron with special Babbitt metal linings; either oil or grease may be

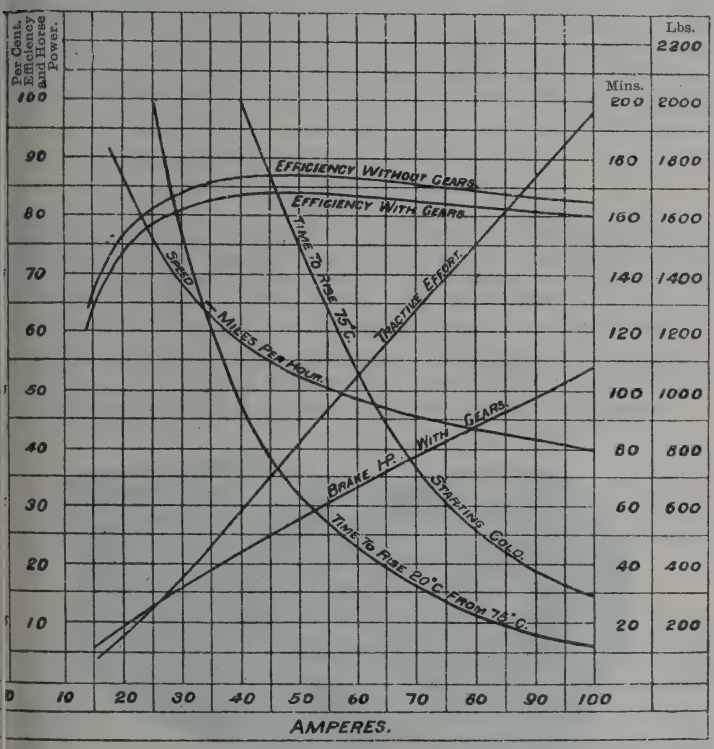

FIG. 35.

l. The pinion is of forged steel and the gear wheel of cast steel made in two parts bolted ther. The gears that may be used vary from a 15-tooth pinion and 70-tooth gear to a 22-tooth on and 63-tooth gear; the standard gear ratio is 16 to 69.

The method of suspension in this case is what is known as the cross-bar type. A rectangular ension-bar is supported on the truck frame, and the motor is bolted to this through machined ngs on the upper field-frame. On the other side the motor is supported on the gear wheel axle he usual way.

The weights of this motor are as follows. Motor complete with gear-wheel and gear-case, 4 lbs. Armature and pinion alone, 540 lbs. Axle gear-wheel and case alone, 340 lbs. The rance between the top of the rail and the lowest part of the motor with 30 in. wheels is $2\frac{3}{8}$ ins.

Fig. 35 gives the characteristic curves for this motor, from which all necessary information

regarding the performance of the motor may be derived. The curves given are those of efficien speed, tractive effort, horse-power, and temperature.

The upper temperature curve shows that under the standard conditions under which tramw motors are generally rated, i.e. 75° C. rise in temperature after one hour's continuous run, t corresponding current for this motor would be 75 amperes, which at 500 volts represents input of 37,500 watts. Following the 75-ampere line to the speed curve, the speed for t current and volts is seen to be 11·1 miles per hour, and continuing the ampere line up to t tractive effort curve the tractive effort is seen to be 1,380 lbs.; this is the useful draw-bar p with gear and driving wheel used in the test. Using the formula watts $= 2 \times S \times T$, t output in watts is found to be 30,600, or 41 horse-power, giving an efficiency of 82 per cent. shown on the efficiency curve for 75 amperes. The corresponding efficiency without gears given as 85 per cent., representing a draw-bar pull of 1,430 lbs., showing a loss of 50 lbs. in t gears. The above rating of 41 horse-power is that for one hour's run; the continuous rat will be considerably less than this, and depends upon the mean terminal voltage. The continuo capacity at 300 volts is given as 38 amperes, and is equivalent to a load of about 550 lbs. at t draw-bar. On the other hand, the motor will stand large momentary overloads without inju or sparking.

G.E.C. 'Witton' D.C. Interpole Tramway Motors.

(The General Electric Co. Ltd.)

These tramway motors are designed for direct voltages 500 to 600 volts, and outputs from 30 90 b.h.p. They can be adapted for operating at 1,200 volts. The weight per b.h.p. has be reduced 28·3 lbs. While the majority of machines in this range are intended for car drivi wheels 33 in. in dia. (new), special motors are available for wheels 24 to 27 ins. in dia. The mot are designed within a minimum track gauge. Among the points of advantage incorporated are

1. Strongly proportioned box frame construction of high permeability cast steel.

2. Positive axial ventilation of the 'parallel flow' type (Oerlikon system), a double fan at pinion end drawing two distinct streams of air through the motor.

3. Hoffman roller armature bearings with lubrication and grease sealing, and reliable locki

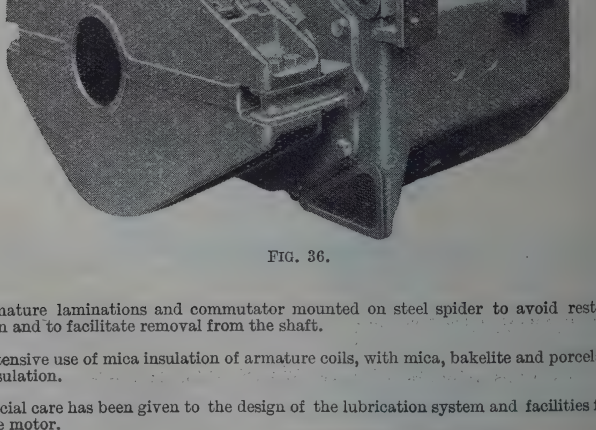

Fig. 36.

4. Armature laminations and commutator mounted on steel spider to avoid restriction ventilation and to facilitate removal from the shaft.

5. Extensive use of mica insulation of armature coils, with mica, bakelite and porcelain bru holder insulation.

6. Special care has been given to the design of the lubrication system and facilities for insp tion of the motor.

7. Large diameter commutator tightened from the front and permitting of renewal of any
nent without removal of commutator.

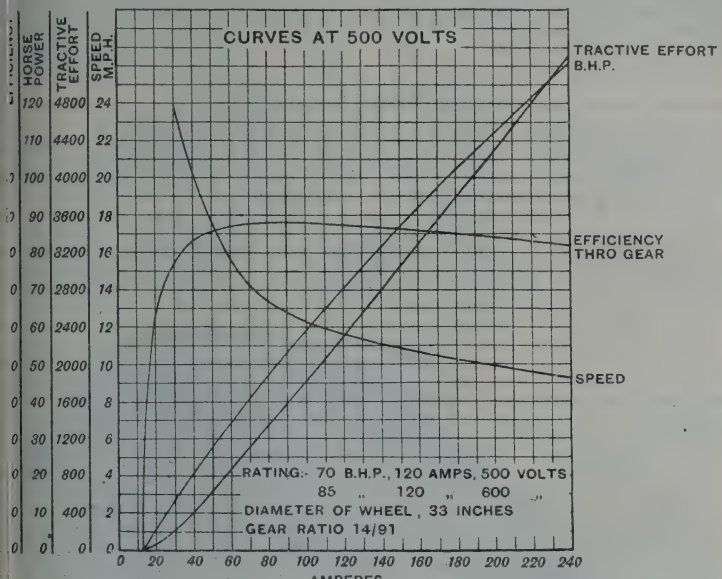

FIG. 37.—Characteristic Curves of G.E.C. 'Witton' D.C. Traction Motor, Type W.T. 32 R.

3. Exceptionally high efficiency.

A general view of the G.E.C. traction motor is shown in fig. 36 and the performance curves in
f 37.

The B.T.H. Co.'s Self-Ventilated, Interpole Traction Motor.

(The British Thomson-Houston Co., Ltd., Rugby.)

As an example of the most modern type of light-weight direct-current series motor made by the
1 .H. Co. may be mentioned the motor rated at 52 h.p., 88 amperes at 525 volts, for a temperature
r by thermometer on the windings not exceeding 25° C. on an hourly rating. The weight of the
n or complete with gearing, gear case and axle linings is 1,865 lbs. for use with wheel diameters of
2 o 27 ins. and 1,990 lbs. for wheel diameters of 30 to 33 ins.

t *Magnet Frame.*—The magnet frame is of cast steel, and is provided with machined seatings for
pole pieces and brush holders.

Armature Bearings.—The armature is carried in roller bearings, designed to take end thrust,
i ddition to the radial load. The bearings are arranged for lubrication with grease; greasers
s fitted with non-return valve, and screw threads for the connection of the grease gun.

Pole Pieces.—The four exciting pole pieces are built up of soft iron laminations, mounted on a
s l key, into which are screwed the bolts for holding the poles to the magnet frame. The
i rpoles are made of drop forged steel.

Armature.—The armature is built up of soft steel laminations, assembled and pressed together
l raulically, and keyed to ensure that no rotational movement takes place with respect to the
s ft. The shaft can readily be removed without disturbing the windings; the commutator can
a be removed independently if necessary.

Ventilation.—The motor is self-ventilated by the parallel method. A double-sided fan is
1 vided at the pinion end of the armature which draws air into the frame at the commutator end,
e elling it at the pinion end. Air flows in two streams, one stream passing over the surface of the
a nature and field coils, while the other passes through the armature, by means of longitudinal
(ts in the commutator shell and core punchings.

Axle Bearings.—The axle caps are of cast steel, tongued and bolted to machined surfaces on

the magnet frame. The caps have liberal-sized oil boxes designed for lubrication by means oily waste. Auxiliary wells are provided for filling and for gauging the supply of oil.

Gear Case.—The gear case is made of malleable cast iron, bolted to the frame at three poir and provided with a door in the upper half, spring closed, for inspection and for lubrication of gearing.

The English Electric Co. Direct-Current Traction Motor.

(*The English Electric Co., Ltd.*)

The direct current series wound traction motor gives in result the effect of the change-sp gear of a motor-car engine, which enables a small-powered motor to exert a big effort when requi for acceleration or for climbing gradients. It is capable of working both large and small ur both for short distances and main line traffic. The three features of design which have contribu to give the d.c. motor its present wide range in traction work are :—

(*a*) commutating poles ; (*b*) ventilation ; (*c*) high-tension design.

(*a*) *Commutating Poles.*—The coils are connected in series with the armature, and their eff is to counterbalance, under the brushes, the field set up by armature reaction, so that commutat under all conditions of loading is practically sparkless, even with the field shunted, thus givin range of economical speed to traction equipments.

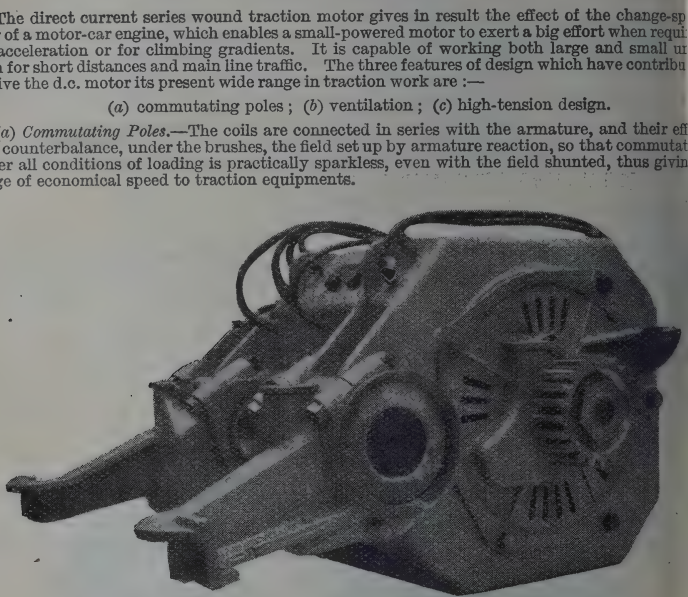

Fig. 38.—English Electric Co.'s Direct Current Traction Motor.

(*b*) *Ventilation.*—Through the introduction of ventilation, it is now possible to transmit u 450 h.p. on a single axle, on standard gauge, with 50-in. wheels, on the one hour rating of the mo

All traction motors manufactured by *The English Electric Company*, ranging from 30 h.p 400 h.p., are fitted with commutating poles and are either self- or forced-ventilated. S ventilated motors range from 30 h.p. to 330 h.p. Ventilation is effected by means of a fan wh forms part of the armature spider at the pinion end. The air is drawn in through apertu at the commutator end of the motor, and expelled at the pinion end. The fan is provided v two sets of blades, one of which draws the air through ventilating ducts in the armature, and other over the surface of the armature and round the fields. Forced-ventilated motors ra from 180 h.p. upwards, the ventilating air being supplied by motor-driven fans.

(*c*) *High-tension d.c. Motors.*—High-tension d.c. motors have been supplied in connec with the following schemes, amongst others :—L.M.S. Railway (England) and Cataluña Rail (Spain), both with a line voltage of 1,200 ; Midi Railway and Paris-Orleans Railway (Fran Midland Railway (New Zealand) ; Imperial Government Railways (Japan) and The Great In Peninsula Railway : the last five having a line voltage of 1,500 ; Montreal Harbour (Canada) voltage 2,400. Motors of similar design are also being supplied for the Morocco Railways f line voltage of 3,000.

An experimental line at 3,500 volts gave entirely successful results.

The high-tension motors are specially insulated, mica and mica compound being u throughout for the insulation of armature, field coils, and brushes, so that the dielectric stren of the machines is not affected at high temperature.

MOTORS "English Electric"

OVER 160 "English Electric" MOTORS

This picture shows a group of motors which is part of an order for over 160 machines built for The Associated Daimler Company's new works at Southall. A large number of these motors are applied to both individual and group driving of various classes of machine tools.

MOTORS ARE STOCKED IN A VARIETY OF TYPES AND SIZES.
The most up to-date designs are available to meet all requirements of efficiency, starting torque and power factor.

ALTERNATING-CURRENT MOTORS.

lternating-current Motors may be divided into the following classes:—Synchronous I ction, Induction-type Synchronous, and Commutator Motors.

Synchronous Motors.

n alternating-current generator will, if brought up to speed, excited, and connected to a s able alternating-current supply, run as a motor at a speed in revolutions per second equal t e frequency divided by the number of pairs of poles. Such motors are called synchronous n ors, and they will operate only at synchronous speed. They will not start under l , and have to be started by auxiliary means. If overloaded beyond a certain point t will fall out of step with the supply system and come to a standstill. Their sphere of u ulness is limited, and they are most commonly employed as phase regulators on trans- n ion lines, or for driving direct-current generators.

The English Electric Co. Synchronous Motor.

(The English Electric Co., Ltd.).

The following is a specification of a synchronous motor (Class G.L.), made by the Engli Electric Co.

These machines are made in various standard types as follows: The Engine Base Ty the Sole Plate Type, the Bedplate and Two-Pedestal Bearing Type, the Bedplate and Thr Pedestal Bearing Type, and the Engine Shaft Type.

The *Engine Base Type* consists of a stator frame with feet, core, coils, terminals, and shrou one pedestal bearing, a rotor with poles and field coils, shaft, slip-rings and coupling, compl collector gear, screws for fixing stator frame and pedestal to the engine base, and screws adjusting the height of the frame.

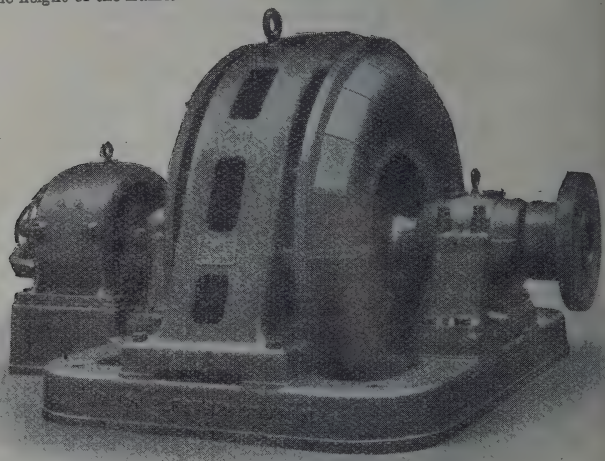

Fig. 40.—English Electric Co.'s Synchronous Motor.

The *Sole Plate Type* is practically the same as the Engine Base Type, with the additio three sole plates suitable for building directly into the foundations.

The *Bedplate and Two-Pedestal Bearing Type* is similar to the Engine Base Type, but a second pedestal bearing and a bedplate on which the stator frame and the two pedestal bear are mounted. The shaft is suitable for drive with solid or flexible coupling or, in special c with a gear wheel, or pulley for belt or rope.

The *Bedplate and Three-Pedestal Bearing Type* is the same as the above, but has a t bearing with a correspondingly extended bedplate. The shaft is suitable for fitting with wheel or pulley for belt or rope.

The *Engine Shaft Type* differs from the Sole Plate Type by the omission of the shaft, coup and the pedestal, together with its sole plate, the rotor being suitably bored for forcing dir on to the engine shaft.

Stator.—The cast iron stator frame is of substantial design and great stiffness, the forming an integral part of the casting.

For the small machines the frame is cast in one piece, but on account of transport limita the larger sizes are cast either in two or four pieces, which are held together by bolts.

Machines of small and medium size can be supplied with either high or low height of cen

The core is built up of best quality core plate stampings of high permeability and low loss, effectively insulated from each other to reduce eddy currents to a minimum. In the sm sizes the stampings are complete rings, in the larger sizes they are in segments.

The outer circumferences of the laminations are located on steel dove-tail keys, and laminations are firmly held in position by means of heavy clamping rings. Ventilating are provided at frequent intervals to allow free circulation of air.

The inner circumference of the core is slotted for the reception of the stator winding.

Semi-closed slots are used whenever possible, as they afford a mechanical support for coils and tend to reduce the excitation loss and the eddy current loss in the pole tips.

The stator winding is usually of the hairpin type held in place in the slots by means of wedges f insulating material. The coils are amply insulated and thoroughly impregnated before being ut into place.

The outhanging portions of the coils are protected from mechanical injury by shrouds secured) the frame. In all cases where the pole pitch is large or the duty gives rise to forces likely to istort the windings, these portions of the winding are supported by special brackets so as to ive as strong a mechanical construction as possible.

Terminals.—Connections from the stator windings are brought out as heavily insulated flexible ads which pass through a cleat board supported on the frame. This arrangement of terminals resents the safest and simplest means of connecting the machine to the external circuit.

Rotor.—The rotor consists of a cast wheel of steel or iron to which the poles are attached.

For the largest sizes the wheel is cast in two or more pieces, the sections being held together y shrink keys and bolts. The hub is held together by shrink rings.

The hub is provided when required with register and bolt circle suitable for bolting direct to ie engine makers' coupling or with a sleeve extension for bolting direct to the engine makers' ywheel. In small and medium-sized rotors, the centre, sleeve and coupling are cast in one piece.

The poles are rectangular in shape, being either steel castings or built up of steel stampings, either case of high permeability material. They are secured to the wheel by means of bolts rovided with lock washers, which pass through the rim from the inside.

For the small sizes when space does not permit of these bolts, the pole laminations are punched ith dove-tails for fixing into the rotor centre. These dove-tails are held in place by two taper edges.

The pole stampings are held together by heavy rivets passing through cast steel flanged end ates, the flanges being formed so as to serve also as supports for the field winding.

All pole pieces are built to permit the use of a damping winding when required, as, for example, connection with synchronous motors, single-phase machines, and generators driven by gas oil engines and generally to facilitate parallel operation with other generators. The bars hich pass through the pole face are efficiently connected by welded joints to the end rings.

Field Coils.—Whenever possible the field coils consist of copper strip wound on edge and refully insulated from the pole limb. This form of winding is specially recommended owing the excellent cooling of the windings and its great mechanical strength. It is advisable, herefore, to select a low voltage for excitation, so that a strip-on-edge winding can be used.

Slip-rings.—These are of gun-metal and are subjected to special heat treatment which makes r good wearing quality of the rings and brushes. The rings are shrunk on to a cast-iron bush sulated by a micanite sleeve. The complete bush with rings is pressed on to the shaft. The ds connecting the rings to the rotor windings are designed so that they can be replaced if ecessary without removing the rings.

Brushes and Brush Gear.—The brush holders and brushes are liberal in size, and there are ually two brushes for each ring mounted in one holder.

The brushes used are of a special composition of copper and carbon, which gives low brush sistance, low contact resistance, and low coefficient of friction.

The bearing at the collector end is provided with a seating for supporting the brush spindles hich carry the brush holders.

Shaft.—The shaft is designed on ample lines. It is of forged steel finished to size by grinding the bearing surfaces. The rotor centre, which is pressed hydraulically on to the shaft, is held place usually by one key sunk in the shaft, but where the drive renders it advisable, tangential ys are used.

Bearings.—The bearings are of the self-aligning sleeve type liberally designed. All bearings e split horizontally to facilitate inspection and removal.

Best quality white metal only is used for the lining. The bearings are of the self-oiling type th adequate oiling rings, the housing being made with a generous reservoir of oil provided th a definite system of oil circulation for the proper lubrication of the bearing and the cooling the oil.

The housing is furnished with overflow, oil gauge, and drain plug.

Means are provided to prevent oil creeping along the shaft outside the bearing and so reaching e windings.

Balance.—Great importance is attached to smooth running, and the rotor is balanced both ring manufacture and at final erection to ensure this feature.

Ventilation.—In these machines special attention has been given to providing a positive stem of ventilation. Air is driven outwards by fan blades on the rotor and is directed on to e windings and core by the special formation of the shrouds protecting the overhanging portions the stator winding.

Exciters.—Whenever conditions permit, direct-coupled exciters are used. In most cases e direct-coupled exciter has its armature overhung on an extension of the main shaft at the llector end, no outboard exciter bearing being used.

The exciter frame is mounted either on a stool fitted to the bedplate or sole-plate, or ernatively on a cast-iron bracket bolted to the bearing housing. In exceptional cases belt iven exciters are used, in which case the exciter has to be supplied with a sliding base, belt d the necessary pulleys both on the exciter and synchronous machine.

Induction Motors.

Induction motors may be classed as polyphase or single-phase induction motors. Th action of a polyphase induction motor may be likened to that of a direct-current moto in which both the fields and the armature are capable of rotation. Supposing the fields of suc a motor to be fully excited and rotate with the armature at rest and short-circuited, a curren of any desired magnitude may be induced in the armature, since the generation of a curren depends simply on the relative motion of the fields and the armature. The torque produce by the action of the fields on the induced current will tend to turn the armature, and if the field be kept rotating at a uniform rate, the armature will speed up until the relative motion of th fields and the armature is sufficient to generate a current that exactly balances the load ; uniform speed has then been reached. The slip, or the difference between the speed of the armatur and the speed of the fields, is generally stated in per cent. of the speed that would be reache if the armature were rotating at the same speed as the fields. This speed is spoken of as th speed of synchronism. In a polyphase induction motor the rotation of the field is produce by magnetising the fixed part, or stator, by two or more alternating currents in such a wa that the resultant magnetic field rotates at a uniform speed. Generally three alternating current are used differing in phase by 120°. One advantage of such a motor over the direct-curren motor is found in the absence of a commutator, for the current in the armature, or, as it is called the rotor, can be induced by short-circuiting its coils, the current from the line being led directl into the stator without any moving contacts.

In the single-phase induction motor there is an inductive action between the field and th armature, similar to that which takes place in a polyphase induction motor : the field, however is not a simple rotating field, but may be regarded as two fields rotating in opposite directions The result of this is that at starting the armature is subject to an equal pull in both directions— in other words, the motor will not start by itself. But when once the armature has been started in either direction, the torque in that direction increases while that in the opposite directio decreases. As a result, the motor works as an induction machine at a speed just belo synchronism similarly to the polyphase motor. This type of induction motor therefore need some special starting device.

In a polyphase system the ratio of the power component of the current to the total current as measured by the power factor, depends mainly upon the width of the air-gap between th fixed and moving parts of the motor. Hence it is of great importance to reduce the clearanc to the smallest limit consistent with safety. This necessitates very careful construction, espe cially for polyphase motors on railways. Experience shows that induction motors can be con structed to run well under all conditions.

Variation of Speed with Load.—In a normal polyphase motor the speed is nearly independen of the load. This is in marked contrast to the d.c. series motor, but shows a strong resemblanc to the torque-speed characteristic of a normal shunt motor.

Maximum Load.—As the load increases the speed slightly decreases, until the maximum loa is reached. If the load be increased beyond this the motor is brought to a standstill. In prac tice the working load should not exceed 50 to 60 per cent. of the maximum load.

Speed Regulation.—If resistance be placed in the circuit of the rotor so as to increase th total resistance, say, to double its value, the slip for equal torque will be double what it wa with the original resistance. Thus with any load not greater than the maximum, any require speed can be obtained by merely altering the rotor resistance. This is a wasteful method o speed regulation, and various methods are in use for obtaining economical speed control. Thes include :—

(1) Changing the number of poles, with or without change in the number of phases.

(2) Cascade connection with one or more motors.

(3) Addition of variable-speed set.

Starting.—There is a certain rotor resistance corresponding to standstill with maximu torque. If the rotor resistance has this value at the moment when the motor is connected t the line, it will start with its maximum torque. If the resistance is suitably taken out of th circuit as the motor speeds up, the torque during starting can be maintained constant at an value not greater than the maximum. In other words, the torque, and therefore the acceleratio can be maintained practically up to full speed.

Windings.—There are two kinds of windings. In the first the rotor winding consists o copper bars, rather longer than the rotor core, which are all connected together at their end In the second the rotor has a winding arranged in such a manner as to allow of an outside resis ance being introduced into the rotor at starting to supplement for the time being the resistanc of the winding. The former is shortly described as a ' short-circuited ' or ' squirrel-cage ' roto the latter as a ' slip-ring ' rotor.

Comparison of Motors.—If the full voltage is applied to the motor at starting with the rotor short-circuited there will be, owing to the low resistance of the bars, a considerable rush of current at starting. In the motor with the slip-ring rotor the current at starting may be kept quite low by means of the supplementary resistance. When giving its full-load effort at starting, such a rotor with resistance in its circuit will take its normal full-load current. A short-circuited rotor will take several times this, but the current can be kept down by using a starting transformer or star-delta switch. These appliances feed the motor at reduced pressure until it begins to get up its speed, but they render motors with short-circuited rotors suitable only for moderate starting torques.

On account of the constructional simplicity of short-circuited rotors it is preferable, whenever possible, to use motors having these. Save as regards starting current, the short-circuited rotor is superior in every respect to the wound rotor. The momentary excess of current it takes at starting does no harm to a small motor, but its effect on the regulation of the supply system may be sometimes objectionable, a point which must be carefully considered.

Effect of Starting Motors.—In choosing motors it is necessary to distinguish between those intended to work on town supply mains where the greater part of the current is used for lighting, and those suitable to a scheme in which the bulk of the current is used for power, the lighting being but incidental. In the former case it is necessary that the working of motors should not interfere with the constancy of pressure on the lighting circuits; in the latter case an occasional jump in the lighting may be of no importance.

The effect of a sudden overdraft of current at a low power factor is disturbance to a greater or less extent of the whole supply system, and fluctuations in pressure such as would cause no inconvenience in the working of a power transmission plant would not be permitted on town lighting circuits. The magnitude of the disturbance depends primarily on the amount of the overdraft relatively to the capacity of the generating plant, and to the margin of current-carrying capacity in the supply network.

Choice of Motors.—It will be evident from the foregoing that the choice of the motor depends upon circumstances, and that neither class can be pronounced the better under all conditions.

Motors with short-circuited rotors take momentarily up to five times their full-load current, if at starting they have to give their full-load effort, or from one to one-and-a-quarter times their full-load current giving 25 to 30 per cent. of their full-load effort, and using a starting device. For connection to town mains it is usual, consequent on the possibility of disturbance to neighbouring lighting circuits which might arise from the starting, to limit this class of motor to 5 h.p. or so, when it has to start at full load effort, or to 10 h.p. when operated with a starting transformer.

In a power transmission scheme where there are no neighbours to consider and the lighting is subsidiary, the short-circuited class of rotor can be employed for large sizes, provided that at starting no individual motor takes a current great enough to prejudicially affect the working of the plant. Thus, in a 500 h.p. transmission, motors of 25 h.p. may be switched right on to the mains without the use of starting transformers, while if the starting effort required is only from 25 to 30 per cent. of the full load effort, motors of 50 h.p. provided with starting transformers are quite permissible.

The conditions under which motors with **slip-ring** rotors should be used are determined by elimination, that is to say, motors of this class are installed in all cases where it is not advisable to use the other. They have their place on town mains for sizes above 5 or 10 h.p., and in power transmission work, when they have to start at full load effort, and their sizes are comparatively large in proportion to the generating plant. Again, in all cases where motors have to start with overload effort, a slip-ring rotor should be used. Not only do motors of this class give at starting their full load effort with only full load current, but 50 or 100 per cent. over the full load effort can be obtained with a current proportionately increased. This control of the current at starting constitutes the advantage of motors with slip-ring rotors.

The curve in fig. 41 shows the power-factor at full-load of polyphase induction motors, as designed by Messrs. Crompton & Co., plotted as a function of the horse-power per revolution. Other things being equal, the maximum power-factor that can be obtained depends upon the number of poles with a given core diameter. For the same size of machine the larger the number of poles the lower will be the power-factor. It will be noticed from the curves that as the size of the machine increases the curves become very flat, and therefore after a certain point a very large increase in size will only increase the power-factor by a very small amount. For the smaller motors, however, the power-factor increases much more rapidly with the size. The horse-power ratings shown are for a normal temperature rise, and show the maximum power factor that can be reached in these conditions.

The standard windings of these motors are arranged to work on voltages of 110, 220, 440, and 500. They can, however, be wound for any other periodicity and for any higher voltage. The machines can be supplied for polyphase or single-phase circuits with either slip-ring or short-circuited rotors. They are manufactured in 19 standard sizes and are supplied in the same types, and are of the same substantial design and construction as the direct-current motors.

The machines are designed to give a high power-factor at all loads, and to withstand heavy overloads before stalling. When required to start against a load, it is advisable to use motors with slip-ring rotors and starting resistances. Motors with short-circuited rotors are capable of exerting their full-load torque when starting, but the sudden rush of current may be as high

CURVE SHOWING THE POWER FACTOR OF POLYPHASE INDUCTION MOTORS PLOTTED AS A FUNCTION OF THE H.P. PER REVOLUTION.

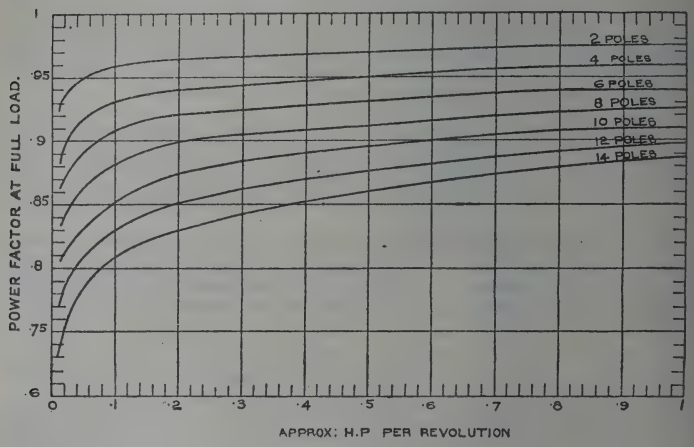

FIG. 41.

as four or five times the normal full-load current. Motors of this type may be either switched direct on the line or a special auto-transformer may be used to reduce the line current at starting. Special motors can be designed with permanently short-circuited rotors, and with high resistance winding, capable of starting up against the full-load or even higher torque, but such motors are usually required for special kinds of intermittent working, such as hydro-extractors.

SPECIFICATION FOR INDUCTION MOTORS.

(*The English Electric Co. Ltd.*)

The standard machine consists of stator frame with end shields, rotor, terminals, and complete internal connections. Unless otherwise stated in the quotation, the machine is supplied without pulley, coupling, sliding base, foundation bolts, or spanners.

These motors are usually supplied in the Protected or in the Enclosed-Ventilated type, but they are also made as Pipe-ventilated or Drip-proof Motors.

The *Protected type* motor is so designed that the internal rotating parts and live parts are protected mechanically from accidental or careless contact, a perforated metal cover being fitted to the cylindrical opening over the rotor fan.

The *Enclosed-ventilated type* is similar to the protected type, but a perforated metal cover is fitted over both cylindrical openings in the frame.

The stator frame is of cast iron. The stator core is built up of insulated stampings bedding directly on the stator frame. The coils are of the 'push-through' type in the larger sizes and of the 'dropped-in' type in the smaller sizes, the slots being nearly closed.

The rotor is built up of stampings with nearly closed slots.

In the case of squirrel-cage rotors the end rings are cast on to the rotor bars. The winding is specially designed to give a good starting torque.

In slip-ring rotors the ends of the windings are separated sufficiently to allow a free circulation of cool air.

A cast-iron terminal box is provided on the stator frame, and is fitted with a flange to take screwed conduit. Up to 650 volts, six terminals are provided, but for certain 210-volt motors the standard terminal box will take three terminals only. For pressures above 650 volts three porcelain-insulated terminals are provided.

A trifurcating box can be supplied to fit the above-mentioned terminal box. A trifurcating box can also be supplied for the rotor leads.

End shields are in the form of end plates bolted to facings on the stator frame, and form substantial supports for the bearings.

Ball or roller bearings, or in certain cases a combination of both, are used, and are of ample proportions. On the larger machines a ball-thrust bearing is fitted.

The bearings are enclosed in dust-proof housings.

This type of bearing has stood the test of lengthy experience in practical use, and is particularly advantageous in the case of induction motors, as there is no appreciable wear of bearings and consequently no change in the length of air gap after extended use. As the bearings will work equally well in any position, provided the shaft is horizontal, the motor may be fixed to wall or ceiling, without altering the position of bearings or end shields, as is necessary with ring-lubricated machines.

The slip rings are of phosphor bronze, and are arranged outside the end shield on an extension of the motor shaft. There is no earth connection to the slip rings.

The standard design permits of the addition of a short-circuiting and brush-lifting device, by which, through the movement of a hand wheel, the slip rings are short circuited and the brushes lifted out of contact with the rings, thus increasing the efficiency of the motor and reducing wear on both slip rings and brushes. With this device, a cover giving total enclosure to the slip rings is always supplied, and the brush holders are of the lever type.

If the short-circuiting and brush-lifting device is not provided, the slip rings are enclosed in a perforated metal cover and box-type brush holders are used.

The following accessories are supplied as extras, if required :—

Pulley, standard or otherwise, or half-coupling or flexible coupling.

Sliding base, with adjusting screws and four bolts for fixing the motor to the base.

Foundation bolts for fixing the sliding base to the foundations.

Spanners and spanner rack.

The Cascade Induction Motor.

The 'cascade' principle was originally applied to two motors mechanically coupled with heir windings electrically connected in such a way as to make it possible to obtain two speeds. n the case of induction motors, the arrangement adopted was to connect the rotor slip-rings of notor No. 1 to the stator windings of motor No. 2, the torque of the combination being conrolled by resistances placed in the circuit of the rotor of No. 2, slip-rings being used. If both nachines had an equal number of poles, the 'cascade' connection gave effects equivalent to loubling the number of poles. Or if, for example, one was an eight-pole and one a four-pole notor, the speed for 'cascade' connection was that for a twelve-pole machine. Considerable ise has been made of this system, notably on railways, the locomotives on the Valtellina line nd for the Simplon tunnel being operated on this principle. The same effect may be secured y connecting the two rotors in series : the starting resistances may then be placed in the stator ircuit and the use of slip-rings can be avoided.

In the Hunt 'Cascade' Induction Motor made by Sandycroft, Ltd., this principle has been deeloped so that the advantages secured hitherto only with two motors can be obtained in a single notor. In an ordinary induction motor, the stator acts on the rotor and there the inductive ction stops. Starting torque and speed regulation can only be obtained by inserting resistances n the rotor winding. In the 'Cascade' motor, the rotor, by means of a supplementary magnetic eld, reacts inductively upon the stator, to which the starting and speed regulating resistances re connected. The rotor in fact reflects back to the stator part of the energy received from t. This is accomplished by winding the rotor in such a way that it can, under the inductive ction of the stator, simultaneously produce two magnetic fields of different numbers of poles ; ne of these reacts on the stator and generates in its winding induced currents. Each branch f the stator winding is divided into two parallel circuits which are tapped at suitable points. n the case of single-speed motors, or two-speed motors requiring starting or regulation with educed rheostatic losses below two-thirds speed, these points are connected to resistances by hich the torque and speed are controlled.

Owing to the presence of two magnetic fields, one of which is at its maximum when the other s at its minimum, a very even turning movement is obtained at slow speeds, and a perfectly even pull with maximum torque can be obtained at as low as two revolutions per minute. This s a feature of importance with all kinds of winding engines. The slip of an induction motor lepends upon the resistance of the windings in which the secondary currents circulate. In the Cascade' motor, these windings are in the stator and are of very low resistance, consequently he slip in these motors is very much less than that of ordinary induction motors, and the speed

variation between full load and no load is only about 1·2 per cent. For constant speed wor the absence of slip-rings is a matter of moment, especially in mining installations. These moto develop full-load starting torque with full-load current, and have a higher power factor tha ordinary motors at low speeds where the tendency is for the power factor to become unfavourabl

The question of economical running at two or more speeds is one of great importance. Th synchronous motor must run in step with its generator, and the induction motor runs at a spee very nearly that of synchronism. The speed of the former cannot be varied, the speed of th latter can only be varied by inserting resistances in the rotor at great loss of efficiency. A simpl modification of the windings of the 'Cascade' motor, described above, enables two speeds to b obtained without rheostatic losses. Slip-rings are connected to a normal rotor winding in sta mesh connection. When these rings are open circuited, the portion of the winding connecte to the slip-rings is idle, the rotor reacts on the stator, as previously described, and the moto runs at 'Cascade' speed. When the slip-ring circuit is closed, the rotor winding becomes sym metrical, and produces only one number of poles; there is no reflex action on the stator and th motor runs as an ordinary induction motor. Thus, for example, in a twelve-pole 'Cascade motor, running at 500 r.p.m., there are two fields, one of eight and one of four poles, the latt being the result of rotor reaction. When this is removed by current through the slip-rings, th effective number of poles is eight, and the motor runs at 750 r.p.m. without any resistance. I intermediate speeds are required, they may be obtained by the use of resistances in the usua manner. Other economical speed changes can be obtained in addition by Creedy's extension o the principle of the cascade motor, or by pole-changing, etc. A special application of the two speed motor, apart from economical running at two speeds, is the avoidance of large startin peaks by two-speed starting in connection with winding and similar work, combined with a reduc tion in starting losses.

A self-synchronising synchronous type of Hunt motor is now on the market and has man unique features. It resembles the Cascade Induction Motor, but has a modified form of stato winding. At synchronous speed the auxiliary field is stationary, and is excited by direct curren supplied to the stator windings. These windings are connected to form two parallel-connecte star windings, and the exciter is coupled to the neutral points. The direct current produce a field having half as many poles as the main field. The machine is started by resistance connected to the slip-rings, and when so connected the speed can be taken up to synchronou (Cascade) speed or even above it, so that all the usual difficulties of pulling-in are obviated The motor will start and synchronise with loads of two to three times normal, and with a high starting-power factor and low current consumption. With motors designed for a leading powe factor of 0·7, the starting current for full-load torque is of the order of 10 per cent. to 15 pe cent. more than normal full-load current, and the starting-power factor is 88 per cent. to 9 per cent., depending upon the speed for which the machine is built. A remarkable featur possessed by this machine is its entire immunity from 'hunting' or 'phase-swinging.' Extensiv tests have been made, but no trace of these troubles has ever been found.

The latest development of the Hunt machine is a self-paralleling generator. This moto closely resembles the synchronous motor, but, as slip-rings are not required, the rotor windin is of the low-voltage short-circuited type as used for the induction motor. These machine possess the same properties as the synchronous motor, and will run in parallel under condition which would be impossible with generators of the usual type.

Induction-type Synchronous Motors.

The induction-type synchronous motor is a polyphase motor with a cylindrical rotor; it i started as an induction motor of the slip-ring type, and synchronises itself when direct curren is switched on the rotor. It combines the good starting characteristics of the induction moto with the property of power-factor correction of the synchronous motor, and for this reason its use is extending. It may with advantage be run at a leading power factor at all loads; th leading current increases somewhat as the load is reduced, and the speed is constant at all loads A small d.c. exciter is mounted on the motor shaft. The stator is identical with that of the ordinary induction motor; the rotor may be wound three-phase or single-phase. Whilst starting, with a resistance in the rotor circuit, the machine exerts a large torque, and can be made to accelerate against more than double full-load torque. The maximum current during starting is about twice the full-load current, and persists for a very short period. The overload above which the motor falls out of step is 100 per cent. or less, depending on the power factor for which the machine is designed; on falling out of synchronism it will usually continue to run as an induction motor until the overload is reduced. In the operation of starting, the main notch is closed, and the rotor starting resistance is gradually cut out and short-circuited. The rotor circuit is then momentarily opened, and closed on the exciter; and the exciting current is adjusted to give the desired leading power-factor.

In some cases the power is supplied to the rotor, and the excitation to the stator.

The efficiency is slightly lower than that of a plain induction motor; the cost is 25 to 40 per cent. higher (including all accessories). The machine is most suitable for a continuous load of 100 h.p. or more.

AVERAGE EFFICIENCIES OF POLYPHASE INDUCTION MOTORS.

Alternating-current Commutator Motors.

Alternating-current commutator motors are in most respects similar to ordinary direct-urrent motors, and may have either series or shunt characteristics. They operate under serious lisadvantages, owing to the transformer e.m.f. induced in the coils short-circuited by the brushes, ıecessitating a low commutator voltage; but for certain purposes they are practically indis-ıensable. For single-phase railroad traction the 'neutralised series' motor is used, the speed ıeing controlled by a variable-ratio transformer. For smaller powers the single-phase 'repul-ion' motor is very suitable, the speed being controlled by moving the brushes over a range rom standstill to 30 per cent. above synchronism. Single-phase commutator motors with hunt characteristics are also satisfactory machines. The efficiency of single-phase shunt commu-ator motors is somewhat lower than that of direct-current motors, and the cost somewhat higher, ut the weight is less.

Three-phase commutator motors are also made to work with a series or with a shunt charac-eristic, but have not come into extended use, except for special applications such as steel rolling-ill drives. Where variable speed is necessary, the multi-speed or the cascade induction motor an be considered as alternatives to a.c. commutator motors.

VARIABLE SPEED POLYPHASE COMMUTATOR MOTORS.

(*The British Thomson-Houston Co., Ltd.*)

This motor, known as the Schrage motor, has been developed by The British Thomson-ouston Co. for industrial applications requiring variable speed. While possessing the speed ıaracteristic of a d.c. shunt-wound motor, it is suitable for operation on polyphase alternating ırrent circuits.

The motors are provided with the following windings:—

(1) Primary winding located on the rotor and, by means of slip rings, connected to the supply ads.

(2) Secondary winding located on the stator.

(3) Regulating winding placed in the same slots on the rotor as the primary winding. The gulating winding is connected to a commutator and thence, by means of brushes, in series with ıe secondary winding on the stator.

For normal speed regulation, no external resistance is required in order to effect speed variation, ıd hence the motor operates with high efficiency at all speeds. Normal speed variation obtained simply by turning the handwheel provided, which changes the position of the brushes ı the commutator. The movement of the brushes can also be effected very conveniently from distance either mechanically by means of wire rope and pulleys or by spindle and bevel gear heels, or electrically by means of a small pilot motor coupled to the brush-shifting spindle and ntrolled by push buttons.

The polyphase shunt motor—unlike the d.c. variable-speed shunt-wound motor, where the aximum torque is developed at the lowest speed and decreases as the speed increases—exerts constant torque throughout the whole speed range, i.e. the output is directly proportional to ıe speed.

The normal speed range of the standard motor is 3 : 1.

The motor operates at speeds above or below the synchronous speed and at any speed between ıe maximum and minimum values. When running near synchronous speed the motor operates ctly as an ordinary induction motor, the secondary winding being short-circuited through ıe brushes across one or more commutator segments. According to the amount that the two ts of brushes are displaced in one direction or the other, so the speed will vary either above or elow synchronous speed. It is usual, therefore, to select a synchronous speed about midway etween the maximum and the minimum speeds desired.

The difference between the no-load speed and the full-load speed for any brush setting is pproximately 5 per cent. to 10 per cent. of the maximum speed of the motor, the exact per-ntage depending on the size of the motor. A creeping speed can be obtained by inserting a nall resistance in each phase of the stator winding.

This motor is more stable than the ordinary induction motor when running at creeping speeds ecause it has normal operating speeds much below the synchronous speed.

Reversal of direction of rotation is effected by interchanging two of the line leads connected ı the slip-rings.

Carbon Brushes.

*British Standard Specification for Parallel-sided Carbon Brushes for D.C. Commutator Machines No. 96—1922.**

Definitions are given of centre line, brush dimensions, chamfer, and bevel, and these ar exemplified by figs. 42 and 43, chamfer being the slope produced by removal of the four edges t prevent binding in holder box, and measured by taking one-half of the difference in side dimen sions before and after chamfering (see Table II.). Flexibles to be of twisted copper strand, th diameter of each individual wire not exceeding 0·0048 inch (0·12 mm.). One terminal only c the shoe type pressed on to the flexible shall be provided, the copper terminal shoe for all size

British Standard Switchgear.*

Specifications for air-break switches and circuit breakers for pressures up to 660 volts are ven in the *British Engineering Standards Association's Reports* Nos. 109 and 110, 1923. ıe specifications do not apply to switchgear for use in circuits containing high inductance. sts of standard current ratings are given, and it is specified that the temperature rise on con- ıuous full load shall not exceed 20° C. for switchgear rated below 100 amperes, or 30° C. for 0 amperes and upwards.

Distinction is made between: (1) A switch, being a mechanical device for non-automatically eaking a circuit carrying load-current; (2) An isolating switch for disconnecting a circuit only en carrying no load current; and (3) A circuit breaker, a mechanical device for breaking tomatically a circuit under abnormal conditions such as that of short circuit.

Marble or slate slabs must be free from metallic veins, and, if of slate, must be treated all er with a damp-proof medium; the slabs are to be insulated from fixing bolts and the sup- rting framework. The sizes of round copper-back connections and their spacing are tabulated the Reports. The test pressure to be applied to a switch or circuit breaker is 1,000 volts us twice the rated pressure, with a minimum of 2,000 volts alternating.

* By permission of the British Engineering Standards Association.

In the case of circuit breakers, the temperature rise of coils is not to exceed 50° C. when the insulating material is impregnated cotton, silk, or paper, or enamelled wire, and 70° with materials such as asbestos, micanite, and built-up mica, and bare coils. Reverse-current devices must be capable of operating with 15 per cent. or less of the rated current; low-voltage releases must not operate unless the pressure falls to 65 per cent. or less of the rated pressure, but must operate before the pressure falls below 25 per cent. of the normal, at the rated frequency. A reverse-current circuit breaker must not be rendered inoperative if the pressure across the potential coil falls to (Class A) zero, (Class B) 50 per cent. of normal, and a reverse-current device must not operate with a forward current of any magnitude. Magnet-closing circuit breakers must operate between the limits 20 per cent. below and above normal pressure, and pressure-operated tripping coils must operate between the limits 50 per cent. below and 20 per cent. above normal pressure, at 40° C.

When type tests have been made by a recognised authority, a millivolt drop test is to be accepted in lieu of a temperature test.

Specification 116—1923 gives the standard ratings, sizes, and marking, the temperature and voltage tests for oil-immersed switches and breakers for alternating current circuits. The temperature rise above the cooling air at any part must not exceed that measured at the hottest part of the oil, viz. 30° C. for ratings up to and including 2,000 amperes, 40° C. above 2,000 amperes when the temperature of the cooling air exceeds 40°C the temperature rise must be such that the total temperature attained does not exceed 80° C. Temperature limits of coils and test voltages for switches as in Nos. 109 and 110; but, when operated from secondary of transformers the maximum testing voltage for coils to be 2,000, and for switches rated for 1,000 volts and upwards 2,000 volts *plus* 2¼ times the rated voltage. These conditions shall also be fulfilled after erection on site. Type tests specify that the circuit breaker shall interrupt its rated k.v.a. breaking capacity twice at a two-minute interval. A switch shall break twice in succession twice the rated current at rated voltage and after this carry its normal current without exceeding limits of temperature rise and then break twice the rated current a third time. A mechanical endurance test is to be carried out by operating 500 times with the main contacts carrying no current. Method of calculating k.v.a. to be broken and notes on selection of oil circuit-breakers are given in appendices.

Specifications for totally enclosed air-break switches (No. 124—1923) and air-break circuit breakers (No. 130—1923) for circuits not exceeding 660 volts provide, in addition, for efficient earthing of containing case, arc shields and lining, and insulation of the interlocked handle. The insulation resistance must not be less than 10 megohms.

Condition to be fulfilled by flame-proof air-break switches and circuit breakers (Nos. 126 and 127—1923) require a test of flame-proofness by subjecting the apparatus to a single breaking test when filled and surrounded with the maximum explosive mixture of methane and air or the equivalent. Switches must then break a circuit carrying a current 50 per cent. in excess of normal at rated voltage on a non-inductive load; circuit breakers to operate under same conditions of current, voltage, and impedance as in service.

ELECTRO-MECHANICAL BRAKES.

Electro-mechanical brakes are used in connection with a variety of electrically driven machines, such as lifts, cranes, hoists, elevators, conveyors, rolling mills, paper reeling, slip ways, presses, machine tools, etc., where either a quick 'stop' or adjustable gradual 'stop' is desired when the power is cut off either intentionally or unintentionally.

These brakes consist primarily of an electro magnet which operates the brake blocks through a system of levers or other medium. The magnet is so arranged that, when the current is applied, the magnet is energised and lifts the brake blocks from the drum. If for any reason the current is cut off the magnet is de-energised and the brake blocks are pressed against the drum, the requisite pressure being obtained by springs, weights, or a combination of each.

The brakes are quite automatic in action; thus, in the case of an electrically driven crane as soon as the driver applies the current to the motor to raise the load the brake is automatically released, and when he switches off the current to stop the brake is immediately applied. Should for any reason the supply current fail, the brake automatically goes on and takes charge of the load.

It is desirable that an electro-mechanical brake should have the following features: compactness of design, robust construction, few and simple working parts, easy adjustment of brake blocks and pressure exerted by same. Coils should be liberally rated, well insulated, and protected from mechanical injury, and so placed that they are not likely to be damaged by oil exuding from the machine. The brake blocks should be readily renewable. If springs are used they should be of the compression pattern.

Motor Starters and Controllers.

'Starters' are devices for starting and accelerating a motor to normal speed, and comprise (*a*) Rheostatic starters (face-plate, drum, multiple switch, contactor, and liquid starters); (*b*) Compensation or auto-transformer starters for 2- or 3-phase motors; (*c*) Switch starters star-delta connections for 3-phase starters, series-parallel connections for 2-phase machines).

'Controllers' (including shunt regulators) are used to regulate the speed of a motor, and may or may not be used for starting.

The following British Engineering Standards Association Specifications deal with starters:—

No. 117—1923. Drum starters for electric motors.

No. 118—1923. Drum controllers and resistances for use therewith, for electric motors (D.C. and A.C. slip-ring).

No. 123—1923. Face-plate controllers and resistances for use therewith, for electric motors D.C. and A.C. slip-ring type).

No. 123—1923. Face-plate controllers and resistances for use therewith, for electric motors (D.C. and A.C. slip-ring type).

No. 129—1923. Contactor controllers and resistances for use therewith, for electric motors (D.C. and A.C. slip-ring type) (excluding controllers for traction purposes).

No. 140—1923. Liquid starters for electric motors (D.C. and A.C. 2- and 3-phase induction with slip-rings).

No. 147—1923. Multiple switch starters for electric motors (D.C.).

No. 155—1923. Contactor starters for electric motors (D.C. and A.C. 2- and 3-phase induction with slip-rings).

No. 167—1923. Auto-transformer starters (hand-operated pattern for electric motors (A.C. 2- and 3-phase induction without slip-rings).

No. 246—1927. Face-plate starters for electric motors (D.C.).

No. 247—1927. Face-plate rotor starters for electric motors (A.C. 2- and 3-phase induction with slip rings).

AUTOMATIC CONTROL GEAR.

An automatic controller entirely eliminates the personal judgment of the operator in many cases, which is a distinct advantage where men accustomed to heavy work such as is met with in shipyards, steel mills and the like, are called upon to start up large machines. The controllers are now made suitable for practically any purpose, any horse-power, any supply, and for any particular design of motor requiring special starting apparatus.

The foolproof nature of automatic gear is not the only or the principal argument in its favour as compared with hand-operated controllers under frequent and heavy service.

An automatic controller is one in which the current supply to the motor is regulated by means of one or more switch units, each unit being operated by an electro-magnet; the operation of the magnet is controlled by an auxiliary switch, which therefore only has to deal with very small magnet-currents. This auxiliary switch can be put at any distance from the motor in the most convenient place, whereas the main automatic controller can be installed beside the motor, thus effecting the greatest economy in cable connections.

The original face-plate type of starter, which is still the standard type for moderate size motors starting up only a few times per day, has had to give place to the drum type controller for frequently operated motors as on cranes. This type of controller has been greatly improved in its mechanical and electrical construction, but its design has such inherent limitations when it has to deal with the large currents now employed that excessive wear of the contacts is produced. This necessitates constant attention to the wearing parts, and high maintenance charges. By inherent limitations is meant the fundamental fact that in order to carry larger currents the contact pressures must be increased, and such increase greatly increases the mechanical wear, so that in some cases the contacts may have to be renewed after a few weeks' operation. With an automatic controller of proper design, the wear is very much less, and does not increase with the size of the controller. Contacts operating under severe conditions will only require renewal about once or twice a year.

D.C. motors are controlled by a number of solenoid-operated switches or 'contactors' fitted with powerful magnetic blow-outs and arc shields; they are electrically interlocked so that they can only close in correct sequence, and so arranged that the motor cannot be started up except with all resistance in the armature circuit.

In some cases the time intervals between the closing of successive contactors depend upon the acceleration of the motor. This is generally determined by means of series relays fitted to each contactor except the last one. These relays are in the main motor circuit, and are adjusted so as to operate when the motor current drops to the value at which further acceleration is impossible. The operation of the relay closes the control circuit of the next contactor, which therefore closes, thereby cutting out a section of the resistance and speeding up the motor. This is repeated each time until the motor reaches full speed. It is thus evident that the motor current is kept within safe limits while the motor is accelerated to full speed in the minimum time, which means the minimum loss of power in the starting resistances.

The automatic control of any a.c. motor is now as reliable as with a d.c. motor for a.c. switches and contactors are manufactured for controlling motors of any horse-power on high or low tension supplies. A standard controller for a slip-ring motor consists of a stator switch or contactor and a number of D.P. rotor contactors complete with relays, the number depending on the h.p.

The stator switch coil is controlled by a small switch, accumulator switch or float switc pressure regulator or other means, and on being energised closes the stator switch automaticall and the motor is connected to the mains with all the rotor resistance in circuit.

A time element controls the closing of the first D.P. rotor switch, which, on closing aut matically, cuts out a section of the resistance in the three phases of the rotor circuit. As wi the d.c. set, this is repeated until the motor is up to full speed with the leads to the rings shor circuited.

Pumps are arranged to stop and start according to the rise or fall of water in a tank by mea of float gear and an automatic controller. The automatic control of air compressors is bei universally adopted on account of the great convenience and economy effected in many case irrespective of the benefit of the elimination of skilled attendance.

Each plant requires individual investigation in order to ascertain the most economical meth of control. On a d.c. or a.c. supply the compressor can be arranged to stop and start at max mum and minimum pressures only, or to stop and start at maximum and minimum pressure the speed being reduced or increased between certain definite pressures, unloading at startin or to run continuously, unloading only at maximum pressure, when the demand for air is grea

For certain duties, such as lifts, plate-edge planers or live rolls, operated by a.c. slip-ri motors, where a large initial starting torque is usual, the ' Eddystat ' controller has many uniq advantages. This controller is called an ' Eddystat ' controller because it utilises the surpl power required when accelerating, to produce eddy current losses, just as the ordinary resistan type of controller uses up the surplus power in creating an ohmic loss in the resistances. Th controller has no moving parts, but requires a contactor for operating in the stator circuit, a when the duty is such that the motor runs continuously for a considerable period of time, it preferable to have a double pole switch to short-circuit the ' Eddystat ' controller.

The arrangement consists of three solid steel cores and insulated copper windings with tapping which are connected across the sliprings, as shown in fig. 44. On starting the motor the rot current is forced through the controller at line frequency, and the highest rotor volts, and pr duces the maximum eddy current loss. As the motor speeds up, the voltage and frequenc decrease in proportion, and consequently the eddy current losses decrease automatically.

DIAGRAM OF CONNECTIONS OF ' EDDYSTAT ' CONTROLLER.

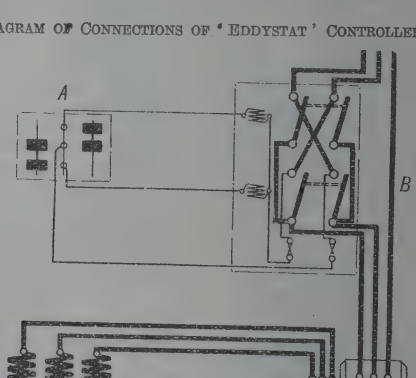

Fig. 44.

A—Master Controller. *B*—Reversing Contactors. *C*—' Eddystat ' Controller.

NOTE.—An increase in the starting torque can be obtained by moving the star connectio *a b c* up to the tappings immediately above.

A further increase is possible by connecting the coils in delta.

Braking and Reversing.—This controller also acts as a very powerful electric brake, becaus if the stator circuit is reversed when the motor is at full speed, twice line frequency and twic standstill rotor voltage will be applied to the controller. For automatic reversing equipments such as plate-edge planers or live rolls, this reduces the time of reversal, and increases the output The maximum current when reversing in this manner is very little in excess of the current take when starting up from standstill. The controller thus acts like a plugging resistance, but with

he additional advantage that a single-speed master controller is sufficient. This eliminates he judgment of the operator, which is necessary when plugging with a three-point master ontroller. As the 'Eddystat' controller is always connected in the rotor circuit the motor s fully protected, a valuable feature absent in other forms of control.

Oil Immersed Type.—The 'Eddystat' controller is specially suitable for installation in iery mines, explosives factories and chemical works, as, in addition to having no moving parts, t can be totally immersed in an oil tank, like a transformer.

For the control of large cranes, whether the supply is direct or alternating current, the standard ractice at the present time is to install contactor controllers on the crane with small master irum controller in the driver's cabin, in preference to the large drum controllers previously ised.

Absolute control is afforded, and the manipulation is more efficient, with the added advantage hat, due to interlocking, no damage can be caused to the gearing through carelessness. When owering, the driver can vary the braking effect according to the load; in fact he has as efficient ontrol as with a drum controller, but the apparatus being foolproof needs less care and attention, nd frequent repairs are eliminated.

Automatic controllers are being installed in all up-to-date steel works and rolling mills, on harges, blast-furnace hoists, screw-down gear, live rolls, lifting tables, skids, and main rolls.

TRANSFORMERS.

Transformers in Parallel.

The simple distributing transformer usually has two high-voltage leads and four low-voltage eads coming out from its windings, as indicated in 1, fig. 45. It will be seen from fig. 2 that he two centre leads of the low-voltage coils are crossed inside the transformer before they are rought out through the case. This does not make any change in connecting the two sections in eries on the outside of the transformer, as this is the same as connecting two batteries in series.

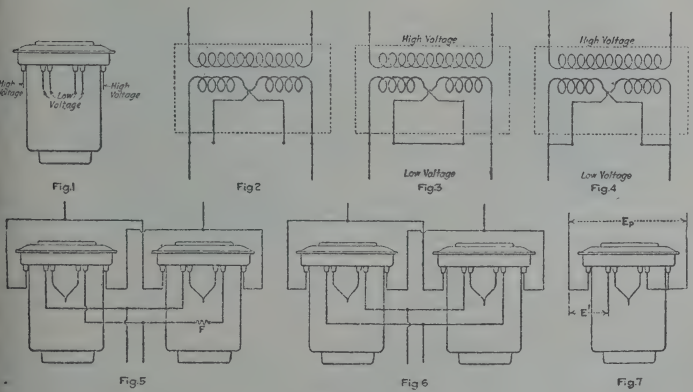

FIG. 45.

When the coils are connected in parallel, care must be exercised and adjacent leads connected ogether, as in fig. 4. Looking at the connections from the outside of the transformer, it would ppear as though the two sections of the winding were short-circuited, but the diagram shows hat the right-hand terminals of each section are connected together, also the left-hand terminals. his is just what is done in connecting batteries or other direct-current elements in parallel—ke poles are connected.

Transformers to operate in parallel should be the same voltage, frequency, size, and possess the same characteristics, which means that they should be of the same make. In connecting transformers in parallel, it is only necessary to observe the same rules as used for connecting two or more pieces of direct-current apparatus in parallel; namely, connect like poles to like poles. The question now arises which are like terminals on two or more transformers. This is easily determined in most cases. After the transformers are arranged symmetrically, as in fig. 5, connect the right-hand terminals together and the left-hand terminals together and bring out a lead from each junction point, as indicated.

There is, however, a chance that one of the transformers may have its leads brought out in such a way as to cause a short-circuit when the transformers are connected as shown in the figure. To guard against this a piece of small fuse wire may be connected, as indicated at F. If the connections are correct, the fuse will not blow when the transformers are made alive without load; otherwise the fuse will blow. In case of a wrong connection it may be remedied by crossing either the high or low-voltage leads on one of the transformers, as indicated in fig. 6. A better way would be to test the transformers and find out which has wrong polarity and correct it.

The polarity may be tested as represented in fig. 7. Connect the high-voltage terminals to the line and with one terminal of the low-voltage coil to the high-voltage winding, as indicated in the figure. Measure the electromotive force at Ep and E'. If it is greater at E' than at Ep the transformer has the correct polarity; if less, the polarity is wrong and either the high or the low-voltage leads must be crossed inside the transformer. The test may be made with 110 or 220-volt current.

THE ENGLISH ELECTRIC CO.'S. TRANSFORMERS.

In these transformers the windings are designed so that there is ample provision for the circulation of oil; this assures a very low temperature gradient between copper and oil, so that any danger of excessive heating is eliminated. Two patterns are manufactured, viz. the 'core' type and the 'shell' type. The principal advantage of the latter type, which is specially suitable for single-phase units and for exceptionally heavy currents, is that the windings are completely boxed in with insulation, which is built round with the core or the clamping gear; this design results in a very robust and solid construction, which is very well able to withstand the forces caused by short circuit. The disposition of the windings is such that the oil ducts are in a vertical plane, which is an ideal condition to produce rapid circulation of oil, and, consequently, improved temperature conditions.

Fig. 46 (p. 2297) shows the general arrangement of these transformers.

All coils are rectangular and are wound in flat single sections with one turn per layer. In general, three types of coil are used, the choice depending on the current and voltage. For 'low voltages' the conductor consists of one or more rectangular double-cotton-covered wires. Insulation between the single-turn layers is provided by strips of hard insulating material. For 'high voltages' the conductor is a flat wire with half-round edges. It is encased in a sleeve of insulation consisting of several layers of highest quality paper. Each layer is applied as a strip wound spirally with the edges butting but not overlapping, and successive layers are staggered so that their edges do not coincide. In addition a strip of hard insulation is inserted between layers.

For 'very heavy currents' the conductor consists of a number of rectangular double-cotton covered wires wound one over the other. Each coil or section has only one turn, and a complete group of adjacent sections is wound as a continuous single layer coil of several turns. This arrangement avoids the necessity of joints between adjacent sections.

In all types of coil, to the inside of the first turn and to the outside of the last turn is taped a strip of insulation which maintains the necessary creepage distance between adjacent coils round the projecting edges of the washer that is placed between them.

As before stated, a very important feature in the design of the windings and insulation is the adequate provision that is made for the circulation of oil, so that a very low temperature gradient between copper and oil is assured, and any danger of excessive local heating eliminated. With this object the H.V. and L.V. windings are arranged in a sandwich manner, the number of groups depending on the output of the transformer and the reactance required. Adjacent coils are separated by a washer and oil duct, the latter being maintained by suitable spacers of insulating material. Along the vertical portions of the coil these spacers are wave-shaped and are so disposed that every wire is supported and is also exposed to oil for the greater part of its length. At the corners of the coil specially formed spacers are used to deflect oil into the horizontal portions which are not in the direct line of oil flow. The complete set of coils in a group is assembled with the various channels, angles, and sheets of insulating material which provide the necessary insulation between H.V. and L.V. windings, and between the windings and the core, and the whole is bound together with strong webbing. Finally, all the groups are banded tightly together so that the

omplete windings and insulation can be handled as a single unit. The insulation used is suitable or forming into the various shapes required, and possesses the property of very readily absorbing il, in which state it has the useful feature that its dielectric constant approximates to that of oil.

The amount of insulation between turns is determined not by the normal volts per turn, but y considerations of line voltage and service conditions. At the ends of the windings adjacent o the line this insulation is considerably reinforced to withstand the effect of surges. The rein- orcement is graded down through approximately 5 per cent. of the total number of turns, to the ıormal insulation used in the body of the winding.

The core is built of thin laminations of very high quality non-ageing silicon steel, and one ide of each lamination is coated with an insulating material that does not deteriorate with heating. The shape of the laminations is rectangular, and for single-phase transformers there are only two lifferent sizes, while for three-phase transformers only four sizes are required. The complete set of windings and insulation is placed in position in a massive structural steel frame on which the ore is built, and the laminations are stacked around the vertical coil sides with the corner joints arefully interleaved. The completely assembled core is clamped very tightly by means of strong ie-bolts that unite the bottom frame with a similar one placed on top of the stack of laminations, vood packing being inserted between the frames and the core. In the largest transformers liagonal cross braces are used between the upper and lower frames to prevent distortion of the ore during transport.

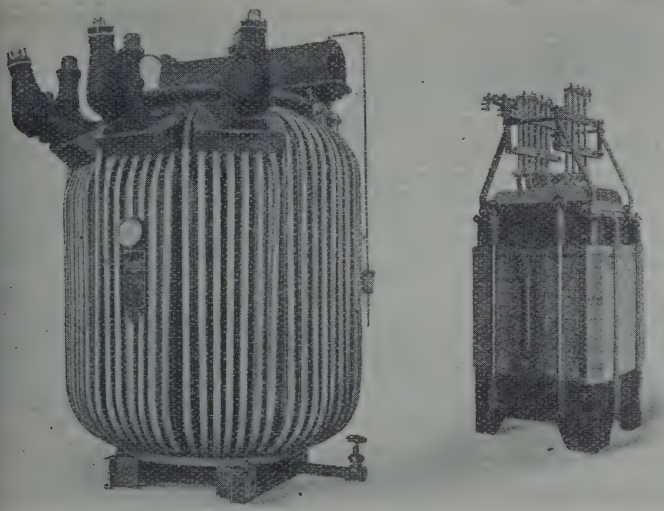

FIG. 46.

For single-phase transformers circular tanks are used : for three-phase transformers the tanks ıave flat sides and half-round ends. These designs result in tanks of great strength and remarkably leasing appearance. All tanks are of boiler plate with welded seams. Round the top of the ank side is welded a strong rim of steel to which the flat boiler plate cover is bolted. Massive ifting lugs are riveted to the tank side, and in order to prevent oil leakage along the rivet holes . thin plate of steel is welded inside the tank so as to enclose all the rivet heads. The design of he tank and lugs is such as to permit the complete transformer filled with oil to be lifted. The ank is supported on a structural steel base in which plain or flanged rollers can be fitted if required. A valve is fitted at the lowest point of the tank, so that it may be completely drained of oil. A auge is supplied so as to indicate at all times the level of the oil. A thermometer pocket suitable or the insertion of an ordinary mercury thermometer is provided on the tank side or cover.

In general, outlet terminals are located in the cover. For low voltages solid porcelain bushings ıre used : for voltages above 40,000 the bushings are of the condenser type. For very heavy urrents the outlet terminals consist of copper bars brought out through the cover.

Metropolitan Vickers Electrical Co.'s Transformers.

Metropolitan Vickers transformers include a wide variety of power and distribution transformers for either indoor or outdoor service; specially designed transformers for use with rotary converters, electric furnaces, high-voltage tests, and for collieries; also voltage and current transformers for use with all forms of electrical instruments and protective relays.

Both 'core' type and 'shell' type constructions are employed, but for normal conditions and capacities, single-phase units are most commonly made of the shell type, and three-phase units of the core type. Shell-type, single-phase transformers have been supplied in units up to 18,13 kva., and three-phase, core-type transformers up to 25,000 kva.

The highest pressure for which 'Metrovick' transformers have so far been built for publi service is 132,000 volts, but all experimental work has been done and designs have been com pleted for transformers for service up to 220,000 volts. Transformers to give 500,000 volts hav been installed in the high-tension research laboratory, and enabled routine tests and research wor to be carried out at pressure up to over one million volts.

Considerations affecting the choice between groups of three single-phase transformers an three-phase transformers are capital cost, spares, floor space, and continuity of supply. A three phase transformer is approximately 10 to 15 per cent. lighter in weight than a bank of thre single-phase transformers, while the latter require approximately 50 to 70 per cent. more floo space than the three-phase unit. On the other hand with groups of single-phase units a singl unit can be carried as a spare for three or four groups; also a breakdown fault would be confine to one unit, whereas in a three-phase transformer a failure on one phase may cause damage t the other two phases.

Self-cooled transformers can be built in sizes up to approximately 20,000 kva. capacity, but i sizes above 4,000 kva. a saving can usually be made by artificial cooling. Methods of artificia cooling of oil-immersed transformers include a water-cooling coil fitted inside the tank at the top an outer sheet metal casing for cooling by air blast from motor driven fans; pumping the o through a cooler of either the water or the air-blast type mounted outside the transformer.

Dry transformers up to about 150 kva. single-phase and 200 kva. three-phase are supplie protected by an expanded metal screen. Above this capacity, dry-type single-phase, air-blas transformers have been supplied to a limited extent for ratings from 300 to 1,500 kva.

The increasing cost of erecting buildings has emphasised the advantages of installing trans formers out of doors. This practice is being favoured for large power transformers in the layou of modern large generating stations and sub-stations, for which Metrovick transformers of th outdoor type have been installed for service up to 132,000 volts, and also is being adopted in creasingly for power and lighting transformers in rural distribution systems.

A development that is finding increasing favour is a tapping switch mounted within th transformer and operated from outside the case. This switch enables voltage changes to be mad quickly and without opening the tank, so that interruption is reduced to a minimum and eve at the highest voltages perfect safety is ensured to the operator. Transformers have been supplie so arranged that tap changing can be effected without any interruption in the continuity of supply Another convenient device for tap changing on distribution transformers is a set of sockets an adjustable plugs. This device enables transformers of a standard voltage to serve the require ments of a whole system, the voltage of individual transformers being adjusted, at the time o installation or subsequently, to compensate for voltage drop in the transmission lines.

Notes on Transformers.

To seal up holes in transformers or oil-switch cases where wires pass through, a mixture o sulphur and plaster of Paris may be used; a mixture containing equal quantities gives a materia which sets very hard, and which is impervious to transformer oil. The sulphur should be melte in a ladle or pot and then an equal quantity of plaster of Paris mixed thoroughly into it. Thi mixture should be poured into place while hot.

Trouble is often experienced from oil being siphoned out of transformer cases on account of th braided insulation on the lead wires. When this takes place it is usually found that the insulatio on the wires dips down into the oil. If the oil level is lowered below the terminal board insid the case and the insulation on the leads scraped off so that where the wire enters the surface o the oil its metallic surface only is exposed to possible contact with the oil, and the leads ar properly sealed, there will be little trouble due to siphon action.

Static Balancers in Three-Phase Circuits.

In three-phase distribution circuits, the voltages commonly used for power purposes are ofte too high for lighting circuits; accordingly, where lighting is desired, it is necessary to introduc some means of obtaining a reduced voltage. A customary method of providing for this is to tak

dvantage of the fact that by using a star connected generator or transformer having its secondary inding connected in star, it is possible to obtain between any one phase and the neutral point f either generator or transformer a reduced voltage. For example, in a circuit with 400 volts etween the phases, it is possible, by taking out a connection from the star point, to obtain a

oltage between this point and any one phase of $\frac{400}{\sqrt{3}} = 230$ volts only. To do this, however, the

enerator or transformer has to be star connected in such a manner that a cable can be brought ut from the star point, and this cable must be led to the point where lighting is required. Apart om the cost of this cable, which for any distance is considerable, any out-of-balance lighting ould cause unbalanced voltages due to the resistance of this cable and thus would affect the

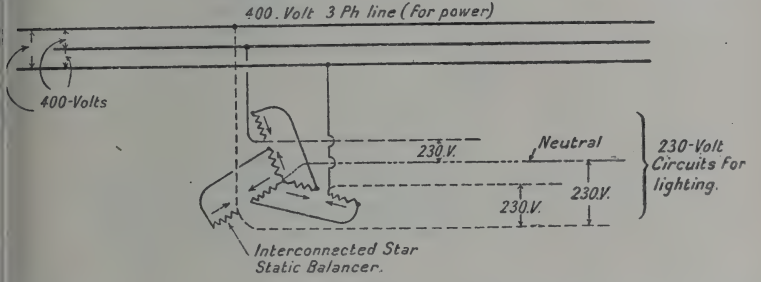

FIG. 47.

ghting detrimentally. Alternatively to the above arrangement, it is possible, by using static alancers, to save the cost of the cable referred to, and also to minimise very largely the out-of-alance effects.

The Metrovick static balancer, which is shown diagrammatically in fig. 47, consists of a hree-phase auto-transformer having a lead brought out from the neutral point of the windings, nd the three phases so inter-connected, that current flowing through the neutral passes equally hrough them.

Static balancers for ordinary industrial conditions are quite small, and of correspondingly ow cost. On a 100-k.v.a. circuit, with a maximum out-of-balance current not exceeding 25 per ent. of the full-load current in the outers, a balancer would be similar in size to a 5-k.v.a. trans-ormer, and under these conditions, the out-of-balance of the phase voltage would correspond o one-third the percentage voltage drop of such a 5-k.v.a. transformer. In cases where the oltage required for lighting is not exactly but only approximately the line voltage divided by $\sqrt{3}$ a combined balance and auto-transformer may be used to advantage.

The advantages gained by using static balancers are: (1) The balancer may be placed at any oint on the system where lighting is required and the length of neutral wire greatly reduced. 2) The drop in the neutral wire is much reduced, so that better voltage balancing is obtained etween the different phases. (3) The current is more equally distributed between the line wires. 4) A standard polyphase wattmeter can be used instead of a special four-wire wattmeter. (5) It s possible to supply a four-wire circuit from a transformer group connected in star-star or star-elta, thereby saving in the cost of the main transformers.

Induction Regulators and Booster Transformers.

(The English Electric Company, Ltd.).

The principal applications of induction regulators and booster transformers are:

1. The regulation of feeder voltage under all conditions of load.

2. The control of the reactive current in ring mains and in interconnector cables linking power areas where it is desirable that the station voltages shall be variable independently of each other.

3. The control of the alternating voltage applied to the slip-rings of synchronous converters in order to obtain voltage control on the direct current side.

Booster Transformers.

The apparatus consists of a potential and a series or current transformer. The primary winding of the potential transformer is connected across the mains and the secondary provided with a number of tappings which are brought out to a regulating switch. The series transformer has its secondary winding in series with the line and its primary excited from the variable secondary of the potential transformer, as shown in Fig. 48. When the reversing arm of the regulating switch

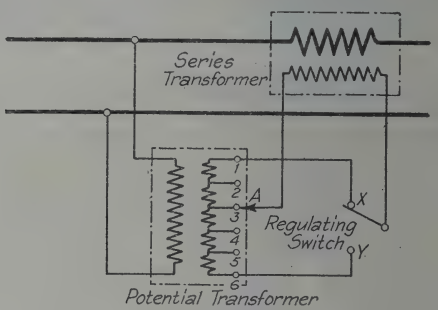

FIG. 48.

is on contact X, and the tapping contact A is on stud No. 1, the primary winding of the series transformer is short-circuited and the secondary of the potential transformer is open-circuited. The voltage of the feeder therefore is unaffected and the potential transformer takes only a magnetising current. As contact A is moved successively to studs 2, 3, etc., a voltage will be induced in the secondary winding of the series transformer and the outgoing line voltage increased. The voltage boost is thus a maximum on stud No. 6. If the operation be commenced with the reversing arm on control Y, then the tapping contact A on stud No. 6 gives normal mean voltage, and movement to successive studs Nos. 5, 4, etc., will induce in the series transformer a voltage opposing the line voltage; while on stud No. 1, the outgoing feeder voltage will be a minimum. To ensure continuity of circuit, the English Electric Co.'s booster transformer has a main circuit breaker and a pilot circuit breaker with renewable contacts which take all the arcing, the pilot breaker completing a circuit through a choke coil or buffer reactance. A 3-phase booster transformer consists of three separate identical units coupled together for simultaneous operation by hand, or motor operated from remote control, or by means of contactors. Where the supply voltage does not exceed 3,000 it is possible to omit the series transformer and to use the tapped secondary winding of the potential transformer directly in series with the line.

Induction Regulators.

Induction regulators provide a means of gradual change in the feeder voltage without the interposition of switches. They consist of two elements, one fixed and the other movable at will through 90 degs. for the 4-pole design and 180 degs. for the 2-pole. In double-range regulators the movements are through 180 and 360 degs. for 4- and 2-pole types respectively. The construction is similar to that of an induction motor, but usually with a vertical shaft. The rotor shaft projects through the tank cover and has keyed to it a worm quadrant which engages through reduction gearing with a handwheel or motor.

With single-phase regulators, the magnetic flux produced by the movable primary winding is pulsating and the voltage induced in the stationary secondary winding, connected in series with the line, is proportional to the amount of this flux linked with it. The movable primary carries a short-circuited compensating winding which is electrically and mechanically at right angles to the primary winding. As the regulator approaches the neutral position the reactance of the series winding is neutralised by this short-circuited coil.

In three-phase induction regulators the magnetic field rotates and the secondary windings are linked by a constant value of flux irrespective of the angular position. The secondary voltage is therefore constant and is added to or subtracted from the feeder voltage by varying its phase angle relatively to the feeder voltage. This is shown in Fig. 48A, in which OA is the line voltage, OB is the secondary voltage per phase, and AB the resultant feeder voltage. The regulated voltage AB and the unregulated voltage OA are only in phase with one another at the maximum and minimum

positions of the regulator. In ring mains or in an interconnector cable linking generating systems, phase displacement would cause circulating currents to flow. To correct this displacement it is necessary to resort to (1) the twin induction regulator, where each unit is half the total kva. rating required, or (2) a bank of single-phase regulators.

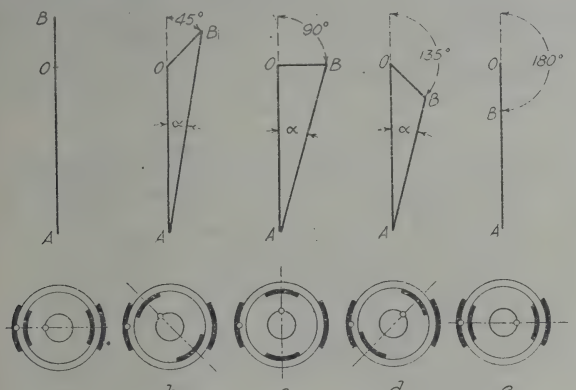

FIG. 48A.

The English Electric Co.'s induction regulators are designed for air cooling and for oil self cooling for upwards of 1,000 kva. in one unit. Very large sizes are designed for forced oil circulation. There is a growing tendency to accommodate induction regulators with the transformers and switchgear of outdoor substations. The operating gear is then enclosed in a weatherproof cover and the control panel, with its sensitive relays, mounted in an air-tight metal cabinet.

Power Factor Improvement.

With the continual growth of alternating current distribution, the necessity of improving the power factor resulting from an industrial load has become more and more apparent, as a low power factor, by reducing the working capacity of the generating plant and mains and lowering the efficiency of the system, adds to both the fixed and the running charges, besides unfavourably influencing the voltage regulation of the network. In fig. 49 curves are given for commercial induction motors at 500 and 1,000 r.p.m., showing the effect of output and speed on the power factor at various loads.

The power factor can be raised by three methods:—(1) Static condensers; (2) Rotary condensers; (3) Phase adjusters.

(1) Static condensers afford one of the simplest and most efficient solutions of the problem, as they require no attendance and involve very little loss of energy. In the *General Electric Review* of August 1918, W. B. Taylor gives a diagram, fig. 50 (page 2303), by means of which the capacity of the static condenser required to neutralise more or less completely the wattless component of the power can be determined. The use of the diagram is best explained by an example. An a.c. feeder carries a current of 500 amperes at 500 volts, and the power factor is 0·6; required the capacity necessary to raise the power factor to 0·9. Taking on the 0·6 p.f. line the point corresponding to 250 k.v.a., it will be found that the wattless k.v.a. (ordinate) is 200 and the energy kw. (abscissa) 150. The 150-kw. ordinate cuts the 0·9 p.f. line at a height corresponding to 73 wattless k.v.a. Subtracting 73 from 200 gives 127 k.v.a. as the required condenser capacity. Similarly 88 k.v.a. would raise the power factor to 0·8 and 47 k.v.a. would raise it to 0·7.

The effect of added capacity is greatest when the power factor is lowest; owing to the relatively large capacity required to bring the power factor up to unity, it is not commercially advisable to attempt to raise it much above 0·9. The condensers should be fixed near the load, in order to improve the power factor in the mains as well as at the generator. The condensers should

be disconnected at times of light load, if the leading current they can then take be no required in other parts of the system. High voltage and high frequency are favourabl to the use of static condensers; they are made for pressures up to 750 volts by the *British Insulate and Helsby Cables, Ltd.*, and for higher pressures they are connected in series. In the case c low pressures such as 400 volts, it may be found economical to install transformers to raise th voltage at the terminals of the condensers, thus reducing the capacity required. Another metho is to insert a suitable amount of inductance in series with the condensers, whereby the pressur across the latter is increased. To protect the condensers, the control switches should be fitte

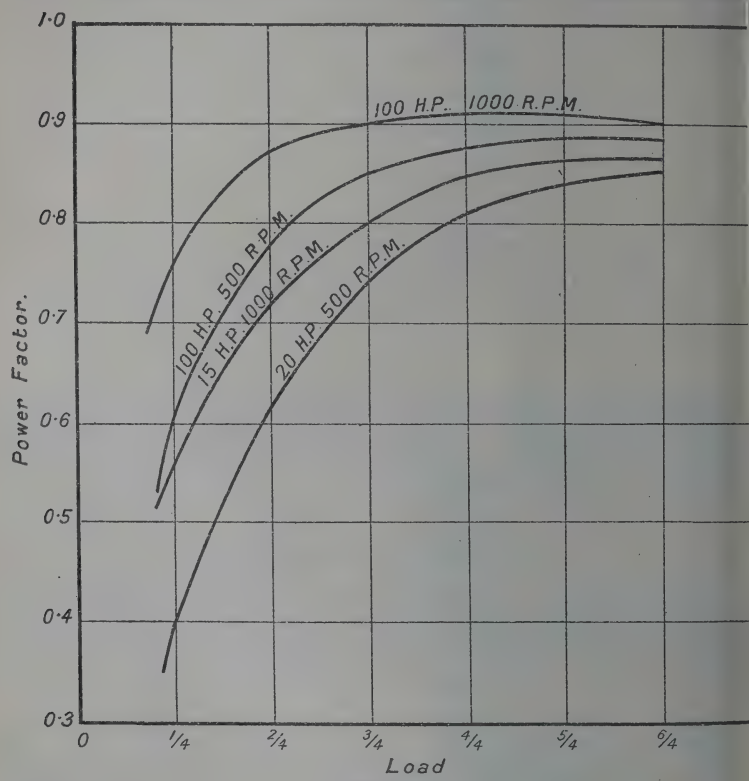

FIG. 49.

with overload trips, and to prevent accidents due to the stored-up charge, provision should be made for discharging the condensers through resistances when they are switched off. The efficiency of condensers exceeds 99·5 per cent.

(2) Rotary condensers are simply synchronous a.c. motors, over-excited so as to take a leading current, in which condition they act like static condensers. The motor may be run without load, but in this case the method is costly, and it is preferable to use a loaded motor. A rotary converter can be employed for the same purpose. The necessary capacity to produce a given improvement in the power factor of the system is determined in the same way as that of static condensers, using fig. 50; the greater the mechanical load on the motor, the less will be its condenser effect, the rule being that the square of the k.v.a. capacity of the machine is equal to the sum of the squares of the kw. load and of the wattless k.v.a., so that the motor is used to the best advantage when the wattless output = the power output × 0·71 of the k.v.a. rating of the motor. The synchronous motor is usually started up as an induction motor with the aid

f an auxiliary squirrel-cage winding embedded in the poles of the field system, or by means of n induction motor coupled to the same shaft, the field being unexcited until full speed is attained; irect-current excitation must be provided, either by a direct-coupled exciter or by an external ource.

(3) The phase adjuster is a special machine, resembling a commutator induction motor, hich is coupled to the slip-rings of an induction motor whose power factor needs correction, and mechanically driven, either from the shaft of the main motor or by a small separate motor, the ower taken being only that required to overcome friction and windage, and being fully compen- ated by reduced losses in the main motor. The function of the phase adjuster is to supply the agnetising current for the motor, thus raising the power factor to unity, or even passing that

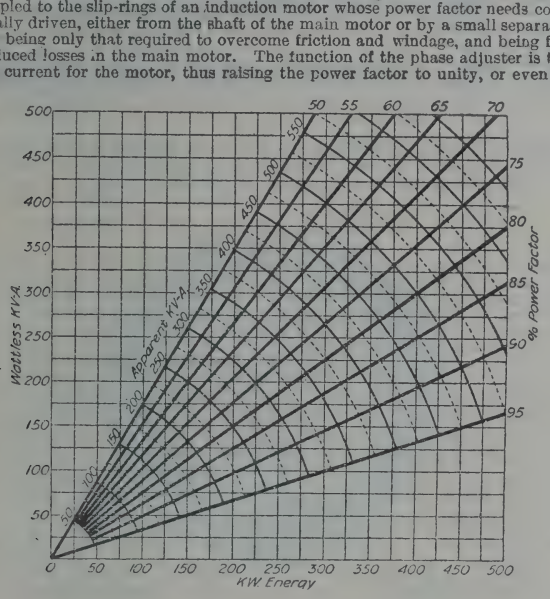

FIG. 50.

int and supplying current to the system to compensate for low power factor in other machines. 1 oscillatory type of phase adjuster is also made. A great advantage of this method is that e power factor of the individual motor is improved, so that a smaller motor can be used, with luced losses. Advantages common to all methods are that the losses in the generators and oles are reduced, and the load factor of the plant is raised so that fewer generators need be), and considerable economy of fuel as well as of capital outlay can be effected.

Electric Measuring Instruments.

Ammeters and Voltmeters.—The types available are (1) Moving-coil, permanent-magnet; Moving-iron; (3) Hot-wire; (4) Dynamometer; (5) Induction type; (6) Electrostatic volt- ters.

The following British Engineering Standards Association Specifications deal with electric asuring instruments:—

No. 81—1927. Instrument transformers.

No. 89—1926. Indicating ammeters, voltmeters, watt-meters, frequency and power tor meters.

No. 90—1927. Graphic (Recording or Chart-Recording) ammeters, voltmeters, and watt- ters.

Sizes of Enamelled Copper Wire for Electrical Instruments.

A 'tentative' British Standard Specification No. 156 (1922), has been issued, giving the ensions and resistances of enamelled copper wire for instruments and apparatus. The sizes

of the bare wires correspond with those given in Specification No. 128 above. Tests are pr scribed as follows:—

Mechanical.—The enamel must not be easily removed from the wire with the thumbna Below 0·0084 in. diameter, a 10-in. sample shall be extensible to 11 ins. without cracking t enamel; above that diameter, a sample shall be wound round a mandril not more than fo times the diameter of the bare wire without cracking the enamel.

Chemical.—The enamel shall not be dissolved when immersed for one hour in absolu alcohol or dilute sulphuric acid (sp. gr. 1·25); and the samples shall pass the mechanical tes after immersion as above.

Baking.—After baking at 266° F. for one hour the samples shall pass the mechanical tests.

Electrical.—Test samples twisted together shall withstand an arc test at a pressure varyi from 150 volts (R.M.S.) up to 0·0032 in. to 1200 volts above 0·029 in. diameter. A samp passed through a mercury bath at a p.d. of 6 volts d.c. shall not make more than forty contac in 50 yards.

The thickness of the coating prescribed ranges from ¼ mil on the smallest wires to ½ mil 6 mils diameter, 1 mil at 28 mils diameter, and 1·1 at 48 mils, but wide limits of variati are permitted. Tables of minimum and maximum dimensions are given.

Weston Standard Ammeters and Voltmeters.

Direct Current.

In these instruments, although the scales are remarkably uniform, no particular 'law' deflections is assumed, as must be done when printed or engraved scales are used. A skeleton each scale is laid out by actual comparison with an accurate standard, and the lines afterwards a inked in. Finally, the work is checked by comparison with the same standard. No multiplyi constant is necessary (except with high-range voltmeters), as simple inspection of the position the pointer on the scale gives the value in amperes or volts. Time in making readings is therefo saved, and errors of calculation are avoided. The scales of all direct-current instruments ha practically uniform divisions from zero to the top mark. The range is thus greater than is commo while the uniform size of the scale divisions permits of their visual subdivision with unifor accuracy. The pointer comes to rest at once, although absolutely no friction can be detecte thus reducing the time required for readings, and preventing unnecessary wear of the moving part

There is no 'magnetic lag,' giving rise to different deflections with the same current or pote tial, as in instruments having iron in the moving parts. The 'temperature correction' is negligib being for all voltmeters having a range above 15 volts, not greater than ¼ per cent. for a range 35° F. above, or 35° below, 70°, and for the ammeter, less than 1 per cent. for the same range temperature. The instruments of the 'Direct Current' type may be kept in circuit any leng of time, as the heating effect, except in the higher ranges, is so small as to be inappreciable. the voltmeters provided with a 'calibrating' coil, changes in scale-value resulting from accident injury are easily checked; this is a very valuable feature, as all instruments are subject to occ sional accidents and to rough usage, which may prove injurious. The user of these instrumen can at any time roughly check their scale-values by applying a single cell of some constant for to the terminals of the calibrating coil.

Alternating and Direct Current.

These instruments can be used in measuring the current or voltage of both alternating a direct-current circuits with equal accuracy, being of the electrodynamometer type. Owing the principle of operation, they cannot be made with a uniform scale throughout, but the upp two-thirds of the scale is practically uniform. To prevent errors from parallax, mirror scal plates and knife-edge pointers are provided. The entire movable and field coil system is mount in a double closed iron shield, which effectually protects it from external magnetic fields a electrostatic influences. Damping is accomplished by means of an air damper, which is ve effective.

In voltmeters it is necessary for great accuracy to have the current taken by the instrume as small as practicable; the Weston Model 341 voltmeter is designed with this object in vie and the current required is much less than is usual in this type of instrument. For ordina measurements no corrections are necessary for temperature or for frequencies up to 133 cycl per second, nor is it necessary to take reverse readings on direct-current circuits. When gre accuracy is required, however, such corrections can be made. The instruments may be l in circuit continuously. In general, they are guaranteed to have an accuracy of ¼ of one per cen of full-scale value on the working portion of the scale.

Similar characteristics are found in the portable wattmeters made by the company.

All ammeters are really milli-voltmeters, as they merely measure the drop of potential acr a constant resistance. This constant resistance is termed a shunt. The potential drop is direct proportional to the current passing through the shunt, and if the shunt is correctly designe the instrument can therefore be graduated in amperes. The resistance of these shunts is ve low: for a Weston switchboard ammeter of 100 amperes the resistance of the shunt is approx mately 0·0005 ohm. The shunt must not be strained when fixing to the bus bars, for strain might affect the resistance and so alter the reading of the instrument. For this reason shunts a usually securely fastened to a base of hard wood. Low-range ammeters up to about 200 amper can have the shunt contained within the instrument case. The resistance of the instrumen

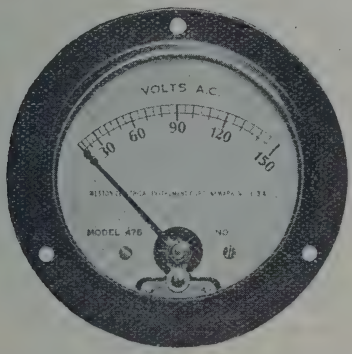
SMALL PANEL INSTRUMENTS FOR ALTERNATING CURRENT



MODEL 476.		MODEL 517.	
Case Diam.:	2·56″	Case Diam.:	2·06″
Flange Diam.:	3·25″	Flange Diam.:	2·56″
Depth:	1·63″	Depth:	1·72″
Scale length:	2″	Scale length:	1·5″

List Price from 40s.

THE SPECIAL FEATURES OF THESE TWO NEW MODELS ARE :

Low Power consumption. Excellent Damping.
High Sensitivity, *i.e.*, 6 mA for 300 volt range and approximately 9 mA for 150 volt range.
Accuracy 2 per cent. for A.C. (commercial frequencies), and also suitable for D.C. circuits.
High Self-contained Range, *i.e.*, up to 300 volts.
Legible Scale. Weston Manufacture.

WESTON

Instruments for Research.

For Research Work the following Portable Instruments are recommended:

	Accuracy.	Scale Length.
Model 1, Standard Portable D.C. Ammeters, Mil-ammeters, Voltmeters and Milli-voltmeters	$\frac{1}{4}\%$	$5\frac{1}{4}''$
Model 5, Laboratory Standard D.C. Ammeters, Mil-ammeters, Voltmeters and Milli-voltmeters	$\frac{1}{10}\%$	$11\frac{7}{8}''$
Model 310, Standard Portable Single-phase A.C. and D.C. Wattmeters, including Special Low-power Factor Instruments	$\frac{1}{4}\%$	$5\frac{1}{4}''$
Model 329, Standard Portable Polyphase Wattmeters	$\frac{1}{2}\%$	$5\frac{1}{4}''$
Model 322, Standard Portable Micro-ammeters	$\frac{1}{4}\%$	$5\frac{1}{4}''$
Model 341, Standard Portable A.C. and D.C. Voltmeters	$\frac{1}{4}\%$	$5\frac{1}{4}''$
Model 370, Standard Portable A.C. and D.C. Ammeters and Mil-ammeters	$\frac{1}{4}\%$	$5\frac{1}{4}''$
Model 326, Electrodynamometer Laboratory Standard A.C. and D.C. Ammeters Voltmeters and Wattmeters	$\frac{1}{10}\%$	$12''$
Model 412, Portable Thermo Voltmeters, Mil-ammeters and Ammeters	$\frac{1}{2}\%$	$5\frac{1}{4}''$
Ranges from 2 M.A. Res. 750 ohms for D.C. and A.C., including radio frequencies. Voltmeters from 0—3 volts, sensitivity 27 ohms per volt to 125 or 500 ohms per volts.		
Model 492, Portable Thermo Voltmeter for frequencies up to approximately 2,000,000 cycles.		
Ranges 1 volt (140 ohms per volt) to 20 volts (500 ohms per volt). Accuracy at 600,000 cycles.	$\frac{1}{4}\%$	$5\frac{1}{4}''$

WESTON Transformers of high accuracy are supplied to operate in conjunction with our A.C. Instruments.

Full particulars will be sent upon application.

NEW ADDRESS,

15 GREAT SAFFRON HILL, LONDON, E.C. 1.

Telephone No.: 2029 Holborn. Telegrams: 'Pivoted, Smith, London.'

(See also previous page.)

oes not exceed about 2 ohms, and about 25 to 30 milli-amperes is required for full-scale eflection.

Voltmeters which are placed directly across the circuit must be high-resistance instruments. hese only require about 10 or 15 milli-amperes for full-scale deflection. For special testing work 'eston voltmeters can be obtained which have a resistance of 2,500 ohms per volt, and only quire 0·0004 ampere for full-scale deflection. It is important to have a high-resistance volt- eter for testing the E.M.F. of dry batteries, etc.

Owing to the temperature coefficient of copper being high, all copper in the instrument ould be reduced as much as possible to eliminate temperature errors. The moving system ould be as light as possible to reduce the wear upon the pivots, which should work in good wels. The air gap must be small to ensure the permanence of the magnet, which must be ecially aged and carefully made. In Weston instruments the air gap is approximately 0·04 in. ny number of different range shunts may be used with moving coil ammeters, so that accurate adings may be taken over a wide range.

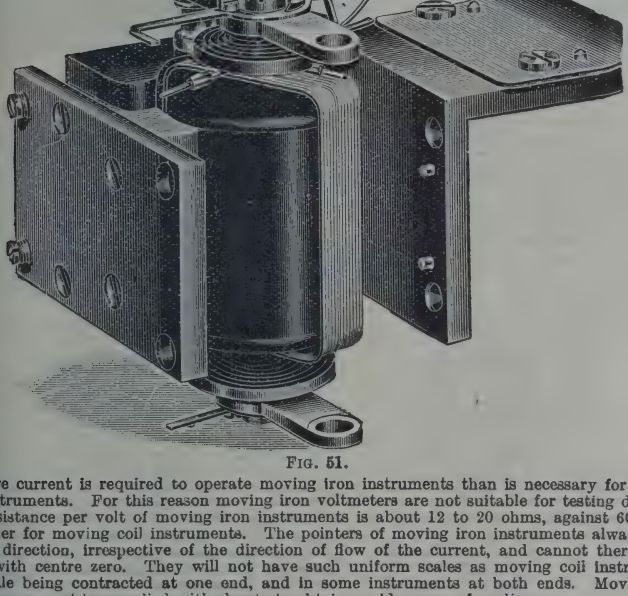

FIG. 51.

More current is required to operate moving iron instruments than is necessary for moving il instruments. For this reason moving iron voltmeters are not suitable for testing dry cells. e resistance per volt of moving iron instruments is about 12 to 20 ohms, against 60 to 100 higher for moving coil instruments. The pointers of moving iron instruments always move one direction, irrespective of the direction of flow of the current, and cannot therefore be ade with centre zero. They will not have such uniform scales as moving coil instruments, e scale being contracted at one end, and in some instruments at both ends. Moving iron ameters cannot be supplied with shunts to obtain a wide range of readings.

In reading instruments, the eye, the pointer, and the mark on the scale should be in a line at ht angles to the plane in which the pointer moves, in order to avoid errors due to parallax. edgewise instruments this line of vision must pass through the centre of the arc swept out by e pointer; one eye must be closed. In multi-range instruments each range should be a simple ultiple of the other ranges; and the figures upon the scale of the instrument should preferably dicate the number of scale divisions. An instrument having a range of 150 or multiples thereof ould be calibrated to have 150 divisions, figured 0–150. There is less liability of error in ading direct in scale divisions, and afterwards multiplying by a correct constant, than in entally calculating the value of a fraction of a scale division, especially if there is a rapidly ctuating load.

The accuracy of an instrument is best expressed as a percentage of the maximum load the strument is intended to measure. For instance, an instrument having a range of 500 volts th an accuracy of $\frac{1}{10}$ per cent. should be correct at every point upon the scale to within half a lt. If the instrument has 100 scale divisions, this corresponds to $\frac{1}{10}$ of a scale division, hich could be accurately read upon a portable instrument with a knife-edge pointer working er a mirror to eliminate errors due to parallax. If, however, the accuracy is taken as a per- ntage of the actual reading, when reading this instrument at 100 volts the error would not

have to exceed 0·1 volt, which would correspond to $\frac{1}{10}$ of a scale division, and would not readable by the naked eye. If the instrument is supplied with an additional range to re 0–100, an accuracy of $\frac{1}{10}$ per cent. upon this range would represent 0·1 volt, and would cor spond to $\frac{1}{10}$ of a scale division.

Fig. 51 shows the moving coil of a Weston d.c. milli-voltmeter in position, for which purpose t magnet and one pole piece have been removed. The moving coil is a light rectangular aluminiu frame, upon which are wound a few turns of silk-insulated copper wire: this frame is pivoted work in hard and highly-polished sapphire jewels. The pivots are small, specially harden and very finely ground and polished, so that no friction can be detected when they work in t jewel centres. The moving coil rotates in the narrow air gap formed between the pole piec only one of which is shown, and a soft iron core. As this air gap is only 0·04 in. it is essent for the moving coil to be very accurately pivoted, so as to move freely in this narrow angu space. With such a narrow air gap it is also necessary for the sides of the rectangular fra to be formed to a radius slightly greater than the radius of the core. The motion of this c is controlled by two flat spiral springs, which are made from a special Weston alloy; they arranged to work in opposition to each other, so that one uncoils and the other coils up when t moving coil rotates. The inside end of each spring is fastened to one end of the winding up the coil, and the outside end fastened to an adjustable arm. One of the binding posts is connect directly to one of the arms, and the other binding post is connected to the other arm through suitable resistance. The magnet, which is very carefully aged, is accurately ground to fit o the pole pieces, to which it is securely fastened.

The Synchroscope.

Apart from special methods only applicable to polyphase machines, two devices are in gene use for synchronising alternators, (*a*) the synchronising lamp or voltmeter, and (*b*) the rotat field synchroscope. The former is more simple, but suffers from the defect of being insensit as regards the exact moment of switching in, which should be when the machines are in ex coincidence of phase. Machines may be as much as 16° out of phase before the s hronising voltmeter shows 1 per cent. of variation from its maximum reading, so that a li rror of judgment may result in a considerable shock on switching in. A further objection is t lthough the rapidity of fluctuation of the lamp or voltmeter reading indicates the differe between the frequencies of the machines, there nothing to show which of the two machines is faster, and considerable time may thus be wast In order to make the lamp method of real servi therefore, it is necessary to combine it with so device for indicating exact coincidence of ph and also whether the incoming machine is fast slow; and this is what has been done in the West Synchroscope.

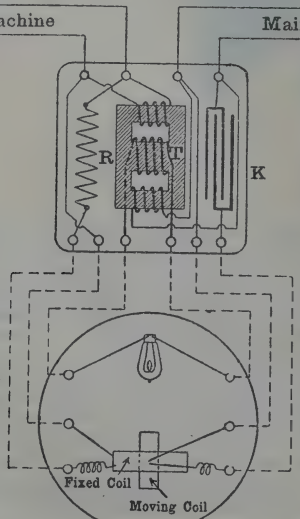

FIG. 52.

If an ordinary dynamometer wattmeter both its fixed and moving coils wound with f wire, and two alternating voltages are applied the terminals of these coils, it will show v accurately when these two voltages are in ex *quadrature*, as the wattmeter will indicate zero this case, and deflect to right or left if the ph difference is greater or less than 90. By conne ing a condenser in series with one of the coils, a introducing a small amount of inductance into t other, it is easy to arrange that the wattme indicates zero when the two voltages are in ph instead of in quadrature, and this can be check by connecting the two circuits to the same supp Under these circumstances, if one circuit is co nected to the bus bars and the other to t incoming machine it is only necessary to see th the synchronising lamp is bright and the wa meter pointer at zero to be able to throw in witho any shock.

But this only indicates when the machin are in exact synchronism, and not whether t incoming machine is too slow or too fast. If t speed of the incoming machine is low or hig the lamp will flicker in the ordinary manner a the wattmeter will also deflect to right and l alternately as the voltage of the machine alternately lags and leads with respect to that of t bus bars. The rate of oscillation of the pointer, like the rate of fluctuation of the light, sho the amount by which the speed of the machine is high or low, although neither of them by its indicates which. But if the lamp and wattmeter are combined, so that the dial of the latter

uminated by the former, the difficulty is at once solved. For if the machine is fast the watt-eter pointer swings over from left to right while the lamp is bright, while when it swings back ie lamp is dark. In consequence the backswing is not seen, and instead of the pointer appearing oscillate it appears to rise with the dawn of light at the left-hand side of the scale, to swing ross in full light and to disappear on the right of the dial with the extinction of the light, almost actly like the rising and setting of the sun, and as if it were steadily revolving in one direction. hen the machine is slow, the lamp is bright as the pointer swings from right to left, and the rection of rotation is therefore apparently reversed. As far as its practical application is ncerned, the instrument resembles in every way the rotating field synchroscopes (except that ie fluctuation of the light is visible), and the arrangement is extremely simple, and free from ıy loose contacts.

The actual indicating instrument is almost identical in construction with the switch-board attmeter, the only differences being that the dial carries a bold central mark with two arrows ıdicating 'Fast' and 'Slow,' and that the synchronising lamp is inserted behind it. This lamp ın be easily withdrawn and replaced. An auxiliary box contains an ordinary synchronising ansformer, T, for the lamp, and a non-inductive resistance, R, and a condenser, K, for connect-ıg in series with the two wattmeter coils respectively. A small inductive coil for adjusting ie exact quadrature is included in the instrument case. Fig. 52 is a diagram of the connections the instrument and box, which will be readily understood from the principle of the instrument.

METERS

In all commercial motor meters there is necessarily a certain amount of friction, which as me goes on tends to increase more or less according to the design, and to cause the meter to ow down.

This defect manifests itself particularly at low loads, and is the more serious as the majority meters are worked at points very low down on their load curves. For long periods the working oint is frequently at or below one-tenth full load capacity, and in many instances, particularly here metal filament lamps are used, the working load is liable to be between one-twentieth and ne-fiftieth the full load capacity of the meter for many consecutive hours daily.

Pointer type clocks should have light machine cut gears, and should run with an exceedingly nall amount of friction, which, being constant, is easily compensated for. This fact constitutes n important advantage in favour of clocks of this type.

Roller cyclometer clocks have more friction than the pointer type, and moreover possess the efect that as the friction is a varying quantity it cannot be compensated for. A meter may have move round one counter only, or again it may have to move up to five counters at one time.

Jumping figure cyclometer clocks are a modification of the roller type, having the friction ad more evenly distributed through the use of a falling weight device. This weight is wound up owly by the meter. It is released at the proper time, and in falling carries round the additional ounters which it is necessary to move.

This partial equalisation of friction makes cyclometer clocks which have springing figures etter than the roller type, although not so good as the pointer type clocks, where the friction is a onstant quantity. An important feature of springing figures in comparison with roller type ounters is that with the former no halving of figures takes place.

In all meters, the friction tends to increase more or less according to the design, etc., of the ieter, and to cause the speed to slow down correspondingly, and it is essential to obtain the ighest possible accuracy initially.

Manufacturers are generally willing to guarantee the accuracy of their meters, so that .c. meters can be obtained which are capable of easy adjustment within plus or minus 2 per ent. from 50 per cent. overload down to one-fiftieth of full load.

The voltage drop in the main coils should be as low as possible. The drop varies with the ze of the meter, being greatest in the smaller sizes and diminishing as the ampere capacity ncreases, due to the fact that in meters of large capacity fewer turns are required to create a milar torque. The loss in the shunt circuit should also be small, but should not be reduced t the expense of the torque, as in meters where the torque is reduced in consequence of the urrent in the shunt circuit being very low, the retarding effect of friction becomes great, affecting ie accuracy of the meter under low load conditions. Moreover, with low torque more com-ensation will be required to balance the friction, and under such conditions trouble from 'creep-ıg' through vibration, due to street traffic or other external causes, will be much more liable o occur.

A record should be kept of the life of every meter on the system of any supply undertaking. s meters are received from the makers they should be checked against a standard which should e certified from time to time by some recognised authority such as the National Physical Labora-ory. This check should be made at various loads, say 125 per cent., $\frac{3}{4}$, $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{10}$, $\frac{1}{20}$ and $\frac{1}{50}$ ull load, at unity power factor, and at half load 50 per cent. power factor, and the results ob-ained should be plotted on a card; a note of any subsequent attention required by the meter hould be added to its record, and at the end of recognised intervals—say every two or three ears—each meter should be brought in for overhaul and tested carefully before breaking any eals. The result obtained should be added to the record, thus affording a means of continuously tudying the behaviour of every meter.

The following tests, arranged in order of their relative importance, are easily made :—

(1) Accuracy at varying currents, from 2 per cent. to 150 per cent. load with volta frequency and power factor constant.

(2) Accuracy at varying voltage with constant current and frequency.

(3) Accuracy at varying power factor with voltage, frequency and current constant.

(4) Accuracy at varying frequency with constant load and voltage.

British Standard Specification for Electricity Meters.*

(*No.* 37—1919.) (*Abstract.*)

— 16. The construction of the meter shall be mechanically sound and suitable for its purp and shall be such as to give reasonable assurance of permanence in all mechanical electrical a magnetic adjustments and shall not be seriously affected by external magnetic fields.

17. The parts of the meter within the case shall be carried on a substantial stiff framew forming, if desired, part of the case. The framework shall not be liable to distortion by chan of temperature, presence of moisture, or other cause. They shall be completely enclosed in substantial dust-tight metal case, the front and sides of which may be glazed. The case sh be of sufficient strength to afford adequate protection to the working parts against mechani injury with reasonable usage, and capable of being sealed in such a manner that access to t working parts and the electric or magnetic adjustments of the meter can only be obtained breaking the seals. Care shall be taken to ensure that the mechanism as well as the inter of the case is free from dust or other extraneous matter immediately prior to sealing.

18. One or more substantially glazed dust-tight windows shall be provided in the front the case in such a manner as to give a clear view of the register, and also of those working pa the observation of which is necessary for rapid testing of the meter. It shall be impossible remove the glass without breaking the seals of the case or breaking the glass itself.

20. The terminals of the meter itself, unless of the switchboard type, shall be enclosed by separate cover suitable for sealing, or contained in an external compartment of the case.

21. All meters of sizes above 100 amperes shall be provided with soldering sockets, exc where provision is made for coupling with strip or bar connections.

22. The pressure circuit shall be connected to the supply side of the main circuit, and disconnecting device shall be provided in the terminal compartment, to enable the pressu circuit to be entirely disconnected from the main circuit, in order that it may be supplied w current from a separate source for purposes of testing. The disconnecting device is not necessa where separate terminals are provided for the pressure circuit.

23. The meter, unless of the switchboard type having external connections, shall be p vided with separate facilities enabling the purchaser to seal independently the terminal co partment and the meter case. Facilities may also be provided for independent sealing by t manufacturer.

24. Every meter, the accuracy of which is affected by small changes in level, shall be provid with means of ascertaining, without breaking the seals, that it is correctly levelled.

25. A diagram of connections to be attached to the meter.

26. The circuits of the meter shall be capable of carrying full load continuously witho injury to any part of the meter, without any permanent change in its accuracy, and witho the temperature of any accessible part of the case exceeding 10° C. above the temperature the surrounding air, except when a shunt is employed in a separate compartment forming integral part of the meter, when the temperature of any accessible part of the case of su compartment shall not exceed 30° C. above the temperature of the surrounding air.

27. Every external resistance shall be completely enclosed in a strong metal case.

Every external resistance shall be so constructed that when the marked pressure is appli to the meter and resistance combined and is maintained continuously, no injury shall be do to any part of the resistance, and the temperature of any accessible part of the case shall n exceed that of the surrounding atmosphere by more than 30° C.

28. The insulation resistance between all the electric circuits of the meter coupled togeth and the containing case, or other metal not intended to be insulated when the meter is in u shall be not less than 5 megohms.

* By permission of the British Engineering Standards Association.

The insulation resistance between the main circuit and the pressure circuit (if any) shall not less than 2 megohms.

The insulating material between all the electric circuits and the containing case, or other tal not intended to be insulated when the meter is in use, shall withstand, for one minute, alternating pressure equal to twice the pressure of the circuit for which the meter is intended, th a minimum of 1,000 volts. All the electric circuits shall be coupled together before plying the high pressure.

The insulation resistance shall be measured with a pressure of not less than 200 volts nor re than 500 volts (direct), applied for a sufficient time for the reading of the insulation indicator become practically steady.

29. The rate of loss of energy in the pressure circuit at marked pressure shall not exceed values given in the following table:—

Meter.	Marked Pressures up to 250 volts.	Marked Pressures above 250 volts.
Direct current	5 watts	2 watts per 100 volts
Alternating current	2 watts	1 watt per 100 volts

The rate of loss of energy in the meter current circuit for all meters having a marked rent not exceeding 50 amperes shall not exceed 10 watts; with the further restriction that pressure drop shall not exceed 2 volts.

When the meter has more than one element the above requirements shall apply to each ment independently.

30. The forward direction of rotation of the rotor, if any, shall be clearly indicated.

32. The following shall be the standard sizes of meters:—2·5, 5, 10, 20, 40, 50, 100, 150,), 300, 400, 500, 600, 800, 1,000, 1,500, 2,000, 3,000, 4,000, and 5,000 amperes.

34. When a current equal to one-hundredth of the marked current of the meter (or when s is less than one-twentieth of an ampere, then one-twentieth of an ampere) traverses its main cuit, the rotor shall start and continue running steadily, the pressure circuit, if any, being ergised at the marked pressure in phase with the current in the main circuit.

35. The error of the meter at the standard or marked temperature, pressure, frequency d at unity power factor shall not exceed the following values:—

PERMISSIBLE LIMIT OF ERROR.

Load.	Meters without external shunts or transformers.	Meters with external shunts or transformers.
	Per cent. from true reading. + or −	Per cent. from true reading. + or −
Full load to one-fifth full load (inclusive)	2	2·5
From one-fifth to one-tenth full load	2·5	2·5
At one-twentieth full load	4·5	5·0

36. If the meter has a pressure circuit, a variation of 5 per cent. above or below the marked ssure at any load from full to one-tenth shall not cause a change in the rate of registration respect of such variation of more than one per cent.

39. The meter shall not be injured, and its accuracy shall not be permanently impaired, by a rrent 25 per cent. in excess of its marked current maintained for a period of one hour, or by e passage of a current in the main circuit not exceeding 30 times the marked current of the

meter for a period not exceeding half a second, the rotor, if any, being free to rotate, and pressure circuit being energised at marked pressure.

40. The meter shall not be injured, and its accuracy shall not be permanently impaired the application of a pressure 15 per cent. above the marked pressure for a period of one hour.

41. Every meter having a pressure circuit shall not register with its main circuit open v the pressure circuit alone is acting, either when marked pressure is applied or when this pres is increased to 10 per cent. above the marked pressure.

INSULATION MEASURING INSTRUMENTS.

(Evershed & Vignoles.)

These instruments are very largely used for the measurement of the resistance of insul and conductors; they embrace ranges from 1 microhm up to 10,000 megohms. All are d reading in the strictest sense, and the ruling feature of each is to provide a means of mea ment which shall be so simple that it can be used by any unskilled person, so rapid to use a test shall occupy but a few seconds, and so portable that the instrument can be taken anyw to do the work required.

THE 'MEGGER' TESTING SET consists of a moving-coil type ohmmeter combined in one with a high-pressure generator driven by a folding crank handle. The general principles o construction and the electrical connections of the set are shown in the following diagram.

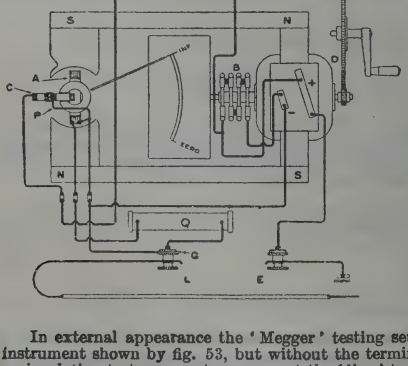

FIG. 53.—Megger Testing Set. Diagram of Connections.

A = current coil; P = pressure C = compensating coil; N, S = magn Q, R = resistances; B = brush g D = driving gear; + − = generator minals; G = guard plate; L = ext 'line' terminal; E = external 'ea terminal.

In external appearance the 'Megger' testing set is similar to the 'Bridge Megger' te instrument shown by fig. 53, but without the terminals at the end of the case. To carry an insulation test on a system, connect the 'line' terminal to the circuit and the 'earth' term to a good earth. If testing between two wires, connect one wire to each terminal.

When the handle of the generator is turned at about 100 r.p.m. the rated voltage wi developed, and the value of the insulation resistance under test will be indicated directly by pointer over the scale. The instruments are fitted with either variable or constant-pres generators; the constant-pressure type should always be used when testing the insulatio circuits having considerable electrostatic capacity, such as large house-wiring installat supply and feeder cables, etc. The constant-pressure device consists of a centrifugal fric clutch, which secures that when the handle is turned above the slipping speed, the speed o generator, and consequently the terminal E.M.F., remains constant. All 'Megger' and 'Br Megger' testing sets are provided with a system of guarded insulation to ensure that no inte or surface leakage can affect the readings. Any error in tests of high insulation due to lea across the surface of the material under test can be eliminated by the use of a guard wire nected to the 'guard' terminal, which is provided on all high-range instruments.

THE BRIDGE-MEGGER TESTING SET, fig. 54, is a combined ohmmeter and generator of usual 'Megger' type for insulation testing, but also arranged so that the ohmmeter can be verted into a Bridge Galvanometer by means of the change-over switch fitted. The cur for the Bridge tests is provided by the generator (constant-pressure type), and a direct-rea

The Value of A Standard Work

Can only be realised when one has it by them, and after using regularly for some time, they will appreciate what it would mean to be without it. The following are standard works that can be relied on and that will be invaluable for years to come.

THE PRACTICAL ELECTRICIAN'S POCKET BOOK. A work recommended by the C. & G. Examiners, containing 600 pp. of useful information, tables, etc., of immense value to all. Details of all Supply Stations. 30th Edition.
2/10 Post Free

WHERE TO SEEK FOR SCIENTIFIC FACTS. By A. B. EASON. A very handy little book that tells you where to find any information you may want. A wonderful time saver.
1/2 Post Free

TELEPHONE TROUBLES AND HOW TO FIND THEM. By W. H. HYDE. Compiled to meet the requirements of telephone engineers, and gives in a clear form details of all possible faults and the best method of rectifying them, and is well illustrated with diagrams. 19th Edition.
10d. Post Free

TELEPHONE ERECTION & MAINTENANCE. By H. G. WHITE. A handbook for Contractors and Wiremen. 3rd Edition.
3/10 Post Free

ROTARY CONVERTERS; THEIR DESIGN, CONSTRUCTION AND USE. By C. SYLVESTER, A.M.I.E.E. A clear and eminently practical description of these machines with numerous diagrams. Of direct value to all station engineers, etc. Cr. 8vo.
2/3 Post Free

DYNAMO & MOTOR ATTENDANTS & THEIR MACHINES. By FRANK BROADBENT, M.I.E.E. A thoroughly practical and reliable work, of which over 40,000 copies have been sold. The best book on the subject. Recommended by the C. & G. Examiners.
4/10 Post Free

ARMATURE WINDING. By C. SYLVESTER, A.M.I.E.E. Splendidly illustrated. An up-to-date manual, carefully prepared and giving full instructions on the various types of windings.
7/10 Post Free

These are published by us and we shall be pleased to supply you with any other books you require. Send for one of our new catalogues giving complete list of electrical books on different subjects.

esistance box of special and convenient design is supplied as a standard of comparison. The hole combination forms the most rapid known means of measuring that range of resistances for hich the Bridge method is adapted, and the value of the resistance is given plainly in a row of gures, which prevents errors. The series of ranges covers Bridge measurements from 0·01 ohm

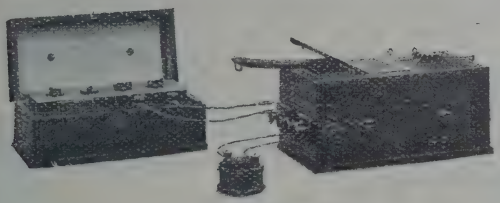

FIG. 54.—Bridge-Megger Testing Set in Use.

pwards, and insulation measurements up to 2,000 megohms. In addition to the measurement f insulation and conductor resistances, the set may be used for the localisation of faults on elephone and telegraph cables, or on electric light cables if their resistance falls within the imits of Bridge methods.

THE 'DUCTER' POTENTIAL OHMMETER TESTING SET provides for the measurement of resistances from 1 microhm up to 100 ohms by the direct deflection method. The current for his set is supplied by a separate battery, and a pair of duplex handspikes are used for making ontact on the resistance under test. With these instruments the resistances of switch and fuse ontacts, armature windings, rheostat coils, rail-bonds, sheathing and earth circuits in collieries, oints and the like, are easily and rapidly determined.

MEG INSULATION TESTER.

The most recent development in Evershed & Vignoles' resistance-measuring instruments, the 'Meg' Insulation Tester (fig. 55), which was introduced in 1922. While the Megger and ridge Megger continue to be the standard instruments where the measuring instrument must e capable of dealing with a very long range of resistance values, it was felt that there was room

FIG. 55.

or a smaller, lighter, and less costly instrument of the Megger type. The 'Meg,' with its ranges p to 20, 50 or 100 megohms, is quite suitable for most classes of insulation testing, and is sed very extensively for switchboard wiring, testing generator and motor coils, etc. Two odels of the 'Meg' insulation tester are made for variable pressure and constant pressure, the tter having a speed-control device which ensures constant voltage, an important feature where he capacity of the insulation to be tested exceeds 0·5 microfarad, as, for instance, house wiring, nsulation, etc.

ELECTRIC LAMPS.*

Metal Filament Lamps.

The gas-filled lamp, like the vacuum lamp, which it is rapidly replacing, has a filament o tungsten, the melting point of which is over 3,000° C.; this fact enables the filament to be ope ated at a higher temperature than any other metal, with the result that a high proportion of i total radiation is in the visible spectrum. While the melting point of tungsten is very high oxidises readily at quite a low temperature (about 300° C.). When new it can be readily ben into any desired shape. It is this property which facilitates the manufacture of the filamen both in the ordinary up and down winding and also in the spiralised form.

In a tungsten lamp an increase in voltage produces an increase in resistance (in a carbo filament the resistance under such variation remains practically constant). Fig. 56 shows th relationship between watts and voltage of a modern Tungsten electric lamp, while the lume characteristic is shown in fig. 57.

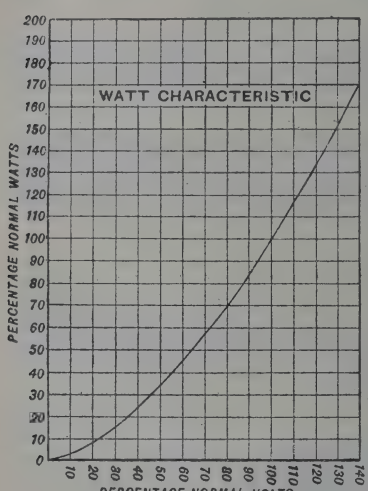

FIG. 56.

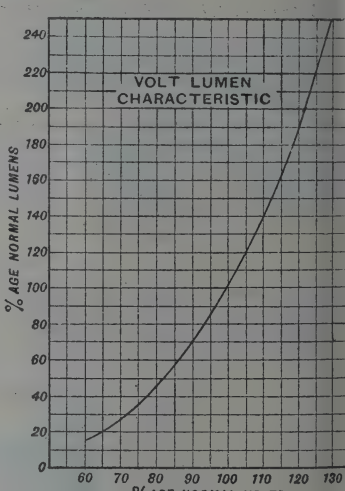

FIG. 57.

An increase in voltage produces an increase in temperature of the filament, so that a ver great volume of light is obtained. An increase of 10 per cent. volts brings about an increa of 41 per cent. in light output, while a reduction of 10 per cent. reduces the light output by 32 p cent. For this reason under-running is to be greatly deprecated in view of the great loss luminous energy. On alternating current of low frequency a flickering is obtained dependen upon the heat capacity of the filament itself, but the remedy in such cases is to eliminate th use of small lamps by installing a smaller number of larger units. This effect of flickering is le conspicuous in the tungsten lamp than in the carbon lamp because of the temperature coefficien As far as possible it is recommended that where difficulties are experienced in this direction th lamps of not less than 100 watts be employed.

In the case of the gas-filled lamp the bulb temperature is considerable, while the lamp whi is not gas-filled remains comparatively cool.

All lamps manufactured in this country by the members of the Electric Lamp Manufacture Association are made in accordance with specifications which ensure that a uniform produ is obtained of a standard quality.

Efficiency of Electric Lamps.

Type of Lamp.	Average Efficiency in Lumens per Watt.	Average Efficiency in Spherical Candles per Watt.
Carbon	3·3	4·1
Tantalum	6·0	2·1
Tungsten (Vacuum)	8·0	1·5
Tungsten (Gas-filled)	12·5	1·0

Intrinsic Brilliancy of Lamp Filaments.—The candle power per square inch of the filame of carbon 3·1 w.p.c., tantalum 2 w.p.c., and tungsten 1·25 w.p.c. lamps is 480, 625, 750, and 1,0 respectively, while the gas-filled lamp is 5,000.

Quality of Light.—The light of tungsten lamps more closely approaches daylight than that other illuminants. It naturally follows that tungsten lamps cause colours to retain more nea their true values than any other artificial light source.

† By permission of the British Engineering Standards Association.

Mazda Lamps.

(The British Thomson-Houston Co., Ltd.)

Mazda lamps, the filaments of which are made from pure-drawn tungsten wire, give a brilliant white light. They can be operated satisfactorily in any position, but in the larger sizes it is better to use the lamps set vertically. The lamps operate equally well on either continuous or alternating current circuits

Mazda lamps, including both the vacuum and gasfilled types, have made it possible to design lighting units of suitable sizes for all lighting conditions, and of such high efficiency as to compete effectually with all other types of artificial illuminants. Users of electric light have a choice of sizes ranging from 5 watts to 1500 watts. Every size is adapted, as regards filament position and shape of bulb, for use in conjunction with specially designed glass or metal reflectors.

The gasfilled lamp is claimed to give, for the same current consumption, considerably more light than the previous best incandescent lamp. The recent development of 30 and 40 watt gasfilled lamps in standard supply voltages has brought the advantages of the gasfilled principle within reach of the ordinary householder.

The strength and durability of the drawn wire filament ensure satisfactory results from Mazda lamps under all conditions of service. They have successfully withstood the severe conditions of use aboard battleships during target practice.

The flexibility of the Mazda drawn tungsten wire has made possible the production of special forms of filaments which could not be produced with a brittle squirted tungsten wire used in previous lamp bulbs. Helical coil filaments, as used in Mazda headlight bulbs, are better in regard to focus than the types of filaments hitherto employed.

The intrinsic brilliancy of the lamp is stated to be eight times that of ordinary metal filament lamps.

The gasfilled lamp is now made in small sizes for headlight use. The master patents governing the manufacture of Mazda vacuum and gasfilled lamps are the property of the makers of Mazda lamps.

Siemens Lamps.

(Siemens & English Electric Lamp Co., Ltd.)

These lamps have drawn tungsten wire filaments, and the Standard Vacuum type operate at an efficiency of, approximately, 1·2 watts per c.p. The 'gasfilled' lamp represents the latest development in metal filament lamp manufacture, and the larger sizes attain an efficiency of, approximately, 0·5 watts per c.p. Both types of lamps are made in an extensive range of voltages and candle-powers.

Siemens Standard Type Lamps.—These are made in voltages from 20 to 260, and in wattages from 5 to 60, and cover the lamps in general demand for ordinary electric lighting schemes of average intensity.

Siemens Traction Type Lamps.—This type of lamp has been introduced to meet the requirements experienced in situations where lamps are subjected to severe shock and vibration, and is now largely used on the leading tramway systems and tube railways. A totally new arrangement of the filament is employed, which ensures maximum strength and adequate support. The complete length of filament is spiralised and carried in a series of loops on a special spider in the usual Siemens manner. The distance between the top and bottom supports is considerably reduced, which ensures maximum strength, while neighbouring lengths of filament are more widely separated, thus obviating short-circuiting of adjacent lengths of filament, which sometimes occurs in the ordinary type of lamp subjected to severe vibration. The filament has no sharp bends, and will not 'sag,' so that the lamp may be used in any position. The vertical candle-power of the lamp is increased, and the light emitted is uniform in all directions other than towards the cap end. It is claimed for this design that these additional advantages have been obtained without loss of efficiency in operation.

Siemens Gasfilled Lamps.—The gasfilled lamp was originally introduced in high candle-power types only, but the range has been increased, with the result that these lamps are now obtainable for standard lighting voltages from, approximately, 30 to 1,500 watts. Owing to their high efficiency, these lamps became known to the public as 'Half Watt' type lamps. It is, however, an essential condition to their production that they should be gasfilled in order to obtain a satisfactory life at the efficiency mentioned. The leading manufacturers are therefore stamping the word 'gasfilled' on the bulbs of these lamps, so that the consumer may be protected should he be offered lamps which, though resembling genuine high-efficiency lamps, are not gasfilled.

The range of Siemens gasfilled lamps now includes automobile head-light lamps, from 4 to 14 volts, from 8 to 48 watts; Siemens gasfilled lamps for railway lighting, 25 volts, can be obtained from 15 to 100 watts. The 50- to 60-volt gasfilled lamps are supplied from 15 to 500 watts; 100- to 130-volt from 30 to 1,500 watts; and the high voltage gasfilled lamps, 200- to

260-volts, from 40 to 1,500 watts. These high candle-power lamps are being employed in large numbers for general lighting in stores, workshops, factories, offices, shops, etc., and for street lighting; they produce illumination without flicker, and require no attention after installation, save occasional cleaning.

Siemens Automobile and Battery Type Lamps.—In addition to the range of gas-filled automobile head-light lamps mentioned above, Siemens Battery Lamps are made for automobile lighting, sign lighting, omnibus and yacht lighting; while there is also a variety of types suitable for use in miners' hand and rescue lamps. The voltages of these vary from 2 to 14, and the wattages from, approximately, 1 to 36 watts.

Osram (G.E.C.) Lamps.

(The General Electric Co., Ltd.)

The Osram (G.E.C.) lamps have filaments drawn from tungsten; they have also pipless bulbs, which greatly improves their appearance and renders them less liable to be broken, both in transit and in use.

The efficiency of these lamps approximates to ½ watt per candle, as compared with vacuum lamps which consume about 1 watt per candle. The Osram gas-filled lamp is known as the 'Gasfilled' type lamp, and is made from 15 to 1,500 watts. The high candle-power lamps are largely used in the place of arc lamps.

The Osram vacuum type lamp is made in sizes from 10 to 600 c.p., and, in addition, standard types have been supplemented by special types for different purposes, such as with concentrated filaments for projection and focusing work; and for use from low voltage batteries, such as miners' and general portable hand-lamps and automobiles (including motor-buses). The Osram (G.E.C.) lamp 'Gasfilled' type is also made for automobile headlights.

A modification of the gas-filled lamp is the 'White Osram,' which is a standard clear Osram lamp, the bulb of which is coated with a film of unglazed porcelain. This coating has the effect of efficiently diffusing the light, and eliminating all glare from the intensely bright filament. White Osram lamps should be used in all positions where the lamp itself is visible.

For industrial lighting, bowl sprayed White Osrams—that is, lamps having only the lower part of the bulb coated—when used with top reflectors, such as G.E.C. enamelled steel reflectors, are specially recommended.

A further development of the White Osram is the 'Colour Sprayed Osram' lamp, which is produced in six standard colours—red, orange, yellow, green, blue, and flame tint. Colour sprayed lamps are the most convenient means of obtaining colour light for both indoor and outdoor decorations, such as dances, concerts, restaurants, seaside promenades, etc.

In addition to the Osram lamps for ordinary lighting, they are made for a wide variety of special purposes, such as the 'Daylight' lamp for colour matching, projection lamps, ship type lamps, candle type lamps, striplite lamps, automobile type lamps, miners' lamps, etc.

The lamps are an entirely British product, every component part, including the brass caps, being produced within the G.E.C. organisation.

The Osglim Discharge Lamp.

(Osram G.E.C. Lamp Works.)

Whereas discharge lamps usually require at least 2,000 volts, by filling the lamp with neon gas the discharge will start on about 200 volts. The current flows through the neon from one electrode to the other, the gas glowing round the cathode with a soft rosy light. By using a resistance inside the cap, the consumption of the lamp is reduced to 5 watts. The faint light from this lamp (known as the 'Osglim') makes it ideal as a night light, or wherever subdued illumination and low consumption are important. By making the cathode in the form of letters or figures, effective indicators or advertising signs are obtained. The lamp can also be made suitable for use in the photographic dark room.

Attachment of Flexible Cords to Sockets

The majority of short circuits occurring in pendant sockets and the attachment-plug caps of portable electrical appliances, according to the Underwriters' Laboratories (America), are due to loose strands of the flexible cord, which become separated from the terminals when the binding screws or terminals are loosened. This loosening is frequently the result of the omission of a knot or its equivalent in the cord inside the cap of the socket or attachment plug, the strain due to pulling separable connections apart or dragging portables around by their cords being transmitted directly to the small binding-screw connections.

The so-called 'Underwriters' knot,' fig. 58, provides an easily-tied strained relief forming a rather flat knot, which will fit snugly in the recess provided for the purpose inside the cap of pendant sockets and attachment plugs.

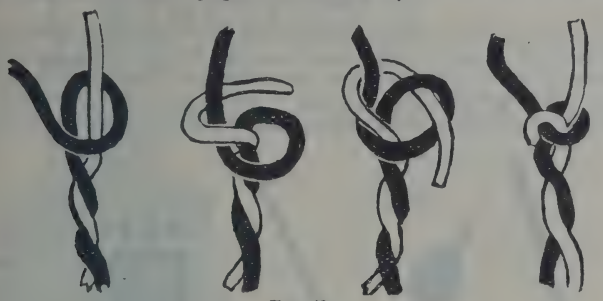

FIG. 58.

ARC LAMPS.

In a D.C. arc lamp the top or positive carbon burns about 1½ inches per hour, and twice as fast as the bottom or negative carbon of the same diameter. A 1,000-candle-power lamp requires carbons about $\frac{9}{16}$ inch in diameter and consumes about 1,000 watts.

SIZES OF CARBONS.

Diam. of Cored Carbons, in mm. .	10	12	14	14	16	16	17	19	21	21	23

THE ANGOLD MAGAZINE FLAME ARC LAMP.

(The General Electric Co. Ltd.)

The Angold Magazine Flame Arc Lamp is arranged to burn carbons of comparatively short length (maximum 15 ins.) without copper coating or metal core; twelve pairs of these carbons can be filled in the magazine at one time, and thereby, according to the type of lamp, 120 to 150 hours be obtained.

The carbons are so arranged that as soon as one pair is consumed the next pair comes into operation. The magazines can be filled up if only part of the trim has been consumed, so that at any time the full burning hours obtainable with a full magazine can be assured. The positive carbons cannot be put into the negative magazine, and when the last carbons are consumed, the feeding gear is automatically put out of action. Partly burnt carbons need not be removed. The interval of time during which the light is extinguished does not exceed two seconds.

The direct current lamp is manufactured for 8 or 10 amperes and can be supplied with self-contained equivalent resistance and automatic cut-out, or it can be supplied without these accessories. In the latter case, however, the lamps can only be used singly, on suitable voltage, or two in series on 100-120 volts. For longer series (or even for two lamps on higher voltage) equivalent resistances and automatic cut-outs have to be provided. If it is inconvenient to have these accessories self-contained they can be supplied in the suspension type, or if it is necessary to lower the lamp from contact gear a box type is recommended.

Both 8-ampere and 10-ampere lamps are designed for 9 mm. positive and 8 mm. negative carbons, 15 ins. long. Each trim of carbons consists of 12 pairs.

An alternating-current lamp of this make will burn in parallel singly on any voltage between 100 and 250 volts—25 cycles to 100 cycles. Each lamp is fitted with a self-contained transformer choker so that it can be connected directly to the mains.

THE STUDIO ARC LAMP.

(The General Electric Co., Ltd.)

The G.E.C. Studio Arc Lamp is of the semi-enclosed type, and the high voltage long arc produced yields the highest possible actinic values.

It is equally suitable for portraiture and blue printing, as, owing to the purity of the light and to the absence of shadows, exceptionally good results are obtained.

It is supplied for use on A.C. or D.C. circuits.

To obtain the high voltage necessary the lamp is run singly on 220-250 volts. For average work a 16-ampere with these voltages is generally used.

ELECTRIC CLOCKS AND TIME SERVICE.

THE PUL-SYN-ETIC SYSTEM.

The 'Pul-syn-etic' system, designed by *Messrs. Gent & Co., Ltd., Leicester*, is arranged to operat any number of impulse clocks, workmen's time recorders, turret clocks, etc., installed i any large building or institution and connected electrically in series. The hands of such dial are all caused to advance simultaneously at half-minute intervals by means of step-by-ste impulse propulsion movements (fig. 59) (or where inaudible working is required, the Silen Triangle Movement Fig. 59A) which, taking the place of the ordinary spring, or weight, an train of wheels, are operated by electric currents sent out periodically by a MASTER PENDULU

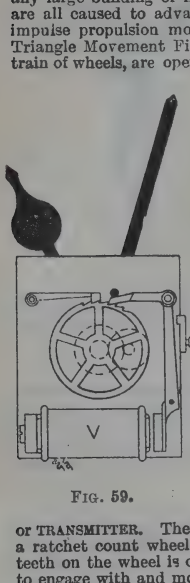

FIG. 59.

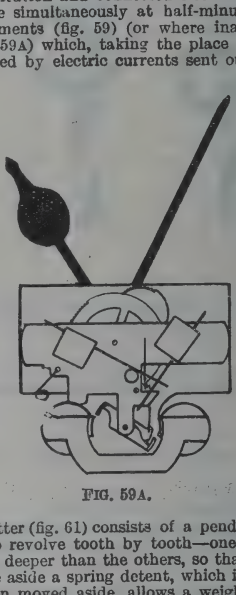

FIG. 59A.

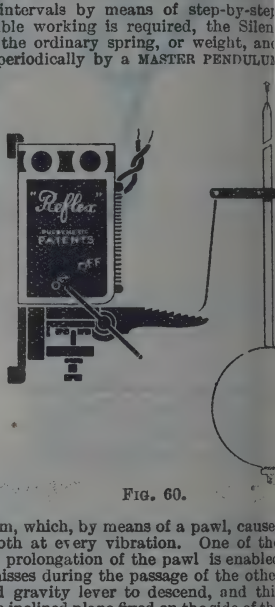

FIG. 60.

or TRANSMITTER. The latter (fig. 61) consists of a pendulum, which, by means of a pawl, cause a ratchet count wheel to revolve tooth by tooth—one tooth at every vibration. One of th teeth on the wheel is cut deeper than the others, so that a prolongation of the pawl is enable to engage with and move aside a spring detent, which it misses during the passage of the othe teeth. The detent, when moved aside, allows a weighted gravity lever to descend, and thi through the medium of a friction roller carried thereon and an inclined plane fixed on the side of th pendulum, gives an impulse to the latter, imparting energy sufficient to enable the pendulum t swing during another revolution of the wheel—that is, for period of half a minute. This gravity impulse is, of course constant and invariable, so that other factors, such a temperature variation, etc., being suitably provided for, th time-keeping qualities of the pendulum are exceptionall good. The descent of the gravity lever is caused to clos an electrical circuit, which fulfils a dual function: (a energising an electro-magnet, which causes the restoration o the gravity lever to its potential position, and (b) sending a electrical impulse through the external circuit to operat the impulse movements. The duration of this contact i about 0·05 second; but, depending upon the total self-in duction of the circuit, its duration is self-regulating, in tha the contact is not broken until the self-induction has bee overcome and all the dials operated.

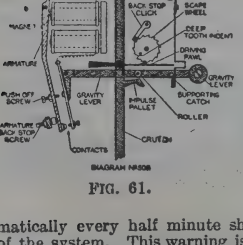

FIG. 61.

The system includes in series with the transmitter an the clocks a weak battery warning-bell which rings auto matically every half minute should the battery run down and so endanger the safe workin of the system. This warning is given before the actual breakdown point is reached, affordin a safe margin of time in which to recharge or renew the battery. The 'Pul-syn-etic' syste is noted for its low current consumption, and it is claimed that it takes the least current of an known Impulse system.

The system lends itself conveniently to the automatic operation of sound signals for th starting and ceasing of work, and also to the convenient operation of output and idle machin recorders. This class of recorder has proved itself useful in connection with textile machine and machines which should not be idle during working hours.

LIGHTNING CONDUCTORS

MANUFACTURED, SUPPLIED, AND SCIENTIFICALLY INSTALLED BY

R. C. CUTTING & CO.,

"L" Dept., 56 Ludgate Hill, LONDON, E.C. 4.

Contractors to: The Lords of the Admiralty; H.M. Government; Office of Works; War Department; Home Office; The Principal Railways, Corporations, Colleges, Cathedrals, Titled and Landed Gentry throughout the World.

Established 1879.

Telegrams: 'ADJUNCTOR, PHONE, LONDON.'

Telephone: 8495 CENTRAL.

Architects' Plans inspected and free schemes and quotations submitted.

Expert advice given on existing installations. Competent mechanics sent to all parts. Detailed instructions for fixing supplied with all exported goods.

Contractors also for erecting, razing, heightening or restoring, with inexpensive scaffolding, STEEL, BRICK, or CONCRETE Chimney SHAFTS, Church SPIRES, Tall TOWERS, and other lofty and dangerous structures.

AERIAL WIRING & EARTHING DEVICES

supplied and fitted for

WIRELESS INSTALLATIONS.

Workmen's Time Recorders are now controlled from the half-minute impulses of the system by means of the 'Pul-syn-etic Reflex' Pendulum Control (fig. 60). With this control the recorders remain independent units, and no mechanical alterations are made, but with the 'Reflex' fitting, as shown in fig. 60, attached to their pendulums, all recorders are compelled to keep in step with the transmitter.

Even if the electrical connections be removed the recorders continue to work under their own power as before, but uncontrolled. This 'Reflex' control is also applicable to the pendulums of large public clocks, and its introduction is a marked advance in the science of the Unification of Time.

For large turret clocks, the accuracy of whose performance is subject to interference from variation in wind pressure or from accumulations of snow and ice on the hands, a special WAITING TRAIN movement is used, in which the hands are driven continuously by a special type of electric movement sufficiently powerful to overcome any such resistance ordinarily to be expected. The hands are caused to travel at a slightly faster rate than usual, to gain in fact about two seconds per half minute. Every half minute, however, the driving train disconnects itself from the hands, which then wait until the driving power is reconnected by means of the usual half-minute electric impulse current sent out by the transmitter driving the other impulse clocks in the building. The waiting period is practically unnoticeable—so that in very large turret clocks immunity from the usual weather interruptions is achieved, together with a greater degree of accuracy in timekeeping than in clocks operated in the usual manner. Efficient electric striking, or striking and chiming apparatus, can be supplied for bells of any size.

This WAITING TRAIN movement has been chosen for driving the hands of the large electric clock, in the towers of the offices of the Royal Liver Friendly Society at Liverpool. This has four 25-ft. dials, and the weight of a pair of hands is 5 cwt. The minute hands are 14 ft. long, 2 ft. 6 ins. wide at the greatest width, and 9 ins. thick where attached to the spindle. The combined weight of each pair of hands, spindles, and internal counter-weights, is a trifle over half a ton. The area of the hands exposed to snow and wind is very great, nevertheless the type of mechanism employed has shown itself able to withstand the disturbing effect of several severe storms since its erection in 1911. The size of the Liver Clock has now been exceeded by the new 'Singer Clock' in the tower of the works of the Singer Mfg. Co., Ltd., Clydebank, which clock has four 26-ft. dials, all driven by a single 'Waiting-Train' movement.

For ship use special clocks are provided, the Impulse Transmitter being fitted with an automatic arrangement, which enables the whole of the ship's clocks to be automatically advanced or automatically retarded, while sailing east or west. These 'Pul-syn-etic' marine clocks are installed in a large number of liners and ocean-going steamers.

LIGHTNING CONDUCTORS.

CODE OF RULES FOR THE ERECTION OF LIGHTNING CONDUCTORS.

(Lightning Rod Conference, 1882, *and Lightning Research Committee, Royal Institute of British Architects*, 1905.)

Two main lightning rods, one on each side, should be provided, extending from the top of each tower, spire, or high chimney stack by the most direct course to earth. Horizontal conductors should connect all the vertical rods (*a*) along the ridge, or any other suitable position on the roof; (*b*) at or near the ground line. The uppermost conductor should be fitted with aigrettes or points at intervals of 20 or 30 feet. Short vertical rods should be erected along minor pinnacles and connected with the uppermost horizontal conductor. All roof metals, such as finials, ridging rain-water and ventilating pipes, metal cowls, lead flashing, gutters, etc., should be connected to the horizontal conductors. All large masses of metal in the building should be connected to earth, either directly or by means of the lower horizontal conductor. Where roofs are partially or wholly metal lined they should be connected to earth by means of vertical rods at several points. Gas pipes should be kept as far away as possible from the positions occupied by lightning conductors, and as an additional protection the service mains to the gas meter should be metallically connected with house services leading from the meter.

Material for Rod.—Copper, weighing not less than 6 oz. per foot run, either in the form of tape or rope of stout wires, no individual wire being less than No. 12 S.W.G. Iron may be used but should not weigh less than 36 oz. per foot run. Subsidiary conductors for connecting metal ridging, etc., to earth may with advantage be of iron and of a smaller gauge, such as No. 4 S.W.G. galvanised iron.

Points.—The point of the terminal should not be sharper than a cone of which the height is equal to the radius of its base; but a foot lower down a copper ring should be screwed and soldered on to the upper terminal, in which ring should be fixed three or four sharp copper points, each about 6 ins. long. The number of conductors or points to be specified depends upon the size of the building, the material of which it is constructed, and the comparative heights of the several parts; no general rules can be given, but even ordinary chimney stacks, when exposed, should be protected by short terminals connected to the nearest rod, as accidents often occur owing to the good conducting power of the heated air and soot in a chimney.

Fixing.—Rods should preferably be taken down the side of the building which is most exposed to rain. They should be held firmly by holdfasts of the same metal as the conductors (not by insulators), but not so tightly as to prevent free expansion and contraction due to changes

of temperature. They should not be bent abruptly round sharp corners; the vertical rods shoul be carried at a certain distance from the wall to prevent dirt accumulating, and to avoid th necessity of running them round projecting masonry or brickwork. In some cases it may b necessary to carry a rod through a string-course or other projecting stonework to avoid curvature in which case the hole should be large enough to give ample clearance to the conductor, but i is better to run outside, keeping the rod away from the structure by means of holdfasts a mentioned above.

Joints.—Joints in series of conductors should be as few as possible. As a rule they shoul only be necessary where the vertical and horizontal conductors are connected, and the mai conductors themselves should always be continuous, without artificial joints. Connection between vertical and horizontal conductors should always be in places readily accessible fo inspection. Every joint, besides being well cleaned, screwed, scarfed, or riveted, should b thoroughly soldered, and should be protected from the action of the air, especially in cities.

Painting.—Iron rods, whether galvanised or not, should be painted; copper rods may b painted or not, according to architectural requirements.

Protection.—Copper rods to the height of 10 ft. above the ground should be protected fron injury and theft by being enclosed in an iron pipe reaching some distance into the ground.

Earth Connections.—It is essential that the lower extremity of the conductor be buried i permanently damp soil; hence proximity to rain-water pipes and to drains is desirable. It i a very good plan to make the conductor bifurcate close below the surface of the ground, an adopt two of the following methods for securing the escape of the lightning to earth: a strip of copper tape may be led from the bottom of the rod to the nearest gas or water *main*—no merely to a lead pipe—and be soldered to it; or a tape may be soldered to a sheet of coppe 3 ft. sq. and $\frac{1}{16}$ in. thick, buried in permanently wet earth, and surrounded by coke, charcoal or pulverised arc-lamp carbons (coke, however, is likely to set up corrosive action on the earth plate), or many yards of the tape may be laid in a trench filled with coke, well rammed. Wher iron is used for the rod, a galvanised iron earth-plate should be employed. A tubular earth connection driven into moist ground makes an effective earth, especially if it is connected t a rain-water pipe. (See also 'Earth Connections,' *below*.)

Masses of Metal.—As far as practicable the conductor should be connected to all extensiv masses of metal, such as ornamental ironwork, hot-water pipes, etc., both external and internal but it should be kept away from all soft metal pipes, and from internal gas-pipes of every kind Church bells and turret clocks should be connected with the conductor. In the case of a lon line of metal ridging, each end of the ridging should be directly connected to earth by a rod Where the ridge is non-metallic, a horizontal conductor should be run at a short distance abov the ridge and be connected to earth.

Factory Chimneys.—These should have a copper band round the top, and stout sharp coppe points, each about 1 ft. long, at intervals of one or two feet all round the circumference. Th rods should be connected with all bands and metallic masses in or near the chimney. As a alternative, the rods above the band may be curved into an arch provided with three or fou points. Two lightning rods should be carried down from the band to earth.

Collieries.—Undoubted evidence exists of the explosion of firedamp in coal mines through sparks from atmospheric electricity being led in to the mine by the wire ropes of the shaft an the iron rails in the galleries; hence the head-gear of all shafts should be protected by prope lightning conductors.

Inspection.—Before giving his final certificate the architect should have the conductor care fully examined and tested by a qualified person, as injury to it often occurs up to the latest perio of the works from accidental causes, and often from the carelessness of the workmen.

Earth Connections.

In making earth connections for electrical circuits, lightning rods, etc., it is desirable to provid several paths to earth, as far apart as possible. Connection should be made with the stratum of permanently moist earth nearest the surface of the ground, rather than to deeper layers o even to the water in a deep well. The best earth connection is a water pipe. For most purpose galvanised iron pipes, about 1 in. in diameter, give satisfactory results; in a series of experiment such pipes, driven into stony clay soil, gave the following average results per pipe.—

1 ft. deep	149 ohms	4 ft. deep	50 ohms.
2 ft. „	88 „	6 ft. „	56 „
3 ft. „	64 „	8 ft. „	29 „

Generally, if moist earth is reached, pipes need not be driven deeper than 10 ft. The resist ance of two earth-pipes in series, driven 10 ft. deep, becomes practically constant at any distanc apart from 10 ft. upwards. Earth-pipes connected in parallel should be at least one foot apar They need not be larger than 2 ins. in diameter.

If earth-plates are used it is better to bury two small plates 20 ft. apart, connected by a stou wire, than one large plate. They should be on edge, with the soil well rammed on both sides In shallow soil over rock, long narrow strips of metal buried in trenches should be used. Patente devices offer no special advantages. Two plates in parallel, each 2 ft. by 4 ft., 6 ft. deep, 5 f apart in stony clay soil had a joint resistance of 16 ohms. A strip of galvanised iron 1·5 ins. wid and 20 ft. long, in a trench 12 ins. deep, had a resistance of 17·7 ohms. The resistance of a wate

ipe is usually less than 1 ohm, averaging ½ ohm. The addition of salt to the soil round the arth connection greatly reduces the resistance; so does the packing of coke or charcoal round he plate, but both these devices hasten the corrosion of the plate. As a high potential gradient nay exist on the surface near the earth connection, unless it is of the buried type, the earth-pipe nd connecting lead should be guarded to prevent accidental contact with them. The joint etween the lead and the earth-pipe or plate should be embedded in concrete for protection, nd the earth-wire should be covered throughout its length. All earth connections should be nspected and tested at least once a year.

Phœnix Office Rules for Lightning Conductors.

The Phœnix Fire Office, in their rules for lightning conductors, point out that the only way o obtain absolute security against lightning is to enclose the building in a metal framework onstituting the 'bird-cage' system of conductors. This can be accomplished generally by tilising the rain-water pipes and gutters as part of the system. The ordinary conductors must be ixed in addition, and the whole system effectively earthed. The material of the conductor should e of copper tape, measuring at least 1 inch by ¼ inch, or, if copper cable be adopted, it should ot consist of less than seven strands, each ¼ inch diameter. Soft iron may be used in place of opper, and, except for chemical reasons and for permanence, the sectional area need not be reater than in the case of copper. Conductors should be kept a certain distance away from alls so as to prevent the accumulation of dirt, but they must not be insulated. If a copper late is used for the earth connection it should not be less than 3 square feet in area and ¼ inch n thickness, and should be adopted only where it will always be in water or moist earth; otherise connection should be made to the water mains, or the 'tubular' system should be employed. he number of connections depends on the ground area of the building, but there are few structures where less than two are necessary. The elevation rod of factory chimneys should be a ircular band placed round the top of the shaft, with points fixed at an angle of 45°, and exending outwards, or an arch of metal, provided with points, may be fixed across the mouth f the chimney.

Domestic Uses of Electricity.

It is seldom that lighting is the only domestic service obtained when an electricity supply is vailable. Provided the cost of electricity is not exorbitant, certain valuable appliances are to e met with in most households, *e.g.* flat iron, vacuum cleaner, desk fan, toaster, coffee percolator, ilk boiler, kettle, warming pan, hair dryer, bowl fire, etc., etc. Such services can be had at a ery small running cost, since the amount of energy consumed is generally small. Where electric nergy can be obtained at a low rate, *e.g.* at an overall charge of ¾*d.* to 1½*d.* per unit, main domestic ervices such as heating, cooking, and hot-water supply are available at costs comparable with ther methods, such as coal or gas. Even where the cost of electricity may be prohibitive for eneral use, it may be low enough for occasional use. In addition the advantages of cleanliness, onvenience, comfort, labour-saving, etc., are valuable assets. Reliable appliances for all the bove-mentioned services are now available, and when the capital costs of wiring and of apparatus re suitably reduced or embraced in hire-purchase systems, etc., a great expansion of domestic lectrification can be looked for. Already electricity at an overall cost of about ¾*d.* per unit to ccupants of all-electric houses is available to about four million people in Great Britain, and upply authorities are becoming widely interested in schemes for assisting consumers.

Data concerning heating, cooking, and hot-water supply in private households will now be iven. In Table I figures are reproduced from p. 305, vol. 64, of the *Journal I.E.E.* These igures were given by Prof. A. H. Barker in the discussion of a paper on 'An All-Electric House,' y Prof. S. Parker-Smith, and are intended to show how many heat units are needed per person er annum for the stated services:

Table I.—Net B.Th.U. used per Person per Annum.

Description.	Estimate for well-to-do Person.	Estimate for Artisan.	From Barker's Experiments for One Person Living Alone.	From Parker-Smith's All-Electric House.
Heating . . .	3,000,000	1,000,000	4,500,000	3,400,000
Hot-water supply and laundry . .	8,000,000	2,000,000	2,100,000	4,150,000
Cooking . . .	400,000	180,000	800,000	474,000
Total .	11,400,000	3,180,000	7,400,000	8,024,000

In table II. the consumption and costs in the ' All-Electric House ' just referred to are given.

TABLE II.—ALL-ELECTRIC HOUSE (10 ROOMS). SIX PERSONS IN HOUSE, EXCLUDING GUEST TOTAL CONSUMPTIONS AND COSTS IN TWO SUCCESSIVE YEARS.

Details.	First Year.		Second Year.	
	Units.	Cost.	Units.	Cost.
	kw. hours.	£ s. d.	kw. hours.	£ s. d.
Fixed charge per annum .	—	12 10 0	—	12 10 0
Day load at ½d. per unit .	10,299	21 9 2	9,713	20 4 8
Night load at ¼d. per unit *	6,043	9 8 10	5,827	9 2 1
Total for year . .	16,342	43 8 0	15,540	41 16 9

In Table III. the consumptions for the several services are analysed (see *Jour. I.E.E.*, vol. 6 p. 888).

TABLE III.—ANALYSIS OF CONSUMPTIONS IN TABLE II. (DIFFERENCES IN TOTALS DUE T METER INACCURACIES.

Description.	First Year.	Second Year.	Remarks.
	kw. hours.	kw. hours.	
Heating . .	5,954	6,636	Obtained by electric fires.
Hot water { day .	1,242	1,245	Hot water stored in 87-gallon tank.
Hot water { night .	6,043	5,827	
Cooking † . .	2,777	1,858	Improvement due to self-contained utensils.
Lighting . .	568	687	Ample lighting at low cost.
Total . . .	16,584	16,253	
House closed . .	19 days.	10 days.	

THE ARTISAN'S ALL-ELECTRIC HOME.

Figures were published by Dr. S. Parker-Smith in *The Electrician* (vol. 96, p. 346). Allowin for losses in the hot water and cooking appliances, the estimate for an artisan given in Table I. i increased to 3,750,000 B.Th.U. or 1100 kw. hours per person per annum, making 5,500 kw hours per annum for a household of 5 persons. At an overall cost of 1*d.* per unit, this works ou at slightly under £23 per annum—a rather high figure for some families. In many areas, however the cost per unit averages ½*d.* to ¾*d.*, bringing the annual outlay down to a figure between £12 an £17, which is well within the reach of many artisans' families, and compares favourably wit alternative methods.

* Used for heating water in well-lagged storage tank during night hours (11 P.M. to 7 A.M.).

† At first boiling plates were used. The open-type proved unreliable when fatty liquid (*e.g.* milk) boiled over. The closed-type proved too slow for ordinary domestic cooking operations Much greater reliability, speed, and economy resulted when utensils with self-contained element (similar to the electric kettle) were used. In the first year the consumption for cooking per perso per day averaged 1·27 units. This was reduced by about one-half with the self-contained utensils

For large kitchens in restaurants, works canteens, etc., various sizes and combinations of ıparatus are made. The following data are taken from actual installations.

Class of Kitchen.	Total kilowatts.	Annual Consumption units.	No. of Meals per week.
Restaurant	247·6	146,500	9,518
Staff feeding	120·6	97·140	2,944
,, ,, ...	40·5	21·141	991
,, ,, ...	32·8	20,690	640

British Standard Specification No. 106 (1920) gives particulars of electric cooking ranges ır 5 and 10 persons respectively.

ELECTRICAL PRECIPITATION OF SMOKE AND DUST.

In recent years the Lodge system of precipitating dust particles or fumes in gases, such as the ıe gases from metallurgical works, cement mills or boiler furnaces, has been greatly developed r the Research Corporation, U.S.A., under Cottrell's patents. The apparatus consists of iron ıpes through which the gases are led, preferably downwards, with a steel or nichrome wire ıspended in the axis of each tube; the wires are charged to a pressure of 30,000 to 100,000 ılts and the pipes are earthed. The electric charge is derived from a.c. transformers with echanical rectifiers driven in synchronism with the alternating pressure so that the polarity ! the wires is always negative. The process can be carried on without cooling the gases and quires little power, from 5 to 50 kilowatts being usually sufficient. Resistance should be serted in the low-pressure circuit to limit the short-circuit current and to provide means of gulation, and reactance in the high-pressure circuit to prevent surging of the electric charge. rom 80 to 98 per cent. of the dust can be deposited; in some cases the introduction of steam is ecessary. In the case of blast furnace and cement mill gases, large quantities of potash can e recovered, particularly if salt is added to the charges of the blast furnace. Particulars of me successful installations are given below:—

Nature of Process.	Number of Pipes.	Length and Diameter of Pipes.	Pressure volts.	Rate of Flow of Gases.	Remarks.
Copper converter	608	10 ft. × 5 in.	30,000	10 ft. per sec.	97·25 per cent. recovered.
Silver furnace .	Chamber 8 ft. × 6 ft. × 16 ft.		50,000	—	Electrodes 6 in. lead strip.
Cement mills .	800	15·5 ft. × 12 in.	70,000	3·5 ft. per sec.	Temp. 900° F. 20 tons per day.
Copper and lead smelting works	384	15 ft. × 12½ in.	60,000	10,000 cub. ft. per day	Plant increased to 1,312 pipes.
Detarring coal gas	—	—	40,000 to 80,000	30,000 cub. ft. per hour	Unrectified alternating current.

Careful tests should be made before deciding on the dimensions, etc., of the apparatus to be stalled. Corrosive substances can be dealt with satisfactorily. At a certain cement factory the otash recovered is worth more than the cement. The kenotron is an efficient rectifier up to 50,000 volts. A similar process is used for separating oil from water.

ELECTRICITY IN AGRICULTURE.

The principal use of electricity in agriculture is to drive machines, in addition to lighting the rm buildings; it is also experimentally used for stimulating the growth of plants. Motors are ed either to drive stationary machines indoors from counter-shafting, or, being mounted on heeled trucks or stretchers, to drive portable machines out of doors, through belting. A farm ad has an excellent diversity factor, and as it does not come on during the evening peak load is very acceptable to a public supply system. Experience shows that for remunerative supply, t least 25 per cent. should be arable or dairy land. At Hereford the average revenue from farms about 20*l.* each per annum. With an electric milker one person can milk six cows

at once, using 20 watt-hours per cow. To churn 165 lb. of butter requires 1 kw.-hour. Cuttu 1 ton of ensilage consumes 1·38 kw.-hours. Threshing corn requires 70 watt-hours per bush of oats, 100 watt-hours per bushel of barley, 160 watt-hours per bushel of wheat. Grinding bushel of oats takes 420 watt-hours. Elevating 1 ton of hay, 200 watt-hours. The most suitab type of machine is the three-phase induction motor, on account of its simplicity and safe from fire; fire risk is a most important consideration in connection with farm work.

Electric ploughing is a special application of electricity under exceptional conditions; is usually effected with hauling gear mounted on trucks, which travel along the sides of the fiel hauling the plough (with three to five shares) to and fro across the land. The tractive effo required for ploughing in light soil is 740–820 lb. per sq. ft. of section ploughed; in heavy so 1,100–1,250 lb. For ploughing a furrow or furrows w ft. wide and d ft. deep, at v ft. per secon rhe horse-power required = $kwdv/550$, k being a constant as above, depending upon the so The speed v should not exceed 5 or 6 ft. per second. The motor should be capable of haulir double the normal load at times. Furrows up to 650 yds. long can be ploughed in this wa On a large farm the capital charges amount to 12*s.* per acre, wages to 2*s.*, energy at 1*d.* per ur to 2*s.* 6*d.* per acre for deep ploughing (12–14 ins. deep), total 16*s.* 6*d.* per acre. For ordina ploughing the cost is 11*s.* 4*d.* per acre. The hauling gear can be used also for harrowing and rollir the land, and for driving other machinery. The motor for ploughing should be of 25–30 h.p. (*Delamarre.*)

A large-sized plough can work 27 acres per day against one acre with horses.

For stimulating plant growth, the silent discharge from fine bare wires suspended abo the crops at a pressure of 50,000 volts or more, d.c., has been much used for experimental pu poses. The Agricultural Discharge Co. suspends the wires 10/12 yds. apart, at a height 16/18 ft., using one pole to 3 or 4 acres.

The Board of Agriculture reported in 1918 that experiments extending over six years show an average increase of 22 per cent. in the yield of spring cereals; some tests gave over 30 p cent. increase. The cost of a 100-acre equipment is estimated at 4*l.* per acre.

In a paper by R. Borlase-Matthews (*Journal I.E.E.*, 1926, vol. 64, p. 801) recent advanc are described and the results of much experimental work given. Details of the results obtain with electric ploughing, rotary tillers, and the reduction of plough friction by passing a curre between the coulter and ploughshare are recorded. Crop treatment has resulted in the productic of a better milling wheat and superior malting barley. The electrical method of preserving gre fodder (silage) has been improved by the addition of tubular heaters. In this case, the load kept constant during the whole time of treatment, energy consumption averaging 1½ kw. hou per cwt. of material. Central manuring plants are in use in which the contents of the manu tank are agitated by electrically-driven revolving arms or by circulation through centrifug pumps. The liquid is pumped out to stands in the fields and distributed by a hose pipe. T mains used for manuring can be employed for irrigating. The consumption for combined wateru and manuring is stated to be 90 units per acre. By illumination of live-stock sheds and poult houses, half an hour per day per man is saved in the feeding of stock, and an increase of 15 43 per cent in egg production during winter months is obtained. Lighting and heating in co nexion with beehives has resulted in an additional 17 lb. of honey per hive per annum.

Agricultural type motors have been developed on the Continent and machines suitable f the very severe conditions which obtain are available. Such a machine is totally enclosed a embodies moisture-proof vacuum impregnated windings and internal ventilation. Ball bearin should be used, simple over-load circuit breaker provided, while the starter should be enclosed the motor frame. Since the motor should be capable of working in any position the cable co nection should be made through a plug and socket. A 5-h.p. motor is the largest size require on most farms except for ploughing, 2 h.p. being a generally useful size. This entails the use suitable farm machinery. Recent practice tends towards the use of permanently installed moto on individual lines. Belt drives should be avoided by the use of self-contained compound r duction gearing, a friction drive replacing gear-wheels for motors of less than 5 h.p. Conducto are generally run outside the buildings under roof-eaves of farm buildings. For interior wirin the use of tough rubber-protected cable is advisable.

TELEPHONY.

Telephonic Transmissions.

The actual frequencies in normal speech range from about 200 to 2,500 periods per secon the mean frequency is assumed to be 800 for all transmisson calculations. Electromaget waves travel along telephone cables with a velocity depending on the electrical characteristi of the cable—i.e. resistance, inductance, capacity, and leakance; hence there is a time-la between the application of an e.m.f. at the end of a cable and the time when it affects a poi some way along the cable. At a certain distance a complete period will have been lost; th length to this point is called the 'wave-length' of the cable (α).

The magnitude of the e.m.f. also suffers attenuation, owing to the loss of energy due to esistance and leakage, according to a logarithmic law, involving the ' attenuation constant ' of he cable (β). These constants are found by the following formulæ :—

$$\alpha = \sqrt{\tfrac{1}{2}\left\{\sqrt{(R^2 + \omega^2L^2)(G^2 + \omega^2C^2)} - (RG - \omega^2LC)\right\}}$$

$$\beta = \sqrt{\tfrac{1}{2}\left\{\sqrt{(R^2 + \omega^2L^2)(G^2 + \omega^2C^2)} + (RG - \omega^2LC)\right\}}$$

er mile in each case, where,

R = resistance in ohms per mile;
L = inductance in henries per mile:
G = leakance in mhos per mile;
C = capacity in farads per mile;
ω = angular velocity in radians per second = $2\pi f$, where f is the frequency in periods per second.

These constants are of the greatest importance, as they measure the speaking qualities of the able.

The relative attenuation of the different frequencies present in the voice—i.e. the ' distortion '—is measured by the rate of change of the attenuation constant β with frequency, and is esignated by δ. Measurements are made at frequencies giving ω values of 3,000, 5,000, and ,000 radians per second, and the distortion is given by the formula :

$$\delta = 25\,(\beta_{7000} - \beta_{3000})/\beta_{5000} \text{ per cent.}$$

Transmission can be improved by decreasing R and C and by increasing L; the two former nethods are limited by the resulting increase in the weight and size of the cable. β would be ndependent of frequency, and the cable therefore distortionless, if R/L were equal to G/C; for n ordinary cable R/L is of the order of 5,000, and for gutta-percha G/C is about 120, so that nductance has to be added, to diminish both attenuation and distortion. This is done either y winding iron wire uniformly in a close helix along the length of the conductor, or by inserting nductance coils at intervals; in the latter case there should be at least nine coils per wave-length t 800 periods per second.

Loading has been extensively adopted for land-lines, but is more necessary for cables, underround or submarine; for the former, coils are used, but for the latter, both methods are employed.

To provide a standard of comparison for different types of cable, the Post Office has adopted ' standard cable ' having the following characteristics (unloaded) per mile: Total resistance, . 88 ohms; inductance, L, 1 millihenry; capacity, C, 0·054 microfarad; leakance, G, 1 microho; G/C, 18·5; wave-length constant, α, 0·1119; wave-length, 56 miles; attenuation constant, β, 0·1062; distortion, 9·5 per cent.

The British Post Office standard for long-distance communication is that the audibility should ot be worse than over 35 miles of standard cable. Allowing 10 miles for the local lines, the alance for the transmission line proper is 25 miles. Examples of the lengths of certain types f line giving this equivalent are given in the table, all being 150 lb. per mile.

Loading.	R ohms	L μH	C μF	G, μ mhos	G/C	α	Wave-length, miles.	β	Standard Cable Equiv't.	Length = 25 m.s.c.	Distortion.

The thermionic valve (p. 2332) is an almost ideal relay for telephonic transmission. For perfe action the impedance of the line must be the same in both directions and for all frequencie for this purpose each side is balanced by an artificial line, enabling even cables to be relay on to aerial lines, but in this connection continuously loaded cables are much more suitat than coil-loaded cables. A double-relay repeater gives an improvement equal to 15–25 mil of standard cable; with the aid of successive repeater stations, good speech is now possit between New York and San Francisco, a distance of about 3,000 miles.

Loaded and Repeated Telephone Cable Circuits.

(*Standard Telephones & Cables, Ltd.*)

The introduction of the telephone repeater to the sphere of practical telephony has made possible to give high-grade telephone transmission over very long distances, and also to redu

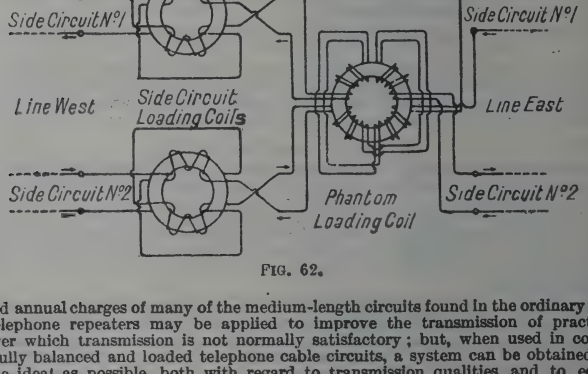

FIG. 62.

the cost and annual charges of many of the medium-length circuits found in the ordinary telephor plant. Telephone repeaters may be applied to improve the transmission of practically a circuits over which transmission is not normally satisfactory; but, when used in conjunctic with carefully balanced and loaded telephone cable circuits, a system can be obtained which as near the ideal as possible, both with regard to transmission qualities and to economic considerations.

Details of modern loading equipment and modern repeaters are briefly described under th following sub-headings.

LOADING.

The loading coils manufactured by *Standard Telephones & Cables, Ltd.* (formerly Western Electric Co., Ltd.), are designed to give the highest efficiency under all conditions of service. They have toroidal cores, which are constructed of a special magnetic material, rendering them immune from magnetisation troubles. The arrangement of the two side circuit coils and the phantom circuit coil, comprising a 'unit of loading,' is shown in fig. 62.

Loading coils can be designed to meet almost any inductance requirement. It has, however, been found convenient to establish certain standard types of coils, which cover the range of inductance required in most cases. These are, broadly speaking, classified (according to the amount of inductance) as 'extra light,' 'light,' 'medium,' and 'heavy' loading coils. The inductance of these coils covers a total range of from 25 to 250 millihenrys. When repeaters are used upon loaded lines it is necessary that the inductance of the coils be maintained within fine limits.

The coils, in suitable numbers, are contained in cast-iron cases, fig. 63, which are approximately cylindrical in form, and which contain vertical spindles on which the loading coils are mounted and completely surrounded by insulating compound.

FIG. 63.

Telephone Repeaters.

The three-electrode vacuum tube is the special feature of the modern telephone repeater as it is the special feature of modern radio-telephony and telegraphy. This vacuum tube is the most successful device for amplifying telephone currents that has yet been produced.

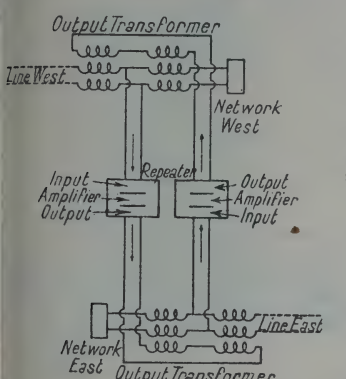

FIG. 64.

With the conducting and magnetic materials available to-day, the transmitted current on the best loaded line ultimately becomes attenuated beyond the value needed for commercial operation of the best telephone receiver. When this condition is reached the limit of improvement by loading alone has been obtained. This limit of distance is reached far short of the distances over which commercial telephony is desired, and other means for extending the range must be sought.

These are found in the telephone repeater, which is an amplifier or a device placed in the line at appropriate intervals for the purpose of adding new electrical energy to the circuit. In general, the current after passing the repeater is not better in wave form than the attenuated current which comes to it, and to this extent the repeater cannot serve one function of loading, which is to reduce the distortion. The modern telephone repeater functions so well, however, that the amplified current is to all intents and purposes an exact magnified image of the control current which it receives. In other words, it does not itself impair the quality of transmitted speech, so that if the line distortion is not too great a number of repeaters may be introduced in tandem between the transmitting and receiving stations for the purpose of extending the ranges.

The one-way repeater is the simplest form of repeater circuit. It is a device which can be connected between two telephone lines. Voice waves enter the input terminals from the transmitting ends of the circuit, and act upon the internal mechanism of the repeater in such a way as to set up an electromotive force in the output circuit which causes an output current to flow through the output impedance of the repeater to the receiving end.

Since it is essential that telephone lines should transmit equally well in both directions, it was found necessary to combine two of these one-way repeaters by special circuit arrangements, and the resulting apparatus is known as the two-way repeater (fig. 64). It will be seen that in addition to the two one-way repeaters there is additional apparatus supplied to prevent the flow of currents from the output circuit of each amplifier into the input circuit of the other. This consists of a three-winding transformer and a network, which are placed at each point where the circuits branch. Each network is made to balance its respective line, and consequently the output circuit of one amplifier and the input of the other have been effectively separated, while at the same time the inputs and outputs of the amplifiers have been left connected to the telephone circuits.

The two-way or 22-type repeater is usually used on circuits up to a length of 350 miles. Over this length the four-wire repeater is used in conjunction with a 4-wire circuit, which consists of two one-way transmission paths connected together at the ends by suitable transformers. The one-way paths may be either physical or phantom circuits. If these are physical circuits, the four-wire circuit really uses four conductors; while if the one-way paths are phantom circuits, the four-wire circuit has eight conductors. In principle the four-wire repeater consists of two one-way repeaters, each of which contains two vacuum tubes connected in tandem.

Poles for Telegraph and Telephone Lines.

Report No. 139, 1921, of the British Engineering Standards Association, provides a specification for red fir poles. They should be felled when the sap is down, and contain the natural untrimmed butt of the tree. After seasoning, the poles should be impregnated with a minimum of 12 lbs. of creosote oil per cu. ft., the specific gravity of the oil being between 1·015 and 1·07 at 38° C. The properties of the oil are detailed in the Report, together with the methods of determining them, and the limiting dimensions of light, medium, and heavy poles, from 16 to 35 ft. long, are tabulated.

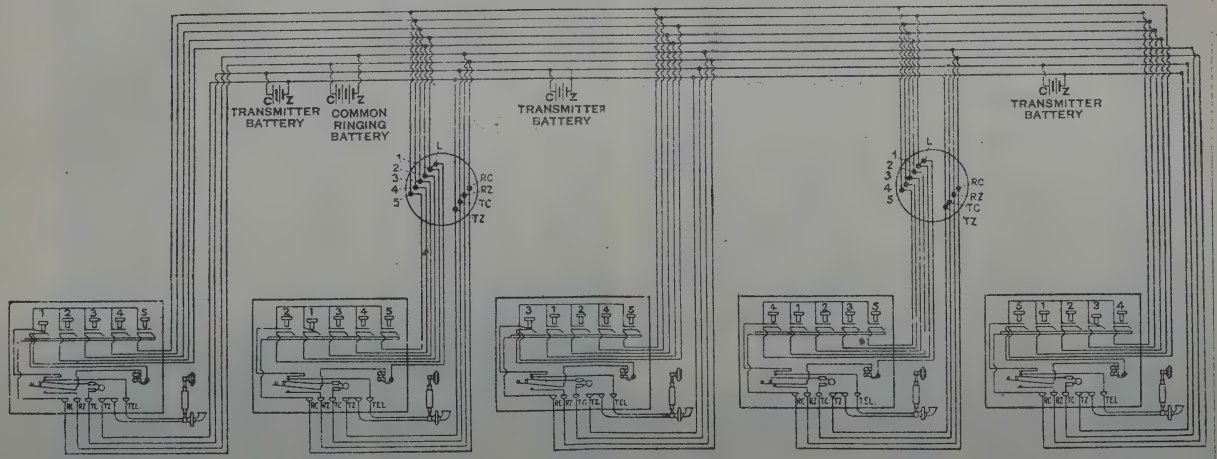

FIG. 65.—Wiring Diagram for G.E.C. Intercommunication Telephone System.

(SPEAKING AND RINGING BATTERIES SHOULD NOT BE LESS THAN THREE CELLS EACH.)

Intercommunication Telephones.

(General Electric Co., Ltd.)

The circuit diagram of the G.E.C. Intercommunication Telephones is given in fig. 65, and a all instrument (metal-cased, electro-magnetic type without induction coils) in fig. 66.

FIG. 66.—G.E.C. Wall Pattern Instrument.

This type of instrument has been specially designed by the G.E.C. with a view to strength and smooth and reliable working.

All working parts are easily removed should it be necessary at any time to make adjustments without disconnecting any of the internal wiring.

The push button line selector, line and instrument bar springs, together with the spring operated by the cradle switch, are all mounted on a steel frame by machine-cut screws, the frame being securely fixed on a stout hard wood base by means of metal bridge pieces at each end. Faults caused by warping woodwork or loose wood screws are thus obviated. The instrument possesses several unique points. It can be used either for a table or wall instrument, the cradle being of a design allowing the instrument to be fixed in either a horizontal or vertical position. This facilitates the keeping of stocks and ordering for export.

The instrument is made from one standard pattern, and can be readily extended from the minimum number of five lines to a maximum of twenty lines, by simply adding extra push buttons and springs, which are supplied at a reasonable price and in banks of five per set. These extra lines can be added without removing the instrument from its fixed position.

It is equipped with a hand combination, buzzer wound to 25 ohms, impedance coil and cradle vitch, the cover being of black enamelled pressed steel.

To reduce inductive cross-talk, which is so noticeable with some types of intercommunication lephones, the G.E.C. have introduced the 'electro-magnetic' circuit in which no induction coil used. Diagram fig. 69 shows a complete system with internal and external wiring. It will noticed that more than one speaking battery of two cells is used, in order to keep the voltage nstant on the common speaking battery leads. One battery only will suffice, providing all the struments are within 50 or 60 feet of the battery. One ringing battery of three cells is usually fficient to operate the calling signal. All lines are fitted with a black button with the exception the home line, which is usually fitted with a red button.

With the electro-magnetic circuit the receiver, transmitter, and impedance coil are in series id connected across the speaking battery terminals marked T. C. and T. Z.

The receiver is constructed with a soft iron core for one pole, and the case as the other, and is ily magnetised when the current is allowed to flow through the coil winding. The usual practice, course, is to have permanent magnets, but if this type of receiver were used with the electro-agnetic circuit the permanent magnets would in time become depolarised unless care were ken to ensure the receiver and battery being so connected as to allow the current to flow in the ght direction. To answer an incoming call the hand-combination must be removed from the adle rest and the red button pressed down; it is automatically held in this position by a sliding ir which is drilled with the necessary number of holes to allow each of the plungers attached the buttons to pass through, the bar being kept under tension by a spiral spring which forces e bar back and automatically holds the button down and at the same time brings the instrument ring in contact with the line spring and completes the line circuit. The bank of springs which e operated when the hand-combination is removed from the cradle rest automatically complete ie speaking circuit.

To call out, the button corresponding to the tablet on which the name of the person required written should be depressed; this movement temporarily connects the line spring on to the mmon ringing battery bar, allowing the current to pass along the line and operate the buzzer the called instrument.

When the pressure is removed from the button the ringing circuit is disconnected and the line id instrument springs are brought into contact, this circuit being completed in the same manner an incoming call. The button last pressed remains down, but is automatically replaced when nother is depressed.

RADIO-TELEGRAPHY.

In a radio-telegraphic system electric impulses from a transformer cause sparks acro a spark gap, which charges, discharges, and recharges the aerial. If the inductance an capacity of the aerial have values of, say, 0·56 microhenry (L) and 0·00004 microfarad (C then there will be oscillatory waves in the aerial whose time interval between the crests successive waves is given by the formula $2\pi\sqrt{LC}$, which with the foregoing values of L and gives the time interval as ·03 millionth of a second. The wave length, that is, the distanc between the crests of successive waves, or more strictly, between points of equal intensity electric stress, is equal to the velocity of propagation, multiplied by the time interval. Henc in the case of the oscillator just considered, the wave length is $300 \times 10^6 \times \frac{0{\cdot}03}{10^6} = 9$ metre

In practical wireless telegraphy the oscillating circuits employed have much larger values L and C, and the wave length is from 300 to 6,000 metres.

A plain aerial radiates energy rapidly, that is to say, it is a good radiator. After eac discharge there are only three or four rapidly damped oscillations, whereas a much greate number is necessary for long-distance work. If the voltage of the charge is too great, the ai breaks down at the top end of the aerial, by what is known as a brush discharge, and thus limit is fixed to the energy which can be imparted to the short train of electro-magnetic wave The practical result is that the maximum range obtainable is about seventy miles.

For long-distance working it is necessary to impress a large amount of energy on the aeria without requiring too great a voltage, and at the same time to produce a long series, or train waves, with very little damping. An arrangement of this kind is adopted in the Marcon system, as shown by fig. 67, and is the foundation of all the practical wireless telegraphy o to-day: it has enabled commercial working to be carried out at a range of 2,400 miles, betwee Clifden, Galway, and Glace Bay, Nova Scotia.

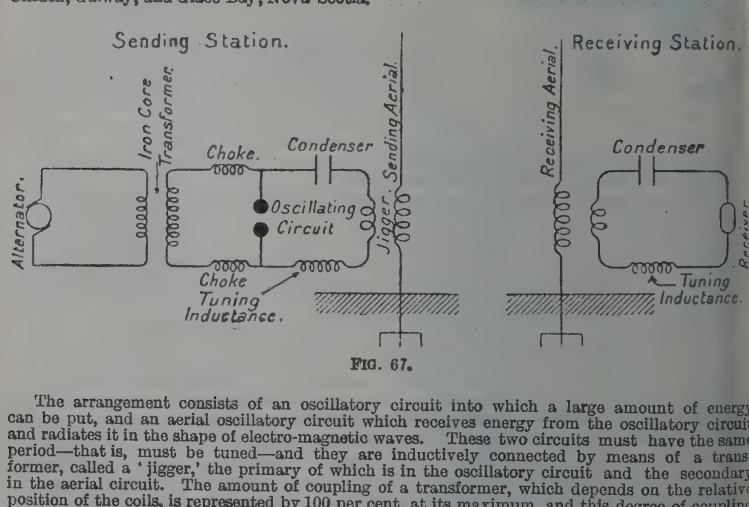

FIG. 67.

The arrangement consists of an oscillatory circuit into which a large amount of energy can be put, and an aerial oscillatory circuit which receives energy from the oscillatory circui and radiates it in the shape of electro-magnetic waves. These two circuits must have the same period—that is, must be tuned—and they are inductively connected by means of a trans former, called a 'jigger,' the primary of which is in the oscillatory circuit and the secondary in the aerial circuit. The amount of coupling of a transformer, which depends on the relativ position of the coils, is represented by 100 per cent. at its maximum, and this degree of couplin occurs when the coils are absolutely concentric; when they are at right angles to each other th coupling is zero. When the degree of coupling is 100 per cent., all the energy (apart from losses is transferred from the primary to the secondary in half a cycle, but if it is desired to transfe only a small portion of the energy at each oscillation from the primary to the secondary, th degree of coupling must be small. In wireless telegraphy the coupling is about 6 per cent. o even less.

Fig. 67 shows both the sending and the receiving arrangement, the signals being received on a telephone receiver. The receiving apparatus can be so arranged that it will not respond to signals sent out with wave lengths other than those to which it is tuned. In this way, a receiving statio can isolate itself from other wireless stations, and thus not be interfered with when receiving message from its own station. The train of electro-magnetic waves maintains oscillations in th

eceiving aerial, which are inductively transmitted to the oscillating circuit, and being properly imed, the energy is accumulated therein, and becomes sufficient in amount to actuate the receiver, nd give signals in the telephone. Unless the time period of both the small and large systems is the ame as that of the waves, there will be no accumulation of energy in the large system at the eceiving station, and the energy transmitted to the oscillating circuit will be insufficient to ctuate the receiver. The oscillating circuits and the aerials at the sending and at the receiving tations must therefore be tuned to the same period, which must be the period adopted for the lectro-magnetic waves.

For small stations, the condenser takes the form of an ordinary Leyden jar with inner and uter coatings of tinfoil. In some cases, for portable wireless stations, the test-tube form is dopted, and the tinfoil at the bottom is strengthened by a copper cap. Recently, however, est-tube condensers have been used, coated inside and out with electrolytically-deposited copper. t is important that the capacity of each jar or tube of a set should have the same capacity. For ship stations, thin zinc sheets are placed either in wooden boxes lined with zinc, or else in alvanised iron boxes which are filled with special oil of high flash point and high dielectric trength. The capacity of these condensers is 0·065 microfarad, and they are arranged in groups o that they can be connected either in series or parallel. For this purpose a commutator—nown as a Swiss commutator—is used, and the connections are made by long plugs split in two irections. For land stations, a satisfactory type of condenser consists of glass plates coated n both sides with tinfoil, a large number of such plates being immersed in oil contained in glazed arthenware vessels. At some high-power stations air-condensers are used; in the latest, they onsist of thin zinc sheets suspended from the roof and placed about 6 ins. apart. The cubic pace occupied by such a condenser is necessarily large. Thus for a capacity of 1·8 microfarad he space required is 200,000 cubic feet. The primary of the high-frequency air core transformer r 'jigger' consists of a few turns of conductor and is placed in the oscillating circuit; the econdary has more turns than the primary and is placed in the aerial circuit.

The secondary of the jigger, which is included in the aerial circuit, consists of a few turns f conductor, and it is connected to an inductance fitted with a suitable arrangement for utting more or less turns in circuit for tuning purposes. The size and nature of the con-uctor used, and the number of turns both in the primary and in the secondary, depend on the ze of the station. Excepting for very large stations, the same aerial is used, both for sending nd receiving. Three principal types are in use, namely, 'T,' 'L' and 'Umbrella.' With the mbrella type the electro-magnetic waves are radiated equally in all directions; with the T type, hich is that generally adopted for ship work, the radiation is almost uniform in all directions, ut with the L type there is a very distinct directional effect, and in this case, the aerials are rranged with a comparatively short vertical height and a long horizontal length pointing away om the station to which it is desired to send messages.

For ship work the masts of the ship are utilised; for land work frequently wooden masts, milar to those on ships, are employed, but recently tubular steel masts have been adopted uilt in sections consisting of half-cylinders bolted together by means of flanges. The longi-udinal flanges are placed alternately at right angles to each other, and by an ingenious arrange-ent the mast forms its own scaffolding for erection. Steel masts of lattice form are also mployed. The earth connection consists of wires led to ground plates, and great care is needed o obtain a good earth. This is a matter which requires expert knowledge. Sometimes, nstead of the actual earth, a wire-gauze net is spread on the ground, and in this case the earth onnection is obtained partially by a condenser effect.

The following table gives the results of observations as to the range, the power absorbed, and he wave length :—

Power Required.	Range in Nautical Miles.				Wave Length (Metres).

(*Sankey.*)

Thermionic Valves.

During the war the 'thermionic valve,' based upon an invention of Dr. J. A. Fleming, w developed to such a degree as to revolutionise practice in wireless telegraphy, and to rend wireless telephony commercially practicable; it has also been usefully applied in connecti with long-distance wire telephony, and in other directions. Its action depends upon the emissi of electrons from a heated filament in an evacuated bulb, and their reception upon a cold pla in the same enclosure, together with a controlling 'grid' to which an electromotive force is applie In wireless telegraphy the grid is energised through a transformer, by the infinitesimal currer received on the antenna, with the result that variations are produced in the current flowi between the plate and filament, which are far greater than the original waves; these effects c similarly be magnified, almost without limit, and thus the reception of wireless signals sent ha way round the world has become possible. The magnified signals, within limits, are practica free from distortion, a fact which enables the device to be used for telephony, speech beii reproduced with great clearness and fidelity. Besides acting as a detector of minute elect oscillations, the valve can also be used to rectify currents which oscillate in direction, and l making the valve react upon itself it can be used as a generator of high-frequency oscillatio In conjunction with the microphone, the valve is used to vary the amplitude of the waves emitte thus solving the problem of wireless telephony. The valves are extremely economical of energ it is stated that wireless telephonic communication can be maintained over a distance of sixte miles with an expenditure of only ten watts. In ordinary telephony the valve is used as a rel on long lines, in which capacity it is far superior to any type of mechanical relay.

Thanks largely to the three-electrode valve, for long-distance transmission much small antennæ now serve, and the continuous-wave system is generally adopted; for receiving signal so great is the magnifying power of the valve that a fixed antenna is almost superfluou a coil of wire wound on a frame a few feet square sufficing for the purpose. The ratio of magni cation of the signals may be several hundred thousand times. Wireless telephony has bee accomplished over distances of several thousand miles between land stations, and is perfect feasible between vessels at sea, and between aircraft, over considerable distances.

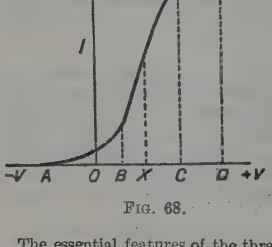

FIG. 68.

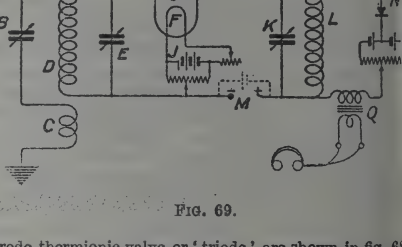

FIG. 69.

The essential features of the three-electrode thermionic valve or 'triode' are shown in fig. 6 which is a curve plotted between the plate current I (a few milliamperes) and the grid voltag or P.D. between the grid and the filament, V, the pressure applied between the plate or anode an the filament being constant. It will be seen that when the grid is slightly negative to the filamen at A, the plate current is completely stopped; when the grid voltage is zero, the plate curren has a low value, but as the grid becomes more positive to the filament the plate current increase very rapidly (between B and C), until a maximum or 'saturation' value is reached at I Assuming the grid voltage to be at the value corresponding to point X on the curve, obviousl an alternating voltage applied to the grid will cause an alternating current to flow in the plat circuit, with greatly increased amplitude, but of similar wave-form. Under these condition the valve acts as an amplifier. When the grid voltage is that corresponding to point B on th curve, a slight increase in the positive voltage of the grid will produce a current wave in th plate circuit as before, but a slight decrease in the voltage of the grid will have little effect on th plate current, the result being that, when an alternating voltage is applied to the grid, a serie of practically unidirectional currents will flow in the plate circuit. The valve under these condi tions acts as a combined rectifier and amplifier. Similar rectifying effects are produced at th point C, but in the reverse direction. The shape of the curve and its position vary with th temperature of the filament and the pressure applied to the plate, but the curve is always of th same nature.

The variations in the connections and combinations of apparatus used in conjunction wit valves are limitless; precise knowledge as to the phenomena which take place within the valv

is not yet available, but its practical operation is well understood; below are given some examples of its principal uses in the simpler forms. Fig. 69 shows the connections of a single valve used as a high-frequency amplifier in wireless telegraphy; the aerial antenna A is connected to earth through a variable condenser B and coil C, and is tuned by means of the condenser, with added inductance if necessary, to the wave-length to be received. The coil C with coil D forms an air-core transformer or 'jigger,' by which the electrical oscillations received on the antenna are transferred to the grid circuit, consisting of coil D and a variable condenser E, tuned to the same wave-length as the antenna. One terminal of the condenser E is connected to the filament F by way of a regulating potentiometer, and the other terminal to the grid G in the valve. The filament is kept incandescent by the small battery J, with a regulating resistance. The plate circuit of the valve consists of the anode or plate P, inductance coil L and variable condenser K, and a high-voltage battery M, of which the negative terminal is connected to the filament. Shunted across the plate circuit inductance is a rectifying crystal N, and the primary of an iron-cored transformer Q, the secondary of which is connected to a pair of telephone receivers. The plate circuit is tuned to the wave-length of the incoming signals, and a current flows round this circuit through the valve.

The incoming oscillations, transferred from the antenna to the grid circuit by the 'jigger,' set up a magnified alternating electromotive force between the grid and the filament, superposed upon the potential difference due to the battery J. Owing to the characteristic properties of the valve, an oscillatory current of much greater amplitude is set up in the plate circuit, which is rectified by the crystal and affects the telephone receiver. A number of valves may be connected together in cascade to produce successive amplifications, the final ratio being of the order of 20,000 or more; with suitable arrangements it is possible to detect with certainty an alternating current in the input circuit corresponding to one-ten-thousand-millionth part of one volt.

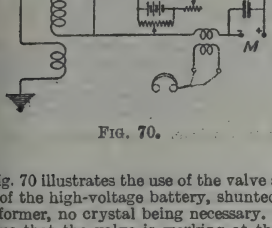

FIG. 70.

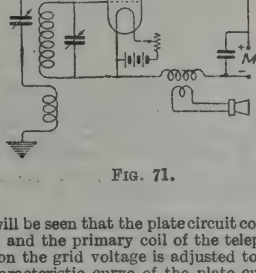

FIG. 71.

Fig. 70 illustrates the use of the valve as a rectifier. It will be seen that the plate circuit consists only of the high-voltage battery, shunted by a condenser, and the primary coil of the telephone transformer, no crystal being necessary. In this application the grid voltage is adjusted to such a value that the valve is working at the bend of the characteristic curve of the plate current (point B in fig. 68). Besides rectifying the current, the device affords a large measure of amplification, and by using a rectifying valve at the end of a series of amplifying valves a highly sensitive and efficient receiving apparatus is obtained.

Fig. 71 shows the connections of a valve used as a generator of continuous oscillations, for the reception of signals on the 'continuous-wave' system, by 'beats.' The frequency of vibration of the incoming signals being far above the limits of audition, a very efficient method of rendering the signals audible is by combining them with locally generated oscillations at a slightly different frequency, producing 'beats' as in music, the frequency of the beats being equal to the difference between the frequencies of the two sets of waves. It will be seen that the circuits are almost the same as those of fig. 70, the only change being the addition of a reaction coil R magnetically coupled with the inductance in the grid circuit. The arrangement is known as a 'self-heterodyne,' the valve performing the three functions of rectifying, magnifying, and heterodyning by the production of local oscillations. These oscillations are produced by the reaction of the current in the plate circuit on the grid circuit, and the necessary adjustment is made by varying the position of the reaction coil with regard to the inductance. The grid potentiometer, which is omitted from fig. 69, can be dispensed with in the other diagrams also, the valve being adjusted by the plate potential. When it is desired to use the valve as a transmitter, impressing continuous waves on the antenna, the plate and high-voltage battery are connected to the tuning circuit, and the grid to the reaction coil, the telephone being omitted. For wireless telephony a microphone is added, so arranged as to vary the amplitude of the oscillations in accordance with the speed vibrations. The foregoing illustrations are taken from the *Wireless World*.

The evolution of the valve has made possible wireless telephony over a distance of 1,800 miles with only 2·5 kw.; communication with aeroplanes at a distance of 200 miles with 75

watts; the recording of time signals with an accuracy of 0·02 second; and the determinatic of the direction of a source of wireless signals, with portable apparatus. Other uses to whic the valve has been put are to actuate a calling-up device on board ship, to maintain a tunin fork in vibration, to produce the rotation of a toothed disc by a direct current, and to measu infinitesimal currents and pressures.

INSULATING MATERIALS.

British Engineering Standards Specifications No. 231—1925, for Pressboard, and No. 216—192 for Vulcanised Fibre for Electrical Purposes, refer to the composition, dimensions, tensile, shearin tearing, and electrical strengths, freedom from conducting particles, and other physical pr perties. The methods of determination are specified. Specification No. 234—1925, for Eboni for Panels for Radio Reception Purposes, in addition to the above information, gives standa values and tests relating to sulphur, acetone, and ash contents, the breaking strength, surfa leakage dielectric loss, and electric strength.

DEXONITE.

This material (*Derine Ltd., Stratford, London, E.*) possesses the properties of vulcanite a ebonite, but unlike the two latter it retains its normal degree of hardness under high temperatu It is easy to tool, screw, and tap, is not brittle, and is capable of being moulded into any sha or size. It has a high electrical resistance, and is non-corrosive and acid resisting. *Speci Gravity* at 60° F., 1·2765. *Tensile Strength:* Stress per sq. in. at maximum load, 6,765 lb equivalent to 3·02 tons.

Articles made from Dexonite include insulating parts for electrical apparatus, medical i quisites, binocular parts, etc. It is also supplied in sheet, rod, or tube form to any convenie sizes.

MACONITE.

See p. 2245.

PAPER AND OTHER MATERIALS.

'Willesden' Paper (*The Willesden Paper and Canvas Works, Ltd.*) is a material largely used f electrical insulation, chiefly on the field magnets and armatures of continuous current dynam and is found by manufacturers to be of great value, as it is less hygroscopic than other materi formerly employed. It can also be used with advantage instead of vulcanised fibre in many plac such as small switches, washers on fuse and switch boards, and for telephone work, etc.

'Press Paper,' and mica in thin lamina or built up into thicker plates and rings, are mu used as insulating materials.

Asbestos Millboard Tubes, for the construction of electrical resistances and other electric appliances, are made in all lengths and diameters with walls of any thickness.

Insulating Oils for Electrical Purposes.

BRITISH STANDARD SPECIFICATION FOR INSULATING OILS FOR ELECTRICAL PURPOSES.*

(No. 148. 1927.) (*Abstract.*)

Classification and Temperature Limits.

Two classes of oil, Class A and Class B, are referred to in this Specification.

2. Class A oils, sometimes referred to as non-sludging oils, are suitable for use in transformers which the working temperature of the oil, measured by a thermometer, exceeds 80° C. (176° F

They are also suitable for use in oil switches in which the temperature exceeds 70° C. (158° F

They may be used with advantage in all oil switches of above 500-amperes capacity having th main contacts under oil and operated for long periods near their rated current or in hot situation

Class B oils are suitable for use in transformers in which the working temperature of the oil do not usually exceed 75° C. 67° F.).

They are also suitable for general use in oil switches not subjected to conditions requiring t use of Class A oils.

3. The oil of each class shall be a pure hydrocarbon (mineral) oil, clean and sufficiently fr

Alternating Currents

Their Elements Explained, and their Calculation Effected without the Use of Hyperbolic Functions

BY

H. R. KEMPE

M.Inst.C.E., M.I.Mech.E. M.I.E.E.

Containing Nine Chapters dealing with the following:—

ALTERNATING CURRENTS AND INDUCTANCE.
ALTERNATING CURRENTS AND CAPACITY.
EFFECT OF ANGLE OF LAG.
JOINT RESISTANCES.
ELEMENTARY COMBINATIONS OF RESISTANCE, INDUCTANCE, AND CAPACITY.
TELEPHONIC TRANSMISSION—ATTENUATION EQUATION.
PRACTICAL FORMULÆ (TELEPHONIC TRANSMISSION).
REFLECTION.
INSTRUMENTAL MEASUREMENT OF AN ALTERNATING CURRENT.

LONDON: CROSBY LOCKWOOD & SON

7 Stationers' Hall Court, Ludgate Hill, E.C. 4

from moisture or other matter likely to injure its insulating properties, and shall satisfy the requirements of the specification.

4. The characteristics shall be within the limits shown in the following Schedule :—

Class of Oil.	Sludge (maximum).	Viscosity at 15·5° C. (60° F.) (maximum).	Electric Strength (minimum).	Flash Point (minimum).	Evaporation (maximum).	Cold Test (maximum).
	Per cent.	Redwood Secs.	Volts.		Per cent.	
A.0	0·1	200	30,000	145° C. (293° F.)	1·6	0° C. (32° F.)
A.10						— 10° C. (14° F.)
A.30						— 30° C. (— 22° F.)
B.0	0·8	200	30,000	145° C. (293° F.)	1·6	0° C. (32° F.)
B.10						— 10° C. (14°F.)
B.30						— 30° C. (— 22°F.)

6. The oil shall not contain any inorganic acid. The acid value per gramme of oil due to organic acids shall not exceed 0·2 mg. KOH.

7. The saponification value per gramme of oil shall not exceed 4 mg. KOH.

8. The oil shall not cause discoloration of copper.

Test for Moisture in Transformer Oil.

While a thorough test for the suitability of oil for transformers and oil switches can be made only with high-tension testing apparatus, very good indications of the presence of moisture have been obtained by Mr. J. K. Mackie, superintendent of the Connecticut Power Co., as follows:—A sample of the oil to be tested is drawn from the bottom of the transformer, oil switch, or storage tank. (Samples from the upper parts of the tank are not considered suitable for the test, as water is heavier than oil and usually collects at the bottom.) In the sample thus taken is placed powdered anhydrous copper sulphate. If moisture is present the copper sulphate will be dissolved, producing a blue colour that will diffuse through the oil if moisture is in suspension. Since enough copper sulphate is added to ensure a saturated solution, the intensity of the blue tint will be a measure of the amount of moisture present. As small percentages of moisture have a very deleterious effect on the dielectric strength of oil, however, the lightest shade of blue is sufficient indication that the oil should be dried by filtering. It may be pointed out that other substances giving a deeper tint than copper sulphate may be used, the only requirement being that they dissolve quickly in water but not in oil.

'No-Mag' Non-Magnetic Cast Iron.

This is a patented non-magnetic cast iron, which combines the non-magnetic property with a high electric resistance, thereby giving great freedom from hysteresis and eddy currents.

The efficiency of 'No-Mag' non-magnetic cast iron is shown as follows:—

Metal.	Magnetic Permeability.	Specific Resistance.
	Maximum.	Micro-ohms per cm. cube.
Ordinary cast iron	330·00	95·0
'No-Mag'	1·03	140·0
Brass	1·00	7·5

The 'No-Mag' can be applied for the purposes of oil switch covers, bus bar clamps, brackets, cable boxes, transformer covers, separating pieces, sealing bells, etc.; by using 'No-Mag' for end plates and shields for generators and motors the losses due to stray flux are reduced to a minimum, thus allowing economies in design.

Anchorage for Overhead Line Structures.

In the *Electrical World* Mr. A. W. Malone describes a cheap and effective method making anchorages for overhead telegraphic or electric light line structures. A small hole bored or drilled into the ground at a suitable angle, and an explosive is ignited at the botto of it; a specially designed steel tension rod is inserted into the hole, which is then filled up wi

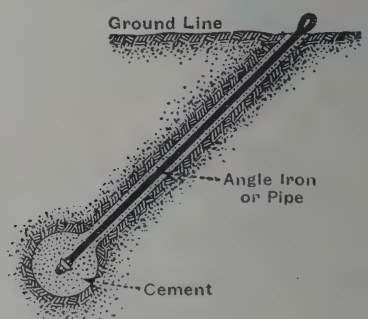

FIG. 72.

concrete. The explosion makes a cavity, which eventually contains a ball of concrete, as shov in fig. 72. Exhaustive tests show that this type of anchorage is many times as resistant uprooting as the ordinary type, whilst it is far cheaper in labour, time, and material. A Malo anchor having a concrete 'bulb' 26 ins. in diameter, 9 ft. below the ground surface, offered resistance of 56,000 lbs. after yielding 2 ins., whereas a grillage type of footing had a resistan of only 15,000 lbs.

X-Rays in Industry.

(C. Norman Kemp, B.Sc., F.R.S. (Edin.), A.I.C.)

The term 'opacity' has reference to a characteristic of certain substances in their reaction ordinary light (λ about 8,000-3,900 Ångström units).

No substance known is totally opaque to X-rays, owing to their extremely small wave-lengt although, of course, a sufficient thickness of a dense material may, in a given case, effect comple absorption, this being proportional to atomic weight and thickness.

From Planck's equation there may be derived the simple and useful relation that the produ of the *maximum* tube voltage and the *minimum* resulting X-ray wave-length is a constant, t wave-lengths being expressed in Ångström units (Å.U.),

i.e.

$$\lambda_{min.} \; V_{max.} = 12{,}400,$$

whence

$$\lambda_{min.} \text{ at } 12{,}400 \text{ volts} = 1.0 \text{ Å.U.}; \quad \lambda_{min} \text{ at } 124{,}000 \text{ volts} = 0{\cdot}1 \text{ Å.U.}$$

Within the range of wave-lengths from 1 to 0·1 Å.U. a vast amount of modern radiologi work is done, commonly employed tube voltages being 45, 60, and 100 kv.

For work on metals, however, the last figure is often largely exceeded, values up to 500 k being used, and 1000 kv. having been proposed, if not actually attempted, with the object reducing exposure times, and increasing the thicknesses which may be examined.

Industrial applications are based on the employment of X-radiations having a penetrati power (a function of λ) and an intensity related to the atomic weights (or numbers) of the co stituent elements of the material under examination, so that, as indicated, very high tube voltag are necessary for the radiography of iron and steel products.

At present, definite information as to the homogeneity of such materials may readily secured with commercially available equipment with an exposure of 30 minutes, this permitti of the detection of flaws in steel down to a sixteenth of an inch in size and up to three inches thickness. Some of the practical uses of X-rays may be conveniently grouped as follows:—

1. Examination of natural objects or substances for information as to internal structure.

2. Examination of substances or objects from stage to stage in manufacturing processes with a view to more effective control, tending towards the elimination of waste, with consequent cheapening of production.

3. Examination of manufactured products or assembled articles for homogeneity or freedom from foreign matter in the one case, and correctness of assembly in the other.

4. General research in the foregoing and other directions whereby new applications and new methods of attacking existing problems are sought.

One of the most recent applications of radiological technique is the study of the internal structure, or, as it has been called, the ' mineral skeleton ' of coals, anthracites, cokes, etc., which may be visually studied, and also photographically recorded if required.

Particularly valuable in this connection is the use of stereoscopic radiography, whereby the interior of the specimens may be viewed in natural relief, and the ash-forming constituents examined as regards nature, quantity, and distribution.

The outstanding feature of X-ray methods lies in the provision of an easy, rapid, and non-destructive test of opaque materials, a field capable of almost unlimited extension as a result of continued research.

NAVAL ARCHITECTURE AND MARINE ENGINEERING. DIMENSIONS AND GEOMETRY OF SHIPS—DISPLACEMENT, STABILITY, AND TRIM—WEIGHTS OF HULL AND MACHINERY—DEADWEIGHT—RESISTANCE OF SHIPS—ADMIRALTY COEFFICIENTS—ECONOMICAL SPEEDS—COAL CONSUMPTION—RUDDERS—ESTIMATING HORSE-POWER—DESIGNING MARINE ENGINES AND BOILERS—TURBINES—REDUCTION GEAR—TURBINE MACHINERY—CONDENSING PLANTS—DIESEL ENGINES—PROPELLERS.

(Contributed and Revised by Professor Percy A. Hillhouse, D.Sc., M.I.N.A., and James Thomson, M.I.N.A.)

DIMENSIONS OF SHIPS.

Moulded Dimensions.

LENGTH L = 'Length between Perpendiculars' = Length on load water-line measured from the fore side of the stem ('F.P.,' or 'Fore Perpendicular') to the aft side of the stern post ('A.P.,' or 'After Perpendicular'), or fore side of rudder stock if there is no stern post.

BREADTH B = 'Moulded Breadth' = Breadth measured over the widest part of the frame at the middle of the length L.

DEPTH D = 'Moulded Depth' = Depth measured from top of keel to top of deck beam at side at the middle of the length L. To avoid error the name of the deck to which the depth is measured should be stated.

Registered Dimensions.

LENGTH = Length from fore part of stem head to aft side of stern post, or fore side of rudder stock if there is no stern post.

BREADTH = Breadth measured over the outside of the shell plating at the widest part.

DEPTH = 'Depth of Hold' = Depth measured from top of ceiling to top of deck beam at the centre line of the vessel at the middle of the length. This depth is measured to the 'tonnage deck,' which is the 'second deck from below.'

Overall Dimensions.

LENGTH = 'Length Overall' = Length measured from the foremost point of the stem or figure-head (but excluding bowsprit if any) to the aft side of the taffrail, or cruiser stern.

BREADTH = 'Breadth Extreme' measured over the outside of the shell plating or belting or paddle sponsons, if any.

DEPTH = Depth from top of keel to top of deck amidships.

Drafts of a Ship.

The DRAFT d of a ship is the distance of the lowest point of the keel (or of the line of the keel produced) below the water line.

The MEAN DRAFT is half the sum of the drafts at the forward and after perpendiculars or at the stem and the stern post.

The MOULDED DRAFT δ is the distance of the top of the keel (or of the line of the top of ke produced) below the water line.

The LIGHT DRAFTS of a vessel are the drafts forward and aft when the vessel is floatin complete, with water in boilers, but without crew, fuel, cargo, stores, water or other loads.

The LOAD DRAFT of a vessel is the mean draft of the vessel when floating complete and rea for sea and with all fuel, cargo, passengers, crew, baggage, stores, spares, water, and other load The maximum load draft is determined by the freeboard tables of the Board of Trade; f passenger vessels the actual draft is limited to that determined by the spacing of the wate tight bulkheads, in accordance with the recommendations of the Convention for the Safety Life at Sea. This draft is called 'The Bulkhead Draft.'

The FREEBOARD of a vessel is the height of the top of the wood deck at side at the middle of t length above the water line. The minimum freeboard allowable for any vessel entering or leavir a British port is fixed by law. It is assigned for each vessel by the Board of Trade or Classificatic Society, and must be marked upon each side of the vessel amidships by the 'Freeboard Disc' 'Plimsoll Mark.'

The 'TRIM' or 'LEAD' of a vessel is the difference between the drafts forward and aft. It said to be 'by the head' or 'by the stern' according as the draft forward or the draft aft is t greater. When the drafts forward and aft are equal, the vessel is said to be 'on even kee 'Change of Trim' is the arithmetical sum of the changes of draft forward and aft produced b the shifting of any weight.

Displacement.

The DISPLACEMENT of a vessel is the amount of water displaced by the underwater portions her hull. It may be stated either by volume or by weight. The weight of the water displaced b a floating vessel is equal to the total weight of the vessel and her contents. If the vessel b floating in salt water, her displacement in tons, Δ, is equal to $\frac{1}{35}$ of her volume of displacement, V in cubic feet. If in fresh water, $\Delta = \frac{V}{35{\cdot}8}$.

The TONS PER INCH of a vessel at any draft is the number of tons weight which must be place on board in order to increase the mean draft one inch.

$$\text{Tons per inch, in salt water} = \frac{\text{area of water plane}}{420} = \frac{A}{420},$$

$$\text{Tons per inch, in fresh water} = \frac{A}{430},$$

where A is the area of the water plane in square feet.

Coefficients of Displacement.

The BLOCK COEFFICIENT, or *Coefficient of Fineness*, C_b, is the ratio of the immersed volum of displacement to the volume of the circumscribing parallelepipedon.

$$\text{Block coefficient} = C_b = \frac{V}{L\,B\,\delta} = \frac{35\,\Delta}{L\,B\,\delta} \text{ in salt water} = \frac{35{\cdot}8\,\Delta}{L\,B\,\delta} \text{ in fresh water,}$$

where V = Immersed volume of displacement in cubic feet,
Δ = Displacement in tons,
L = Length on load water-line, in feet,
B = Moulded breadth in feet,
δ = Moulded draft in feet.

Builders of cargo vessels usually estimate block coefficient with reference to length B.P breadth over shell plating, and draft including keel.

The PRISMATIC COEFFICIENT, C_p, is the ratio of the immersed volume of displacement to t volume of the circumscribing cylinder having the same form of cross-section as the vess below the water-line amidships.

$$\text{Prismatic coefficient} = C_p = \frac{V}{La} = \frac{35\,\Delta \text{ or } 35{\cdot}8\,\Delta}{La},$$

where a is the immersed area of the midship section to outside of frame in square feet.

The MIDSHIP SECTION COEFFICIENT, C_m, is the ratio of the area of the midship section up t the water-line to the area of the circumscribing rectangle.

$$\left.\begin{matrix}\text{Midship section coefficient} \\ \text{or midship area coefficient}\end{matrix}\right\} = C_m = \frac{a}{B\,\delta}.$$

From the above values for the three coefficients it is easily seen that

$$C_p \times C_m = C_b.$$

Mr. W. H. Riddlesworth, M.Sc., gives the following approximate formulas connecting draft, displacement, and block coefficient:—

Let α = water plane area coefficient $= \frac{A}{LB}$.

β = block coefficient.
δ = moulded draft.
Δ = displacement in tons.

Then, approximately,

(1) The waterplane area coefficient is equal to one-third plus two-thirds of the block coefficient, *i.e.*

$$\alpha = \tfrac{1}{3} + \tfrac{2}{3}\beta$$

(2) The change (c) in block coefficient per foot change in draft is equal to the complement of the block coefficient divided by three times the draft,

i.e.

$$c = \frac{1-\beta}{3\delta}.$$

(3) The complement of the block coefficient varies inversely as the cube root of the draft,

i.e.

$$1-\beta = \text{constant} \div \sqrt[3]{\delta},$$

the constant being determined for each ship from any one known draft δ_0 and the corresponding block coefficient β_0; constant $1-\beta_0 \div \sqrt[3]{\delta_0}$.

The above three relations have been found to be both useful and reliable in practical work.

Wetted Surface.

The WETTED SURFACE or IMMERSED SURFACE of a vessel is the total area of the surface of the shell plating, keel, bilge keels and rudder in contact with the water in which the vessel is afloat.

Approximately,

$$\left.\begin{aligned} S &= L(1{\cdot}7\,\delta + C_b B) \quad \text{(Mumford)} \\ S &= 3{\cdot}4\,V^{\frac{2}{3}} + 0{\cdot}5\,LV^{\frac{1}{3}} \quad \text{(Froude)} \\ S &= 15{\cdot}4\sqrt{L\,\Delta} \quad \text{(Taylor)} \end{aligned}\right\} + \text{surfaces of keel, bilge keels, and rudder.}$$

where L = length between perpendiculars, in feet,
δ = moulded draft, in feet,
C_b = block coefficient,
B = moulded breadth, in feet,
Δ = displacement, in tons; V = displacement in cubic feet.
S = wetted surface, in square feet.

Curves of Displacement, etc.

As the draft of a vessel changes, the displacement, area of water plane, coefficients, etc., also vary, and it is customary to record these changes by means of curves whose vertical abscissæ represent draft, while the horizontal ordinates represent areas, displacements, coefficients, etc.

The ordinate of the curve of displacement at any draft is proportional to the area of the curve of water plane areas up to that draft.

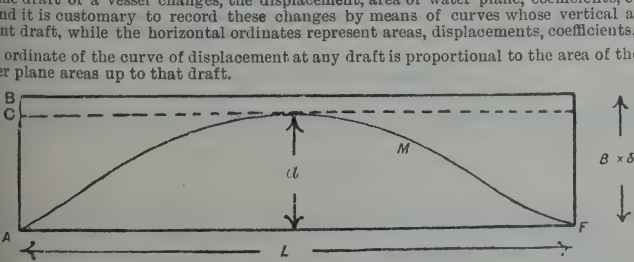

FIG. 1.

The PRISMATIC CURVE or CURVE OF AREAS for any draft is a curve whose horizontal base represents to scale the length of the vessel on load water-line, and whose ordinate at any point is proportional to the immersed area of the corresponding transverse section of the vessel. This curve shows the longitudinal distribution of the displacement, which has an important bearing upon the resistance.

Let A M F (fig. 1) be a prismatic curve, inscribed within a rectangle C F of height repr
senting the area of the midship section, and surrounded by another rectangle B F of heig
representing the area of the rectangle circumscribing the midship section. Then

Area of prismatic curve is proportional to displacement.

$$\frac{\text{Area of prismatic curve}}{\text{Area of rectangle C F}} = \frac{V}{L \times a} = \text{Prismatic coefficient.}$$

$$\frac{\text{Area of prismatic curve}}{\text{Area of rectangle B F}} = \frac{V}{L \times B \times \delta} = \text{Block coefficient.}$$

$$\frac{\text{Height of rectangle C F}}{\text{Height of rectangle B F}} = \frac{a}{B \times \delta} = \text{Midship section coefficient.}$$

Centre of Buoyancy.

The CENTRE OF BUOYANCY, B, at any draft, is the centre of gravity of the volume of displac
ment at that draft. The vertical position of the centre of buoyancy is the same as that of t
centre of gravity of the curve of water plane areas, and its longitudinal position is the same
that of the centre of gravity of the prismatic curve.

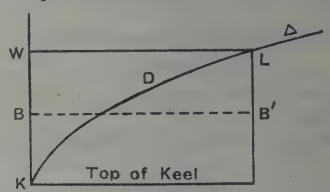

FIG. 2.

To find the height, K B, of the centre of buoyancy above the top of keel, draw the line BI
across the displacement curve so that the area of the rectangle WB′ is equal to the area W L D
above the displacement curve.

MORRISH'S RULE.

$$\text{Very approximately } K B = \frac{5}{6}\delta - \frac{V}{3A};$$

where K B is the height of the centre of buoyancy above top of keel, in feet;

δ is the moulded draft, in feet;
V is the displacement, in cubic feet;
A is the area of the water plane, in square feet;
$\frac{V}{A}$ is called 'Rankine's Mean Draft.'

KB is approximately 0·55 of the draft.

Centre of Flotation.

The CENTRE OF FLOTATION is the centre of gravity of the water plane. The two waterlin
defining any small change of trim or heel intersect at the centre of flotation.

Transverse Metacentre.

If a vessel be slightly inclined to one side the centre of buoyancy, B, will move slightly fr
the middle line towards that side, say to B′, and the vertical line through B′ representing t
upward pressure of the water will cut the inclined middle line at the point M called the 'Tra
verse metacentre.'

$$B M = \frac{I}{V}.$$

where,

BM is the height of the transverse metacentre above the centre of buoyancy,
I is the transverse moment of inertia of the water-plane about its middle line,
and V is the volume of displacement.

MB is approximately equal to 0·77 breadth^2 ÷ draft, at load draft.

The METACENTRIC HEIGHT, G M or m, in any condition of loading is the vertical distan
between the transverse metacentre, M, and the centre of gravity, G, of the whole vessel and i
contents. If, in the upright condition, G lies above M the vessel is unstable and will not rema
upright; if G lies below M, the vessel is stable and will return to the upright position if slight
inclined and set free. G M is a measure of the vessel's 'Initial Stability.'

The value of G M can be obtained either by separate calculation of the heights of G and M
by an inclining experiment.

Inclining Experiment.

In carrying out an 'Inclining Experiment' on a vessel, to determine the height, KG, of the centre of gravity, the following procedure should be observed :—

Have the vessel free from wind, tide, current, transverse mooring ropes, gangways, and particularly from loose water or other weights liable to move when the vessel is inclined. Have no men on board except those engaged on the experiment. Read the drafts carefully at each end from a small boat. Move any known weight w (enough to produce an inclination of about 2°) transversely across the deck through a total distance, a, and observe the corresponding deflection d, of a simple pendulum of length l, suspended anywhere on board. Several shifts of the weights are usually made to each side of the ship and the mean value of d taken. From the draft readings and the curves of displacement and transverse metacentres we can obtain the value of Δ, and of KM.

Then GM as inclined $= \frac{w\,a\,l}{\Delta\,d}$, w and Δ being in tons, GM and a in feet, and l and d in inches,

and KG as inclined = KM − GM.

These results apply only to the vessel in the inclining condition. To obtain the metacentric height for any other condition it is necessary to make suitable corrections for the different amounts and positions of the various items of loading and for the new values of Δ and KM.

It is usual to estimate the value of GM for the following conditions :—

Light Condition.—Ship and machinery complete, boilers and condensers full, but no fuel, cargo, passengers, crew, baggage, stores, spares, fresh or salt water, or reserve feed-water on board.

Docking Condition.

Load Condition.—Fully loaded condition; ship and machinery complete, boilers and condensers full, and with all fuel, passengers, crew, baggage, stores, spares, fresh and salt water, reserve feed-water, and holds filled with homogeneous cargo of such density as to bring the vessel to her load draft.

Spent Condition.—Same as full load condition, but with all fuel, water, and stores consumed.

Ballasted Condition.—Same as spent condition, but with water-ballast tanks filled.

Any other special conditions likely to arise in practice.

Rolling Period of a Vessel.

In Smooth Water.

K=Radius of gyration of the vessel and all weights on board, about a longitudinal axis passing through her centre of gravity.

m = Metacentric height;

2 T = Time of double roll, say from port to starboard and back again, in seconds;

g = Force of gravity = 32·2.

Then

$$T = \pi \sqrt{\frac{K^2}{g\,m}} = \cdot 554 \frac{K}{\sqrt{m}},$$ neglecting water and air resistances.

The period 2T of a double roll varies from about 3 to 30 seconds; in large Atlantic liners it is about 20 seconds.

Stability.

The INITIAL STABILITY of a vessel is the measure of the tendency of the vessel to return to the upright if she is forcibly inclined to a small angle, θ, of not more than about 10°.

Initial Stability or Righting Moment at the inclination θ = $RM_\theta = \Delta\,m\,\theta$ foot-tons.

where,

Δ = displacement in tons;

m = metacentric height in feet;

θ = angle of heel in circular measure

= inclination in degrees ÷ 57·3.

Curve of Stability.—When a vessel is inclined to any angle θ (fig. 3), the centre of buoyancy moves to one side (B to B′). The upward force of buoyancy, Δ, now acts through B′, while the weight acts downwards through G, the centre of gravity. These two forces form the righting couple, whose arm is GZ (the righting arm) and whose moment is W.GZ

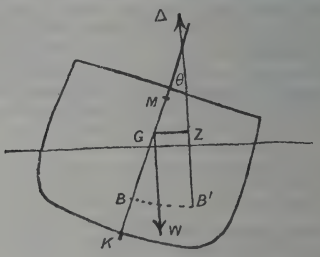

Fig. 3.

(the righting moment). When θ is small, B′Z passes through M, as already stated, and $GZ = m\theta$; at larger angles GZ must be separately calculated, and it is customary to obtain its value at each 10° of inclination and to connect the series of righting arms by a curve which is called the curve of stability (fig. 4).

OR is called the 'Range of Stability,' H the 'Maximum Righting Arm,' occurring at some

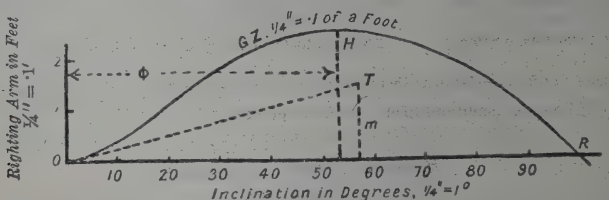

Fig. 4.

angle ϕ, while the initial slope of the curve is measured by the metacentric height, m, set up at 57·3° ($\theta = 1$), as shown in the figure, where OT is tangent to the curve at the origin O. (The scales marked are those to which the curves are usually drawn, but of course do not apply to the reduced figure.) The area of the curve of stability up to any angle is proportional to the work which must be done (by wind or other external forces) in order to incline the vessel to that angle. The work so done is called 'Dynamical Stability.'

Longitudinal Metacentre.

If a vessel be slightly inclined about a transverse horizontal axis, the centre of buoyancy will move longitudinally, and the point in which the vertical line through the new centre of buoyancy cuts that through the centre of buoyancy corresponding to even keel is called the 'longitudinal metacentre.'

The height of the longitudinal metacentre above the centre of buoyancy $= LBM = \frac{I}{V}$, where I is the moment of inertia of the waterplane about a transverse axis through its centre of gravity, and V is the volume of displacement.

The Longitudinal Metacentric Height, LGM, is the height of the longitudinal metacentre above the centre of gravity $= LBM - BG = M$.

The longitudinal GM is used in calculating changes of trim. If any weight, w, be moved longitudinally through a distance, a, the 'moment to change trim' is wa.

The 'moment to change trim one inch' or 'inch trim moment' $= {}''M = \frac{\Delta M}{12L} \overset{*}{=} \frac{I}{420L}$

Approximately, $''M = \frac{30\,t^2}{B}$

where, $''M$ = inch trim moment, in foot tons.
Δ = displacement, in tons.
L = length between draft marks, in feet.
t = tons per inch.
B = moulded breadth, in feet.
I = longitudinal moment of inertia of water plane.

The *change of trim* in inches due to any moment $w\,a$ is $\frac{w\,a}{''M}$. Of this total change of trim half is usually added to the draft at the end towards which the weight w was moved, and half deducted from the draft at the other end.

If instead of merely moving a weight already on board, we desire to find the alteration of drafts due to placing a new weight on board, first imagine the weight to be placed at the centre of flotation F. This will increase the drafts both forward and aft equally by an amount $\frac{w}{t}$. Then imagine the weight moved longitudinally to its assigned position and calculate the change of trim. Then combine these changes of drafts with the additional immersions $\frac{w}{t}$ and so find the total changes of draft forward and aft.

Curves connecting the mean draft with the position of the centre of flotation, the tons per inch, and the inch trim moment should be prepared to facilitate such calculations.

For large additions of weight the above method is not accurate, and it is necessary to prepare a complete list of all the items making up the displacement, together with their moments forward or aft of midships. Then

$\frac{\text{Total moment}}{\text{Total weight}} = \text{G}\,\boxtimes$ or $\boxtimes\,\text{G} =$ distance of centre of gravity aft or forward of midships.

From a curve connecting draft with the distance of the centre of buoyancy for even keel from midships, we can find the value of B $\boxtimes$ or $\boxtimes$ B, and hence the value of GB or BG, that is the longitudinal distance of the centre of gravity aft of or forward of the centre of buoyancy. The moment to change trim is then $\Delta \times$GB, and the change of trim $\frac{\Delta\,\text{GB}}{''M}$.

RALSTON'S STABILITY AND TRIM INDICATOR.

This useful piece of apparatus determines the metacentric height and trim of a vessel by mechanical means instead of by calculation. It consists of a capacity profile of the vessel

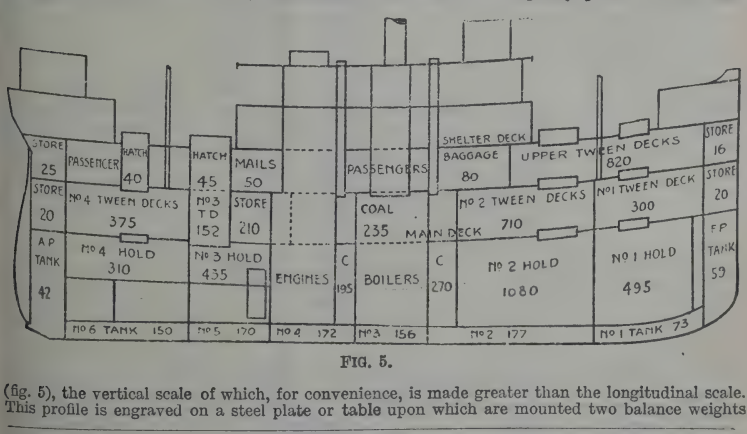

FIG. 5.

(fig. 5), the vertical scale of which, for convenience, is made greater than the longitudinal scale. This profile is engraved on a steel plate or table upon which are mounted two balance weights

* $\overset{*}{=}$ is the symbol for 'approximately equal.'

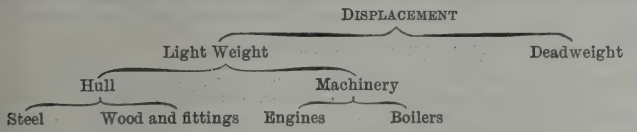
or sliders, one for stability and the other for trim. These are moved by rack and pinion over vertical and horizontal scales of 'index numbers,' engraved on the edges of the plate. The combined weight of table and sliders is made proportional to the light weight of the ship and in the zero position of the sliders the common centre of gravity corresponds in position to that of the ship in the light condition. The weights of cargo, fuel, stores, water, etc., are represented by a series of small brass weights which are placed in position on the capacity profile so as to represent any condition of loading for which it is desired to know the metacentric height and trim.

A separate diagram (fig. 6) gives mean draft and deadweight together with a series of G.M. and trim curves distinguished by index numbers corresponding to those over which the sliders move. The G.M. and trim scale movable over this diagram can be set to any draft and deadweight by means of racks and pinions. In use the table is supported firstly upon a longitudinal axis passing through the light C.G., and the vertical slider moved until balance is obtained and the 'index number' noted. The G.M. scale is then set to the correct deadweight and draft and the metacentric height read at the curve having the same index number. The table is then transferred to a vertical axis passing through the light C.G. and a similar process repeated to obtain the trim.

The instrument is simple, ingenious, and accurate; it takes into account all the features of the vessel's form and weight-distribution, obviates a considerable amount of calculation, and is being extensively adopted in the mercantile marine.

Weights.

The total weight or displacement of a merchant vessel may be subdivided as follows :—



The *Weight of Steel* includes :—

Steel and iron plates and bars of all kinds.
Structural forgings and castings, whether of steel or of bronze.
Pillars.
Steel masts.

The *Weight of Wood and Fittings* includes :—

Carpenter work.	Deck machinery and piping.	Cement.
Joiner work.	Electric lighting installation.	Insulation.
Plumber work.	Refrigerating machinery.	Rigging and sails.
Wood masts and spars.	Heating installation.	Canvas covers and awnings.
Upholstery.	Ventilation.	Sheet iron work.
Boats.	Galley outfit.	Fixed ballast.
Smithwork.	Paint.	Deck Coverings. Etc.

The *Weight of Engines* includes :—

Main propelling engines.	Sanitary and fresh-water pumps.	Piping in engine-room and tunnel.
Shafting and propellers.	Floors, ladders, and gratings in engine spaces.	Water in condensers and piping.
Condensers and circulating pumps.	Feed water.	Tools, etc.
Air-pumps and bilge-pumps.	Oil in forced lubrication system and drain tank.	
Electric generators.		

The *Weight of Boilers* includes :—

Main boilers and donkey boiler.	Piping in boiler rooms.	Floor-plates, ladders, and gratings in boiler-rooms.
Uptakes and funnels.	Feed-pumps.	Tools.
Fans and fan engines.	Feed water.	Etc.
	Hot water in boilers.	

Deadweight includes :—

Spare gear.	Reserve feed water.	Stores and provisions.
Crew and effects.	Water ballast.	Bedding and napery.
Passengers and baggage.	Bilge water.	Cutlery and crockery.
Coal in bunkers and on fire bars.	Cooling water.	Glass and silverware.
Fresh water for ship's use.	Mails and cargo.	Weights added by the owner.
Salt water for ship's use.	Oil fuel in tanks and pipes.	Etc.

Hull weight may be estimated either in detail or as a whole. Detail calculation requires that complete plans of the vessel are available, together with reference lists giving weight-rates or actual weights of all varieties of fittings. An accurate record of the finished total weights of the various items of the outfit of previous completed vessels is of great value in this connection.

For preliminary work, where a rapid estimate of the weights is required, the method of coefficients is largely relied on. In this method the whole weight of the hull, or of certain sectional portions thereof, is compared with some arbitrary parameter or parameters of simple form depending upon the principal dimensions of the vessel or of her sectional parts. For each vessel completed an accurate record of these weights is filed, and the values of the 'Coefficients of Weight' $\left(= \frac{\text{weight}}{\text{parameter}} \right)$ worked out. Then for any proposed new vessel the weight of the hull or of any of its parts, is found approximately by multiplying the proper parameter by a suitable coefficient chosen from among those of similar finished vessels.

The most commonly used parameter is the *Cubic Number*, which is the product of the Length, Breadth, and Depth, divided by 100.

$$\text{Cubic number} = N = L \, B \, D \div 100.$$

where L = Length between perpendiculars, in feet,

B = Breadth moulded, in feet,

D = Depth moulded, in feet, taken to the highest deck to which the shell plating extends continuously or almost continuously throughout the whole length of the vessel;

then,

$$\text{Weight of Hull, } H = N \times \text{Coefficient of Weight of Hull} = N \times C_h$$

Similarly,

$$\text{Weight of Steel, } S = N \times C_s.$$

$$\text{Weight of Wood and Fittings, } W = N \times C_w.$$

The weights of deck machinery, refrigerating machinery, insulation, etc., may either be included in the wood and fittings coefficient or separately estimated.

The following table gives average values of these coefficients :—

Type of Vessel.	C_s	C_w.	C_h.
Torpedo Boat Destroyer	·27	·10	·37
Cruiser	·34	·12	·46
Battleship	·33	·12	·45
River Paddle Steamer.	·20	·10	·30
Channel Steamer	·25	·13	·38
Coasting Steamer	·32	·20	·52
Cargo Tramp	·35	·12	·47
Intermediate Liner	·42	·17	·59
Fast Mail Liner	·40	·16	·56
Oil Tanker	·38	·06	·44

Other parameters sometimes used for estimating the weight of wood and fittings are

$$(L \times B) \text{ and } L \, (B + D)$$

Weight of Machinery.

In making preliminary estimates, the weight of machinery can be taken as proportional to the horse-power, the number of horse-power per ton of total machinery weight being recorded for all vessels completed and tried. A more accurate method is to record separately the weight of engines and the weight of boilers per horse-power, and to employ these rates when estimating the weight of proposed machinery of similar type. The weight of reciprocating engines may be taken as proportional to the product of the square of the diameter and the square root of the stroke of the high-pressure cylinder. For cylindrical boilers a suitable weight parameter is the product of boiler volume and square root of working pressure. For the greatest accuracy the weights of both engines and boilers must be made up in detail from the drawings and the detailed weight records of previous jobs.

Deadweight.

The total deadweight may either be specified by the owner or must be made up in detail from the particulars of the service to be performed.

Spare Gear.—Make up the weight in detail from the specified list of spares or allow a total approximate amount by reference to the actual weights carried by similar steamers. The amount may vary from about two tons in river paddle steamers and fast Channel steamers to about 40 tons in an Atlantic liner.

Crew and Effects.—Allow about one ton per ten men.

Passengers.—Allow one ton for every fifteen persons in ordinary cases and for every twenty persons in excursion crowds including women and children.

Baggage.—For the hand baggage of excursion passengers allow about one ton for every 250 persons. For long voyages allow about three tons for every ten persons.

Fuel in Bunkers = horse-power at sea, including that of auxiliaries × pounds of fuel consumed per horse-power per hour ÷ 2240 × distance between fuelling stations farthest apart ÷ service speed, + coal for galleys etc. + allowance for use in port + a margin of 10 to 20 per cent. for emergencies.

For rates of coal consumption see tables on pages 2363, 2383.

Coal on Bars.—Allow about 35 lbs. per square foot of grate area.

Fresh Water.—Allow about one ton per day for every 25 first or second-class passengers and about one ton per day for every 75 third-class or steerage passengers and crew.

Salt Water.—For sanitary purposes from ½ ton to 5 tons according to the extent of the sanitary accommodation.

Reserve Feed Water.—Allow about 4 tons per 1,000 H.P. per 24 hours for short voyages and about half as much in vessels where distilling apparatus is carried.

Provisions.—Allow about one ton per day for every 75 first and second-class passengers and about one ton per day for every 250 third-class or steerage passengers and crew.

Water Ballast.—As may be required for purposes of immersion, stability or trim during the voyage. Say one-half of weight of consumables.

Bilge Water.—Is more or less inevitable, but should not amount to much if proper care in pumping is continually taken. Allow about one-fifth of the vessel's 'tons per inch.'

Mails, cargo and stores.—As required by owners.

Bedding and napery
Cutlery and crockery } Together about one ton for every 15 persons on board.
Glass and silverware

Resistance of Ships.

The total resistance to the ahead motion of a ship is made up of three parts :—

1. 'Skin-friction resistance,' or 'skin resistance.'
2. 'Wave-making resistance,' or 'wave resistance.'
3. 'Eddy-making resistance,' or 'eddy resistance.'

The two latter are usually considered together under the name 'residuary resistance,' or 'wave resistance' merely, since eddy resistance should be very small in comparison with the other two.

HORSE-POWER.

The horse-power required to overcome any of these resistances is proportional to the resistance multiplied by the speed, and is called the 'effective horse-power.' It is from about ·45 to ·57 of the corresponding indicated or shaft horse-power developed within the vessel, the remainder of the power developed being absorbed by engine and shaft friction and losses in the propeller.

The ratio of effective horse-power to indicated or shaft horse-power is called the 'propulsive efficiency,' or 'propulsive coefficient.'

$$e = \frac{\text{E.H.P.}}{\text{I.H.P.}} \text{ or } \frac{\text{E.H.P.}}{\text{S.H.P.}}$$
$$= \text{from } \cdot 45 \text{ to } \cdot 57.$$

Skin Effective Horse-Power.

Skin E.H.P. is directly calculable :—

$$\text{Skin E.H.P.} = E_s = \frac{S}{100} \times F_{10} \times \left(\frac{K}{10}\right)^{2 \cdot 83}.$$

where,

S = wetted surface in square feet.
F_{10} = Skin E.H.P. per 100 square feet at 10 knots.
K = speed in knots.

The following table gives the values of F_{10} and of $\left(\frac{K}{10}\right)^{2 \cdot 83}$ for various lengths and speeds :—

L.	F_{10}.	L.	F_{10}.	K.	$\left(\frac{K}{10}\right)^{2 \cdot 83}$	K.	$\left(\frac{K}{10}\right)^{2 \cdot 83}$
50	1·999	450	1·832	10	1·00	18	5·28
100	1·918	500	1·826	11	1·31	19	6·15
150	1·888	600	1·816	12	1·68	20	7·11
200	1·873	700	1·807	13	2·10	25	13·37
250	1·863	800	1·798	14	2·59	30	22·40
300	1·854	900	1·790	15	3·15	35	34·65
350	1·846	1000	1·782	16	3·78	40	50·56
400	1·839			17	4·49		

From these figures curves may be drawn upon squared paper from which intermediate readings can be obtained.

Wave Effective Horse-Power.

The wave effective horse-power is not directly calculable, although several empirical formulæ and curves of coefficients have been published.

Taylor gives :—

$$\text{Wave E.H.P.} = E_w = B_e \frac{\Delta^{\frac{2}{3}}}{L} \times \cdot 0030707 \ K^6.$$

Where B_e = from ·35 to ·55, according to the degree of fullness of the vessel and her ratio of length to breadth.

The most accurate method of estimating E_w is by using the results of model experiments of actually tried vessels, and Froude's 'Law of Comparison.' The Law of Comparison may be stated thus :—If two vessels of exactly similar form, but of different size, are run at speeds proportional to the square roots of their lengths, then their wave effective horse-powers will be proportional to the products of their displacements by their speeds. If, then, we are designing a vessel n times as long as a model or similar smaller ship whose speeds and corresponding wave E.H.Ps. we know, the following ratios which various elements of the design bear to corresponding elements of the prototype may be used :—

Linear dimensions	n	Speeds	$\sqrt{n}$
Surfaces	n^2	Wave resistances	n^3
Displacements	n^3	Wave E.H.Ps.	$n^3 \sqrt{n} = n^{3 \cdot 5}$

Speeds related as above are called 'Corresponding Speeds,' and the ratio $\frac{K}{\sqrt{L}}$ of speed to square-root of length is called the 'Speed-Length Ratio.'

Model experiments give us the total E.H.P. at any speed. From this the wave E.H.P. can be obtained by separately calculating the skin E.H.P., as above described, and deducting it from the total. The wave E.H.P. for the full-size ship will be $n^{3 \cdot 5}$ times that of the model, and the skin E.H.P. for the full-size ship can be separately calculated. The sum of these two results gives the

total E.H.P. for the full-size ship. It is then finally necessary to assume a suitable value for e, the propulsive coefficient, and calculate the I.H.P. or S.H.P. by dividing the total E.H.P. by e. If we are designing from the trial results of a similar completed vessel, the procedure is slightly different :—

I.H.P. or S.H.P. of Type Ship $\times e$ = E.H.P. of Type Ship

$\frac{S}{100} \times F_{10} \times \left(\frac{K}{10}\right)^{2\cdot83}$ = Skin E.H.P. of Type Ship } at K knots.

Difference = Wave E.H.P. of Type Ship

Multiply by $n^{3\frac{1}{2}}$

and so obtain Wave E.H.P. for Design

$\frac{S'}{100} \times F'_{10} \times \left(\frac{K'}{10}\right)^{2\cdot83}$ = Skin E.H.P. for Design } at $\sqrt{n}$ K knots.

Sum = Total E.H.P. for Design

Divide by e

To obtain I.H.P. or S.H.P. for Design

where,

S = wetted surface of type ship, in square feet,
S' = $n^2 S$ = " design "
K = speed of type ship, in knots,
K' = $\sqrt{n}\,K$ = corresponding speed of design, in knots,
F_{10} = skin E.H.P. per 100 square feet at 10 knots for type ship,
F'_{10} = " " " for design.

D. W. Taylor's book, 'The Speed and Power of Ships,' which contains a series of curves based on model experiments and covering a large range of proportions of dimensions and speeds, will be found to give very accurate estimates of effective horse-power.

For fast, fine vessels, the paper 'On some Results of Model Experiments,' by R. E. Froude, published in the 'Transactions of the Institution of Naval Architects for 1904,' may be advantageously consulted. Many other experimental results have now been published both in Great Britain and America.

Admiralty Coefficients.

The 'Admiralty Coefficient of Performance' = $\frac{\Delta^{\frac{2}{3}} K^3}{P} = C$

where,

Δ = displacement, in tons,
K = speed, in knots,
P = I.H.P. or S.H.P.

Conversely $P = \frac{\Delta^{\frac{2}{3}} K^3}{C}$, so that if C is known or can be correctly assumed, P can readily be calculated. In similar ships at 'corresponding speeds' $\Delta^{\frac{2}{3}} K^3$ varies as $(n^3)^{\frac{2}{3}} (\sqrt{n})^3$, that is, as $n^{3\frac{1}{2}}$. Hence, if P were also to vary as $n^{3\frac{1}{2}}$, the values of C would remain the same. And also, if for any given vessel P varied as K^3, C would be the same for all speeds. For these reasons C is sometimes called the 'Admiralty Constant,' but as the above relations are theoretical assumptions only, and C is found to vary from speed to speed and from ship to ship, it is better to use the term 'Admiralty Coefficient.'

Although wave-making power follows the law of comparison, and therefore varies as $n^{3\frac{1}{2}}$, skin-friction power does not obey the same law and only increases at the lesser rate

$$n^2 \frac{F'}{F} (\sqrt{n})^{2\cdot83} = \frac{F'}{F} n^{3\cdot415}$$

And hence larger ships have relatively less power and larger values of C than smaller vessels. In the case of large vessels, also, a lesser proportion of power is lost in overcoming internal friction and eddy-making, and a further increase of C is the result.

In spite of its known defects, the 'Admiralty Coefficient' is largely used for estimating horse-power, the assumed value being based upon that for a similar, or nearly similar, completed vessel at 'corresponding' speed, and suitable allowances made for variations in size and proportions.

If the prismatic coefficient of the type ship differs from that of the proposed vessel, we may still find suitable values for C by modifying the 'corresponding speed' of the type ship, thus :—

$$K = K' \sqrt{\frac{L}{L'} \cdot \frac{1 - C_p}{1 - C'_p}}$$

where K, L, and C_p are the corresponding speed, length between perpendiculars, and prismatic coefficient respectively for the type ship, and K', L', and C'_p the desired speed, length, and prismatic coefficient for the proposed vessel.

Economical Speeds.

For each vessel there is a certain 'suitable' or 'economical' speed, determinable in relation to her length and fineness, above which she would be wasteful of power or 'overdriven' and below which she would be unnecessarily fine.

The following table (A) expresses these relations, and Table B gives possible values of the Admiralty coefficient on trial for vessels agreeing with Table A :—

TABLE A.

C_p. Prismatic Co-efficient.	$\frac{V}{\sqrt{L}}$ Speed Length Ratio.	C_p. Prismatic Co-efficient.	$\frac{V}{\sqrt{L}}$ Speed Length Ratio.
·61	·925	·73	·758
·63	·897	·75	·730
·65	·869	·77	·703
·67	·842	·79	·675
·69	·814	·81	·647
·71	·786		

TABLE B.

L. Length on Waterline.	C. Admiralty Coeffi-cient.	L. Length on Waterline.	C. Admiralty Coeffi-cient.
100	137	500	307
150	188	550	310
200	227	600	312
250	255	650	315
300	275	700	317
350	289	750	319
400	297	800	321
450	303	850	323

Table B assumes an efficiency, e, of about 55 per cent.; for large turbine work e appears to be about 50 per cent., so that in estimating shaft horse-power in such cases C should be taken at about 10 per cent. less than is given by the above table. For single-reduction geared turbines e = about 53 per cent.; for double-reduction geared turbines e = about 55 per cent.

The formula $Cb = 1{\cdot}06 - \frac{K}{2\sqrt{L}}$ has also been proposed as expressing a suitable connection between block coefficient and speed-length ratio.

Admiralty Coefficient applied to Fuel Consumption.

A variation of the Admiralty Coefficient much used by superintendent engineers, when comparing performances at sea, consists in substituting the daily fuel consumption in tons for horse-power in the formula $C = \frac{\Delta^{\frac{2}{3}} K^3}{P}$. We thus get:—

$$\text{Fuel Coefficient of Performance} = \frac{\Delta^{\frac{2}{3}} K^3}{T}$$

where Δ = mean service displacement in tons,
K = mean service speed in knots,
T = daily fuel consumption in tons.

Rudders.

The area of a vessel's rudder is determined by dividing the product of her length and load draft by about 30 to 40 in the case of warships, 60 to 70 for fast liners, 90 to 100 for slow cargo

tramps. The most efficient angle is about 35° from the middle line, at which angle the total pressure upon the rudder in tons is about $\frac{AK^2}{700}$ for single screw ships, $\frac{AK^2}{1000}$ for twin screws, where A is the rudder area in square feet and K the ship's speed in knots. The centre of pressure at 35° is found by assuming that the pressure on each elementary horizontal strip is applied at a point four-tenths of the breadth of the strip from its leading edge, summing the moments for each strip, and dividing by the total area.

Let h be the distance of the centre of pressure from the axis in inches, and P the total pressure upon the rudder in tons. Then T, the twisting moment in inch-tons, $= Ph$, and

$$D = \text{diameter of stock, in inches} = \sqrt[3]{\left(\frac{16\,T}{\pi F}\right)}$$

where F = maximum allowable shearing stress in material in tons per square inch.

$$\text{If } F = 5{\cdot}1,\ D = \sqrt[3]{T}$$

In practice the diameters of the rudder stocks of all classified vessels are determined by the rules of the Classification Societies.

Estimate Sheet.

When making preliminary estimates of dimensions, weights, power, etc., the following form will be found convenient:—

Number of Inquiry. Type of Vessel. Owners. Date.

Conditions.

Length × Breadth.

Type. Length × Breadth × Depth. Cubic Number.

S Steel Weight. Steel Coefficient.

W Wood and Outfit Weight. W. & O. Coefficient.

M Machinery Weight. H.P. per Ton.

D Deadweight.

$$\frac{\text{Displacement}^{\frac{2}{3}} \cdot \text{Speed}^3}{\text{Admiralty Coefficient}} = \text{Horse Power.} \qquad \frac{\text{Length} \times \text{Breadth} \times \text{Draft full}}{35} = \text{Block Number}$$

$$\frac{\text{Block Number}}{\text{Block Coefficient}} = \frac{\text{Displacement}}{\text{Keel}}$$

For example, in figures:—

Inquiry No. 42. Cargo and Passenger Steamer. Messrs. Brown and Black. 3.3.28.

To carry 6000 tons and steam 13½ knots on 24 ft. draft. Class, 100 A1 at Lloyd's. Sixty first-class. 100 second-class.

		19200	
T.S.S.	400 × 48 × 30		5760
S.	2200	·382	
W.	850	·147	
M.	750	4·54	
D.	6000		

$$\frac{9800^{\frac{2}{3}} \cdot 13\tfrac{1}{2}^3}{313} = 3400 \text{ I.H.P.} \qquad \frac{400 \times 48 \times 23'\ 10''}{35} \quad \begin{matrix} 24'\ 0'' \\ 2'' \text{ keel} \end{matrix} = 13080$$

$$\cdot 75$$

$$9800$$

These figures are arrived at by a process of trial and error-correction until a satisfactory balance is reached between weights and displacement, block coefficient and speed length ratio, horse-power and weight of machinery.

BASES OF ENGINE AND BOILER DESIGN.

Cylinder Ratios.

Considerations of weight and space usually limit the dimensions of cylinders for the machinery of high speed cross-channel vessels. For ordinary merchant and mail steamers these considerations are of minor importance; coal consumption however is of the utmost importance, and consequently a higher ratio of expansion of steam is utilised, involving larger cylinder dimensions in order to obtain maximum economy of coal consumption. In fast passenger vessels with high revolutions per minute, four-crank triple-expansion engines are invariably adopted, there being one H.P., one M.P., and two L.P. cylinders. This arrangement admits of a satisfactorily balanced engine being obtained, reducing vibration to a minimum, and the weight of the moving parts of the L.P. cylinders is considerably reduced compared with the ordinary three-crank triple engine or four-crank quadruple. The following table of cylinder area ratios is in accordance with modern practice for various types of marine engines:—

TABLE SHOWING CYLINDER AREA RATIOS.

Type of Engine.	Boiler Pressure. Lbs. per Sq. In.	Ratio of Cylinder Areas.			
		L.P. / H.P.	2nd M.P. / H.P.	1st M.P. / H.P.	H.P.
Quadruple expansion	200 to 220	8	4·0	2·0	1
		9	4·3	2·08	1
			M.P. / H.P.		
Triple expansion, ordinary merchant practice	160 to 180	6·5 to 7·5	2·5 to 2·7		1
Cross-channel steamers	180 to 200	6·25	2·4		1
Compound engines, screw	100 to 140	4 to 5	—		1
" " paddle	90 to 130	3·5	—		1

The reciprocating engine is now, however, being displaced by direct or geared turbines in all classes of vessels, from fast passenger and mail steamers and cross-channel boats to cargo vessels, even of the tramp class, owing to the reduction obtainable thereby in fuel consumption.

Mean Pressures and Expansion of Steam.

The total power developed in an engine may be varied by altering the point at which steam is cut off in the H.P. cylinder, and generally provision is made to enable the cut-off in each cylinder to be independently adjusted if necessary to equalise the powers developed in each cylinder. For the maximum designed power the cut-off in the H.P. cylinder takes place at from ·6 to ·75 of the stroke, and the total number of expansions of the steam is

$$= \frac{\text{Volume of L.P. cylinder}}{\text{Volume of H.P. cylinder at point of cut-off}};$$

or

$$\frac{\text{Ratio of } \dfrac{\text{L.P. cylinder area}}{\text{H.P. cylinder area}}}{\text{Cut-off in H.P. cylinder (expressed in fraction of stroke)}}.$$

The total expansion of the steam is usually considered with clearance neglected and neglecting also the fact that release takes place before the end of the stroke. In estimating the mean pressure obtainable in any multiple-stage expansion engine it is referred to the L.P. cylinder, the mean pressure thus obtained being that necessary if the whole of the power were developed in the L.P. cylinder. The actual referred mean pressure is, therefore, in the case of a triple expansion engine equal to

$$\text{Mean pressure in L.P. cylinder} + \frac{\text{Mean pressure in M.P. cylinder}}{\text{Ratio of L.P. to M.P. cylinder area}} + \frac{\text{Mean pressure in H.P. cylinder}}{\text{Ratio of L.P. to H.P. cylinder area}}.$$

The theoretical referred mean pressure may be calculated, assuming that the steam is moderately moist, the curve of expansion being a hyperbola. It depends upon the designed number of expansions and the absolute admission pressure of the steam.

Let Pa = absolute initial pressure,

Pm = absolute theoretical referred mean pressure,

r = total number of expansions,

$\frac{1}{r}$ = cut-off, or reciprocal of r,

then

$$Pm = Pa \frac{1 + \text{hyp. log. } r}{r}.$$

Pressure of Steam in Cylinders of Compound and Triple-expansion Engines.

The values of $\frac{1 + \text{Hyp. Log. } r}{r}$ for Various Expansions are given on page 1759.

The initial pressure, Pa, should be taken 5 to 10 lbs. below the absolute boiler pressure to allow for the drop between boilers and engines, and the back pressure, which must be deducted from Pm as found above, should be taken at not less than 4 lbs. per square inch absolute.

Diagram Factor.

Owing to the losses which occur while the steam is expanding in the various cylinders the actual referred mean pressure obtained from indicator diagrams is less than the theoretical referred mean pressure, and consequently the latter must be multiplied by a diagram factor which takes into account the losses due to clearance, condensation, radiation, friction of ports, compression, drop in pressure between the cylinders, and other losses. The value of this factor is obtained by experience, and, when possible, should be derived from engines similar to the one projected, and working under similar conditions. The values for various types of engines are approximately :—

Quadruple-expansion engines	·63 to ·68
Triple-expansion engines, merchant service	·6 to ·65
„ high-speed cross-channel engines	·56 to ·63
Compound engines	·63 to ·70

When cylinders are jacketed the diagram factors may be increased by about 5 per cent.

The power is usually divided equally among the cylinders of an ordinary compound, triple, or quadruple-expansion engine, and if N is the number of cylinders and P the referred mean pressure (i.e. theoretical mean pressure × diagram factor) the mean pressure in the various cylinders of a triple-expansion engine, for example, will be :

$$\text{L.P. cylinder mean pressure} = \frac{P}{N}$$

$$\text{M.P. „ „ „} = \frac{P}{N} \times \frac{\text{L.P. cylinder area}}{\text{M.P. cylinder area}}$$

$$\text{H.P. „ „ „} = \frac{P}{N} \times \frac{\text{L.P. cylinder area}}{\text{H.P. cylinder area}}$$

In the case of four-crank triple-expansion engines the power developed in each L.P. cylinder is usually five-eighths that of the H.P. or M.P. cylinder.

Piston Speed.

The mean piston speed is usually reckoned in feet per minute and is equal to stroke in feet × 2 × revolutions per minute.

The power which may be obtained from a given weight of engine varies almost directly with the piston speed ; the wear and tear of the engine, however, is increased with the higher speeds on account of the increased inertia stresses involved.

Piston speed may be increased either by increasing the stroke and keeping the revolutions constant or by increasing the revolutions, keeping the stroke constant.

By adopting the former method the cost, dimensions, and weight of the engines are increas whilst by adopting the latter method there is practically no increase in any of the items m tioned. It is evident, therefore, that in cases where weight and space are limited high pist speed must be obtained by high revolutions; these have a limit, however, on account of t stresses due to the inertia of the reciprocating parts.

The piston speed and revolutions of engines fitted in various types of vessels are as shown the following table :—

TABLE SHOWING PISTON SPEED AND REVOLUTIONS OF RECIPROCATING MACHINERY FOR VARIOUS TYPES OF STEAMSHIPS.

Description.	Number of Cranks.	Piston Speed in Feet per Minute.	Revolutions per Minute.
Large mail steamers	4	800 to 900	75 to 90
	3	600 ,, 750	70 ,, 80
Cargo vessels	4	650 ,, 800	70 ,, 100
	3	550 ,, 650	60 ,, 100
Channel steamers	4	800 ,,1000	170 ,, 200
	3	750 ,, 900	130 ,, 180
Paddle steamers	—	550 ,, 650	45 ,, 55

(Also see remarks about propeller revolutions for geared turbines.)

Calculation of Cylinder Diameters.

In determining the diameter of cylinders required for an engine of a given I.H.P., the typ vessel for which the engine has to be designed to a certain extent determines the piston sp and cylinder ratios, due consideration being given to the boiler pressure, the number of expansi being increased as higher boiler pressures are adopted.

Having decided the piston speed and the mean pressure referred to L.P. cylinder as alre described, the area of the L.P. cylinder may be calculated, and from the cylinder ratios deci upon the areas of the remaining cylinders are determined.

Let piston speed = S feet per minute;

referred mean pressure = P lbs. per square inch,

then,

$$\text{Indicated H.P.} = \frac{\text{Area of L.P. cylinder} \times P \times S}{33{,}000}$$

or

$$\text{Area of L.P. cylinder} = \frac{\text{I.H.P.} \times 33{,}000}{P \times S};$$

$$\text{Area of M.P. cylinder} = \text{Area of L.P. cylinder} \times \text{Ratio of } \frac{\text{M.P. cylinder area}}{\text{L.P. cylinder area}};$$

$$\text{Area of H.P. cylinder} = \text{Area of M.P. cylinder} \times \text{Ratio of } \frac{\text{H.P. cylinder area}}{\text{M.P. cylinder area}}.$$

Combined Recipro-Turbine Machinery.

In vessels of say under 18 knots the direct coupled turbine installations are not suita since the comparatively low rotational speed necessary for an efficient propeller necessit for an efficient turbine a considerable increase in dimensions and hence increase in weight cost. In such cases a combination of reciprocating engines and turbines was employed, t being two reciprocating engines to deal with the high-pressure steam and one or two turb to expand the exhaust steam down to the lowest possible pressure. In the steamer 'Otaki' system is credited with a saving of about 17 per cent. in the coal consumption; it has also b fitted to the White Star Liners 'Laurentic' and 'Olympic,' the Orient Liner 'Orama,' other vessels.

In the 'Reina Victoria Eugenia' a four-shaft 'combination' arrangement was adop the two inner shafts being driven by reciprocating engines and the two outer shafts by low-pres turbines. At low powers the reciprocating engines produced about three-quarters of the t power and the turbines one-quarter; at full output the proportions were about two-thirds one-third respectively. The steam consumption was only about 11 lbs. per h.p. per hou about 20 per cent. less than that required for quadruple expansion reciprocating machin

The revolutions of the reciprocating engines were about 113 per min., those of the turbines about 480. The sister vessel 'Infanta Isabel de Borbon' had the usual three-shaft combination, the revolutions of the turbines at full power being 276 per min. and of the reciprocating engines 116 per min.

In a three-shaft combination installation with 92 revolutions per min. for the reciprocating engines and 250 for the turbines, the reciprocating portion of the machinery produced 56 per cent. and the turbine portion 44 per cent. of the total full power, but the propulsive effect of the turbine propeller is rather disappointing. This machinery has been displaced by the geared turbine.

TURBINES.*

The development of the steam turbine as a motor for ship propulsion has progressed rapidly in the last decade. In the earlier stages of its adoption, when the turbine was directly coupled to the propeller shafting, the high revolutions necessary to obtain suitable blade speeds for low steam consumption without abnormally increasing the size and weight of the turbines entailed small propellers which were inefficient except for fast vessels, and even in these the turbines were run at an uneconomically low speed in order to improve the propellers.

The introduction of single-reduction gearing between the turbines and propellers enabled advantage to be taken of high blade speeds and fairly efficient propellers for vessels of over about 16 knots speed, and for all speeds of vessels double-reduction gearing permits the turbine and propeller designers to select the revolutions most suitable for their individual purposes so as to obtain the maximum efficiency of turbine and propeller respectively. The revolutions of the most efficient propeller for a vessel depend on horse-power, speed and form of vessel, and should be worked out in conjunction with experimental results such as those published by Taylor and Froude, but the following method gives very satisfactory results for turbines, gearing and propellers :—

If

R = revolutions of propeller per minute;
SHP = shaft horse-power of each shaft;
V = speed of vessel in knots on trial;

then,

$$R = C\sqrt{\frac{V^5}{SHP}}.$$

Note.—In 3 and 4 the speeds of the turbine vessels are higher than the corresponding vess with reciprocating machinery. If the speeds had been equal the saving would have been grea than as recorded.

Arrangement of Turbines.

Turbine machinery may be arranged to drive one, two, three, or four lines of shafting.

In mercantile vessels with direct-coupled turbines three lines were adopted, the centre sh being driven by a high-pressure turbine, the steam from which was exhausted into two lo pressure turbines driving the two wing shafts. Astern turbines were incorporated in the end of the l.p. ahead turbine casings, and during normal ahead running revolved idly in vacuu A separate high-pressure steam connection was fitted to each astern turbine, and also to ea low-pressure ahead turbine. When manœuvring in and out of harbour the wing turbines o were employed, each turbine being controlled independently of the other.

In some installations of turbine machinery in large mail steamers four shafts were employ and the steam expanded in series through an h.p. and i.p., and two l.p. turbines. This arran ment, while introducing more complication in the intermediate receiver connections, enabl a higher efficiency to be secured than in the usual three- or four-shaft arrangement.

In torpedo boats and torpedo destroyers the practice was to adopt a three-shaft arrangeme similar to that described above. Most of the vessels fitted in this manner were provided wi h.p. and i.p. cruising turbines in order to maintain economy at low speeds, and these turbin were cut out of action as the power increased.

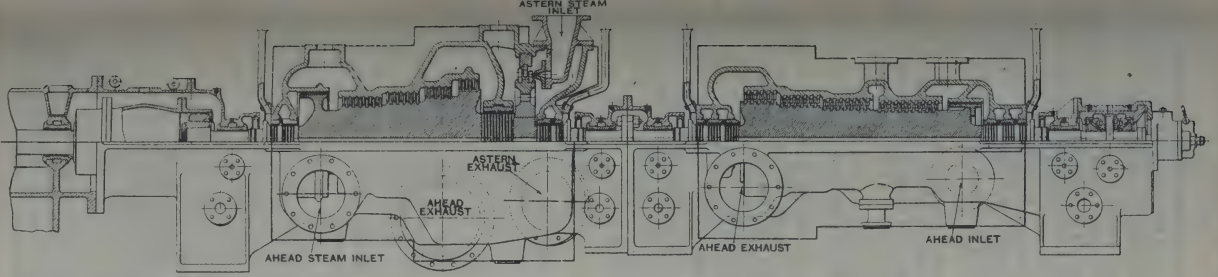

FIG. 8.—Parsons' Turbines, Section through H.P. and M.P. Turbines with H.P. astern incorporated.

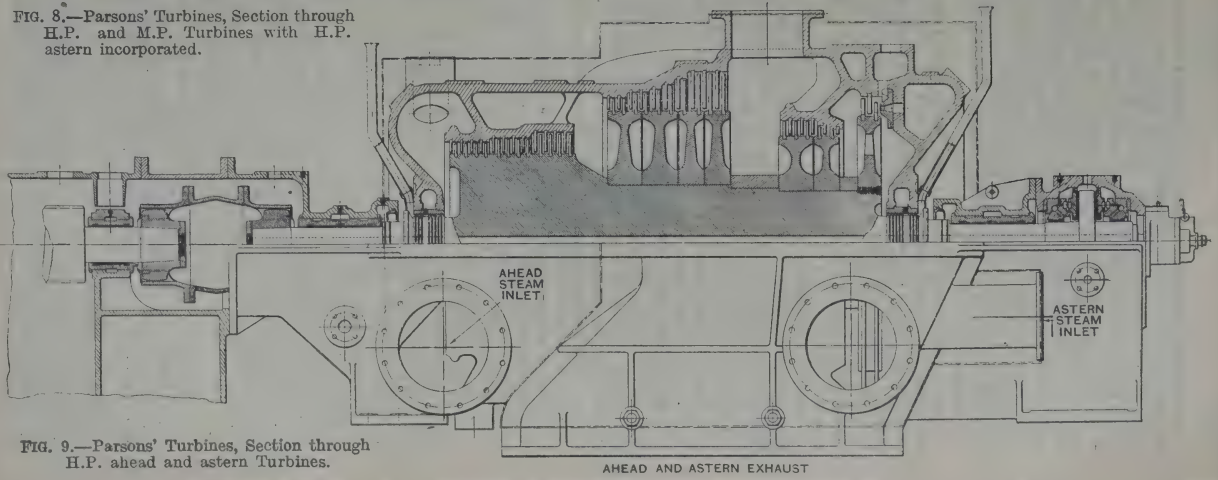

FIG. 9.—Parsons' Turbines, Section through H.P. ahead and astern Turbines.

More recent experience has shown that there are several objections to this arrangement, and in particular to the weight of these cruising turbines, and as a consequence the 'independent' type of turbine has been adopted. Where direct turbines are still fitted the installation usually consists of twin screws driven by turbines of the Parsons' or Brown-Curtis types, having the astern turbine incorporated in the same casing as the ahead turbine.

In light cruisers the machinery usually consists of two independent sets of single-geared turbines fitted in compartments separated by longitudinal or transverse bulkheads, and so arranged that in the event of damage to the one set the other will be available for use. Geared cruising turbines have also been fitted for low power.

In battle cruisers and battleships the turbine installation usually consists of two complete sets arranged in two or three compartments divided by longitudinal bulkheads. In the latter arrangement the h.p. turbines are placed in the wing compartments and the two l.p. turbines in a common central compartment, while in the former the bulkhead is placed between the l.p. turbines.

On each outer shaft there is a h.p. ahead turbine forward and an independent h.p. astern turbine aft. On each inner shaft there is a l.p. ahead turbine, having incorporated with it in the same casing a l.p. astern turbine. All four shafts are thus in use for manœuvring either ahead or astern, the steam exhausting from the h.p. ahead or astern to the l.p. ahead or astern turbine, as the case may be and from thence to the condenser.

With geared turbines each shaft is driven by an independent unit consisting of one h.p. ahead turbine and one l.p. ahead turbine with an astern turbine incorporated in the same casing with the latter.

With double-reduction gearing the high pressure unit is sometimes divided into an h.p. and i.p. in separate casings so as to reduce the length of rotor between bearings and enable higher revolutions to be run without 'whipping.' Where manœuvring requires greater astern power than can be transmitted by one pinion an h.p. astern turbine is fitted at the end of the h.p. or i.p. ahead turbine separately or in the same casing with a diaphragm to prevent astern steam entering the ahead turbine and vice versa. This arrangement is also preferred with superheated steam to minimise the change of temperature in the astern turbine when reversing.

For marine propulsion the two principal types which have been adopted are the Parsons and the Brown-Curtis. In the merchant service turbines of both types with single-reduction gear have been extensively fitted in high-speed steamers for cross-channel mail and passenger service, and the more recent development of double-reduction geared turbines is now being extensively adopted in vessels where the speed is lower, and on that account the propeller revolutions of single-reduction gear are not suitable.

The direct-coupled turbine is rarely fitted now owing to the many advantages and greater economy of the geared installations.

For naval service, so far as this country is concerned, either Parsons' turbines or Brown-Curtis turbines with single-reduction gearing are now being fitted in all battleships, cruisers, or torpedo boat destroyers. With superheated steam it is found that an economy of about 1 per cent. in steam consumption is obtained for each 10° Fahr. of superheat.

With superheated steam and the latest aids to economy, turbine machinery is a successful rival to Diesel engines at large powers. The liner *Empress of Australia*, ex *Tirpitz*, originally fitted with turbo-hydraulic propelling machinery and water-tube boilers, was recently re-engined by the Fairfield S. & E. Co., Ltd., with single reduction geared turbines of the Parsons' type and cylindrical boilers with superheaters. The speed of the vessel was increased from 16½ to 19 knots and at the same time the fuel consumption decreased from 205 to 150 tons per day. The consumption of oil fuel for propelling purposes is less than 0·7 lbs. per s.h.p. per hour. As boiler fuel oil is usually much cheaper per ton than Diesel fuel oil, and the weight, first cost, and maintenance of a turbine installation less than Diesel's, turbine machinery is more economical and suitable for installations of this class for powers above 15,000 s.h.p.

The present tendency is to increase boiler pressures and superheat as in land installations, and the success of this development was demonstrated on a river steamer for the Clyde service, the *King George V.*, which is driven by Parsons' geared turbines of 3,500 s.h.p. The boilers are of the water-tube type generating steam at 520 lbs. pressure and 815° F. temperature. The fuel consumption on the official trials was 1·085 lbs. of coal per s.h.p. per hour for all purposes.

Parsons' Marine Turbines.

Longitudinal sections through typical Parsons' reaction turbines are shown in figs. 8 and 9 and these turbines would be used in the arrangement shown on fig. 13, page 2368, the H.P. and M.P. tandem turbine taking the place of the H.P. turbine shown in the figure.

A set of Parsons' turbines of 3,000 s.h.p. with double-reduction gearing is shown in figs. 10, 11, and 12, p. 2367.

There is one h.p. and one i.p. ahead turbine each developing approximately one quarter of the total power and driving separate pinions geared to one first reduction gear-wheel. The l.p. turbine develops one half power and is geared to the first reduction gear-wheel on the opposite side of the main wheel. An h.p. astern turbine is incorporated in the same casing as the i.p.

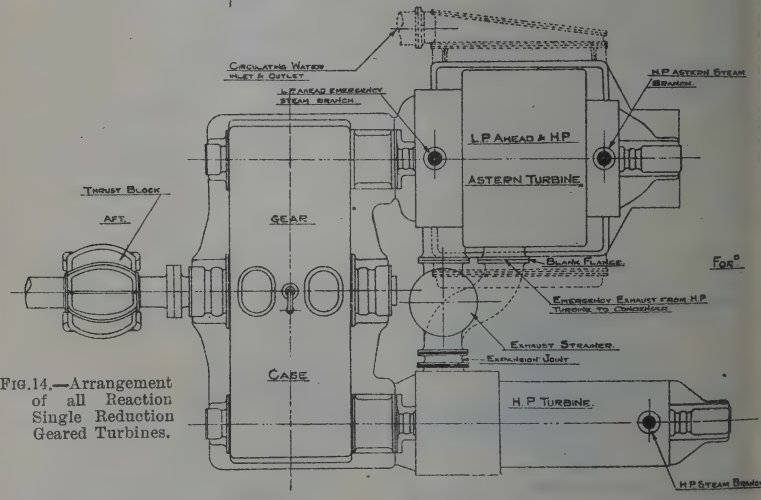

FIG. 14.—Arrangement of all Reaction Single Reduction Geared Turbines.

ıhead turbine but separated from it by a diaphragm and the l.p. astern turbine is also incorporated with the l.p. ahead.

Owing to the high revolutions at which turbines can run with double-reduction gearing, the lesired blade speed can be obtained with a small diameter of rotor and consequently the end thrust due to steam pressure is low enough to be taken entirely on a thrust block of the pivoted ype, thus dispensing with dummies and the leakage caused by them. In addition, the blade ieights to pass the steam are greater than in large rotors of equal power, but as the clearance s not increased the percentage loss due to leakage past the tips is much less in the geared turbine. As a result of these and other advantages the steam consumption is much reduced from that equired for direct-coupled turbines, and if superheat is used, say 200° F., the consumption for urbines only, exhausting to 28 inches vacuum, will be from 8 to 8½ lbs. per hour.

Figs. 11 and 12 show the arrangement of the double-reduction gearing for this set of turbines.

Fig. 13 shows an alternative arrangement with two turbines instead of three. There is one l.p. and one l.p. ahead turbine with a corresponding astern turbine in each casing.

This arrangement is simpler, but the consumption is slightly higher than in the three-turbine ırrangement.

Fig. 14 shows a set of single-reduction geared turbines with one h.p. and one l.p. ahead turbine ınd an h.p. astern turbine incorporated with the latter.

This arrangement is suitable for low powers or where the propellers can be run at higher evolutions as in channel or shallow-draught steamers.

Brown-Curtis Turbines.

Figs. 15, 16, and 17 show a set of Brown-Curtis turbines for a double-reduction geared instalation for one shaft of a liner.

The h.p. turbine is sometimes designed with three wheels each with two rows of buckets r moving blades, and at others with one two-bucket wheel and several single-bucket wheels. The m.p. and l.p. ahead turbines have single bucket wheels, and in the astern turbines there re usually two three-bucket wheels, or if a greater proportion of astern power is required, one hree-bucket and two two-bucket wheels.

The turbines are arranged with the h.p. and m.p. in line and coupled together, driving one inion of the gearing and the l.p. turbine driving a separate pinion. This arrangement enables he designer to choose the revolutions most suitable for each turbine.

The astern turbines are arranged with the first or h.p. stage in the low pressure end of the l.p. ahead turbine casing, but separated from it by a diaphragm, and the l.p. astern in the orresponding l.p. ahead casing exhausting through the common pipe to the condenser. The stern drive is thus distributed over both pinions, and especially with superheated steam the hange in the casing temperature of the first stage when astern steam is turned on is not so great.

The casings and diaphragms are of cast iron, except where superheated steam is used, when ne casing of the h.p. is of cast steel and the diaphragms of special bronze.

The rotors and wheels are of mild steel and specially designed to avoid 'whipping' and to ithstand the stresses caused by the high speed of rotation. The blades or buckets are of special ronze capable of maintaining its strength at high temperatures, and the nozzles are formed of teel plates embedded in the diaphragms during casting. The rotors pass through glands at ach end of the casing, which are packed with carbon rings to prevent the egress of steam at the igh pressure or inlet of air at the low pressure stages.

The end thrust of the rotor is small and is taken up by a thrust block, usually of the Michell ype.

Reduction Gear for Propulsion.*

The development of the turbine has led the way to the adoption of indirect transmission etween the turbine and propeller, in order to utilise to the fullest extent the economy to be erived from running the turbines at high relative speeds and the propellers at reduced speed, s compared with direct-driven turbines. The importance of saving a few ounces of coal per .p. per hour, and five per cent. or more in propeller efficiency in modern large power ships, either aval or mercantile, is obvious. In the former the radius of action with available fuel supply increased, and in the latter a substantial reduction is made in the annual fuel bill.

The following systems have proved successful, and may be now considered beyond the experiıental stage :—

(*a*) Parsons' mechanical gearing.
(*b*) Fottinger's hydraulic transformers.
(*c*) Electric transmission.

(*Continued on p.* 2374.)

* See also pp. 1022, 1869.

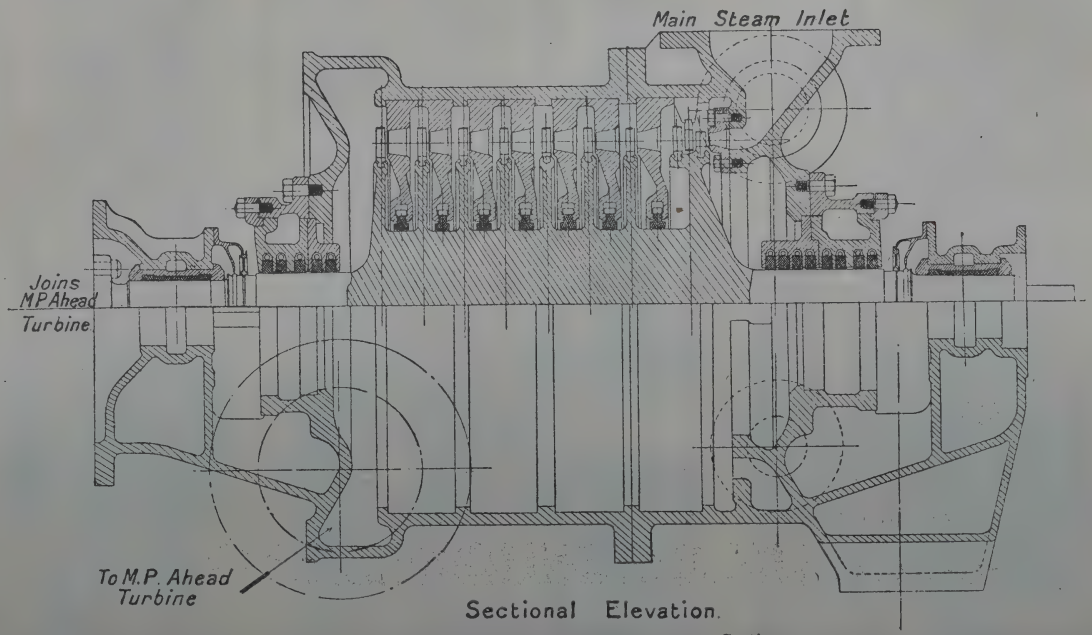

FIG. 15.—H.P. Ahead Turbine (Brown-Curtis).

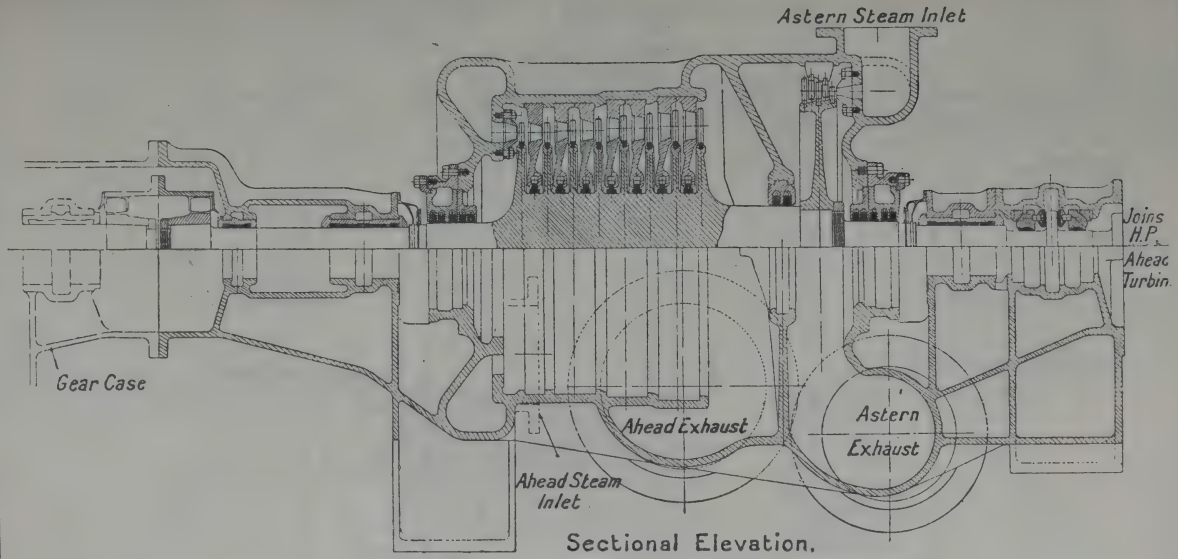

FIG. 16.—M.P. Ahead and H.P. Astern Turbine (Brown-Curtis).

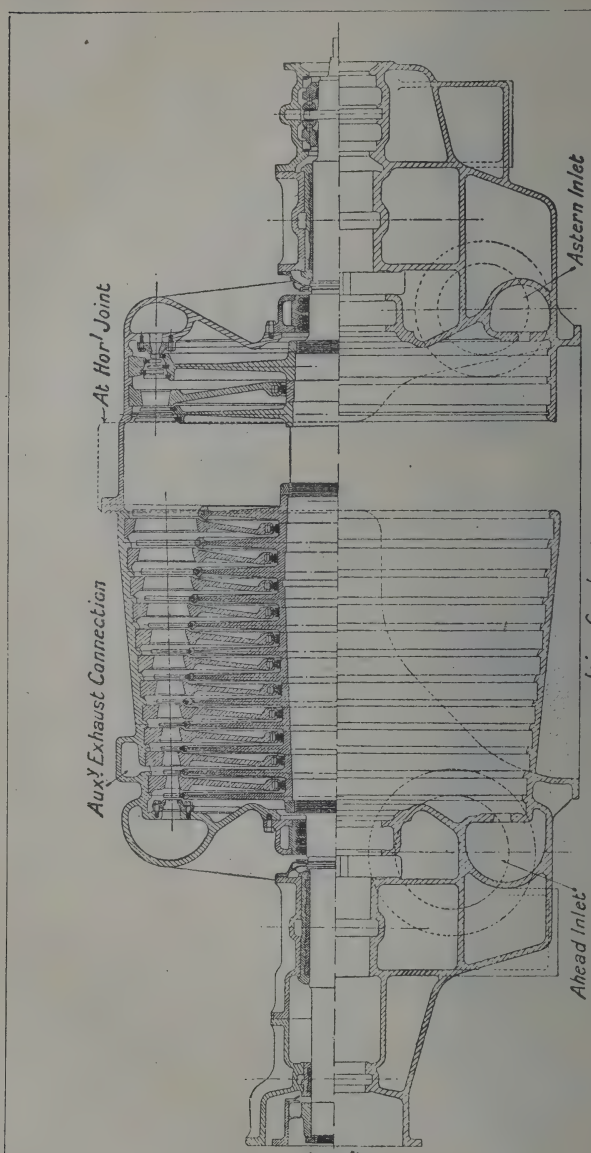

FIG. 17.—L.P. Ahead and Astern Turbine (Brown-Curtis).

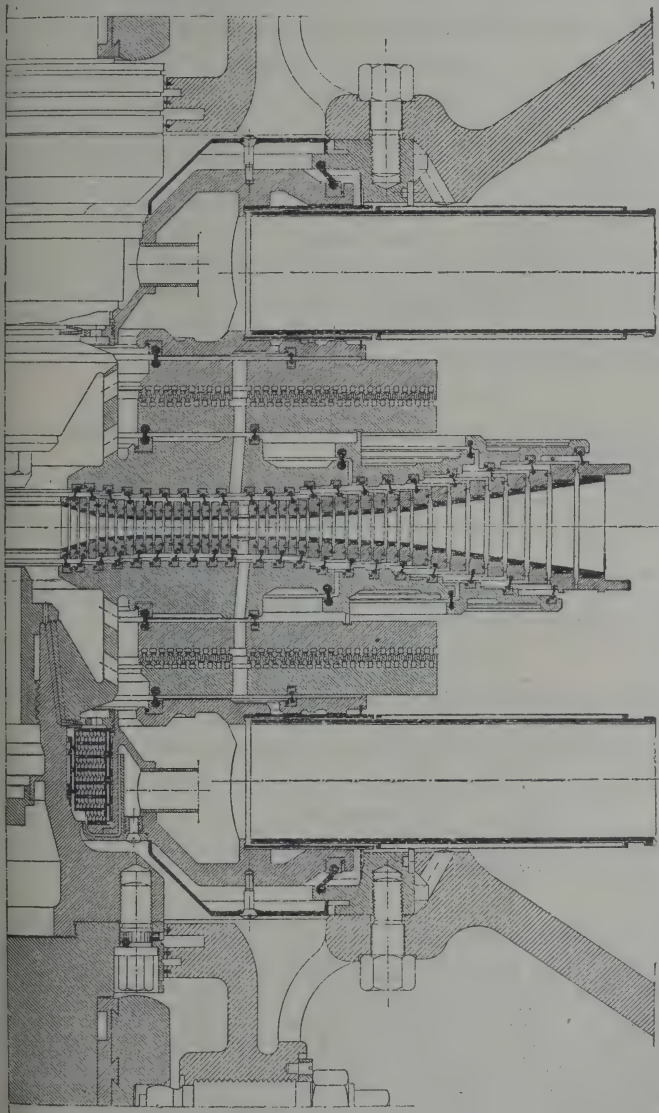

FIG. 18.—Longitudinal Section of a 1,000 K.W. Ljungström Turbine (Lower part).

The details of these systems are described in the following pages.

Each system will have certain fields of application where its particular advantages render its use desirable.

Some of the relative advantages and disadvantages of the systems are as follows:—

(*a*) MECHANICAL GEARING.

Advantages.

(1) Reduction in weight of installation from 10 to 15 per cent. as compared with direct coupled turbines.

(2) Reduction in fuel consumption of 10 per cent. on same basis.

(3) High mechanical efficiency of gearing, 97 to 98 per cent. for double and single reduction gears respectively.

(4) Large speed reduction ratio permissible, so that greatest propeller efficiency can be obtained without impairing turbine efficiency.

(5) Simplicity of mechanism.

Disadvantages.

(1) Separate turbines for astern running are necessary which are only capable of developing about two-thirds of ahead power.

(2) Noise in engine room. This is very slight with the recent improvements in tooth cutting, and is not noticed outside of machinery space.

(3) Wear in teeth. With properly designed gears and properly cut teeth this is very slight. The introduction of the 'Nodal Drive' by removing torsional vibrations from the working range of revolutions has reduced wear and tear considerably.

(*b*) HYDRAULIC TRANSFORMERS.

Advantages.

(1) Astern turbines dispensed with and about 85 per cent. of ahead power available for astern running with reversible transformer.

(2) Absence of noise.

(3) Relatively no wear.

(4) Practically no limitation in power to be transmitted.

(5) Increased manœuvring power due to greater astern power and practically instantaneous reversal.

Disadvantages.

(1) Lower efficiency as compared with mechanical gearing, about 89 per cent.

(2) Limitation in speed reduction ratio, the maximum being about 6 : 1, and in consequence a reduction of efficiency of both turbines and propellers as compared with geared turbines, but not to the same extent as with direct-coupled turbines.

(*c*) ELECTRIC TRANSMISSION.

Advantages.

(1) Astern turbines dispensed with and full power available for astern working.

(2) Absence of noise.

(3) No wear and minimum cost of upkeep.

(4) No restriction in revolutions, so that highest efficiency of turbines and propellers can be realised.

(5) Great economy in multiple screw ships at low power, as one generator can be cut out entirely.

Disadvantages.

(1) Greater first cost than geared turbines.

(2) Higher consumption at full power than geared turbines—say 6 per cent.—due to transmission losses in generator and motor being greater than in gearing.

PARSONS' GEARING.*

This gearing consists of a large gear wheel with double helical teeth about $\frac{7}{8}$ in. pitch, coupled to the propeller shaft, and driven by either one or two pinions, coupled to the turbines. The connection between the pinion spindle and turbine spindle is by means of a claw coupling, which under running conditions permits of any slight lateral movement due to the expansion of the turbine rotor under steam being taken up. The gearing is completely enclosed in a cast-iron casing, which also forms the support for the bearings of the gear wheel shaft and pinion spindles. Jets of lubricating oil from the forced lubrication system impinge on the teeth at the point of contact of the pinion and wheel, and the spindles and shaft bearings are also connected to the forced lubrication system. The double helical gear ensures the transmission of pressure from one tooth to another without shock or vibration, and as the teeth are of true involute form complete line contact exists during the time they are in mesh. The pinions are made of nickel steel, having a tensile strength of about 40 tons per sq. in. with 25 per cent. elongation, and the gear wheels of carbon steel having a tensile strength of about 32 tons per sq. in. with

* See also pp. 1022, 1869.

PARSONS' GEARING.

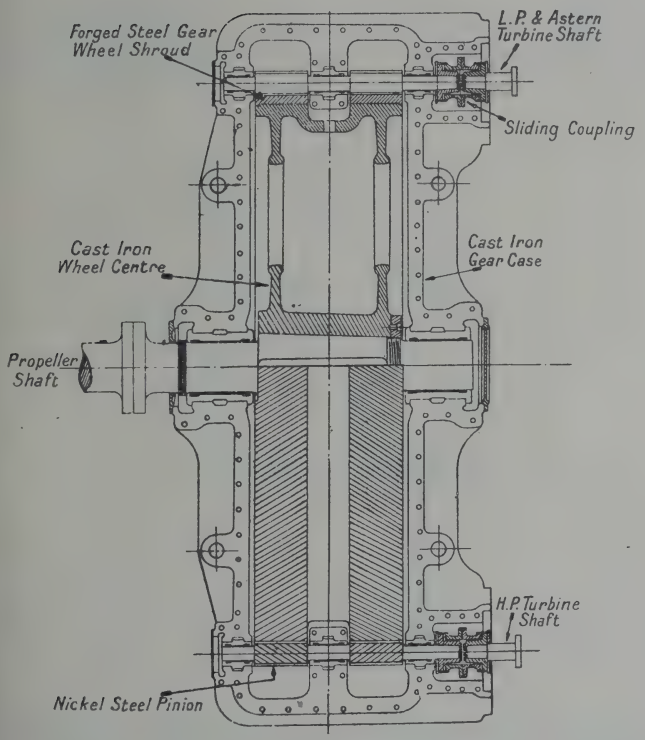

FIG. 19.—Plan with top casing removed.

26 per cent. elongation. Absolute accuracy in cutting the gearing is essential, and any corrective process or hand work after the gear is cut is inadmissible. The machines employed are the result of extensive and costly experiments, both in design and construction. In the double reduction gears the pitch of the teeth in the intermediate pinion and large wheel varies from $\frac{7}{16}$ to 1 inch.

Marine Reduction Gears.

(The Power Plant Co. Ltd., West Drayton.)

According to the ratio of reduction of the turbine speed to the propeller speed, single or double reduction gears are employed; for instance, single reduction gears are quite practicable, and a large number of vessels are running with a reduction up to 20 to 1.

This last reduction has recently been effected for two Dutch Royal Mail steamers by the above company.

Where, however, a power exists about 4,000 h.p., and for any reduction from 20 to 1, the low speed wheel becomes too large for practical purposes; recourse must then be made to double reduction gears.

Up to the present time double reduction gears have been supplied for a total reduction ratio of 70 to 1, but there is no reason why 100 to 1 could not be effected just as easily. The general arrangement of a typical double reduction set is shown in figs. 12 (p. 2367), 19, and 20.

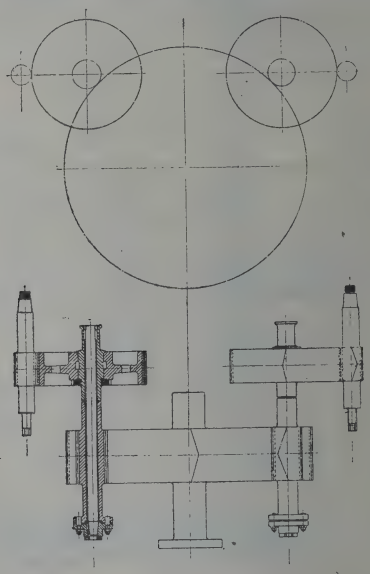

Fig. 20.

The essential feature of these gears is the use of two independent high-speed gear trains, each driven from one turbine, and a second reduction with a common wheel for the drive from both turbines, the low-speed train being arranged symmetrically relative to the high-speed trains. The advantages of the arrangement are that the power from each turbine is transmitted to the final wheel independently, whereby an even distribution of pressure on the teeth of same can be relied upon. The housing of all the gear trains in one casing effects a considerable saving in space fore and aft, where space is of most value, and reduces the gear weight without sacrifice of strength and rigidity. The gear wheels and bearings forming an arrangement symmetrical at right angles to the shafts, the deflections caused by the load are reduced to a minimum. The use of a single gear case simplifies the oiling arrangements and greatly simplifies the construction of the gear seatings in the vessel. The reduction of the number of bearings required to a minimum improves the overall efficiency and simplifies supervision.

With regard to efficiency, single reductions will go up to 98½ per cent., and double reductions up to 97 per cent.

The first steamer to be equipped with reduction gearing (made by *The Power Plant Co., Ltd.*) was the 'Vespasian,' a single-screw steamer of 2,150 tons. This gearing, as tested by Sir Charles Parsons, gave 98½ per cent. efficiency, and a fuel economy of about 13 per cent. was obtained. The cross-channel steamers, 'Normannia' and 'Hantonia' (with gearing made by The Parsons Marine Turbine Co., Ltd.), with a gear ratio of about 7 : 1, consumed only 43 tons of coal per trip, as compared with 70 tons per trip required by direct-driven turbine vessels of similar dimensions and speed, engaged in the same service.

Mechanical gearing for turbines has developed enormously in recent years, and is now being used extensively for ships of all powers and classes. Double reduction gearing makes it possible to run the turbines twenty or thirty times as fast as the propellers, with a consequent gain in overall efficiency.

Fottinger's Hydraulic Transformer.

The hydraulic transformer (fig. 21) consists of two centrifugal pump wheels, A, keyed to the primary shaft, which is driven by the turbine. On the secondary, or propeller, shaft three impulse reaction water turbine wheels are mounted, the after two, B and C, for ahead driving,

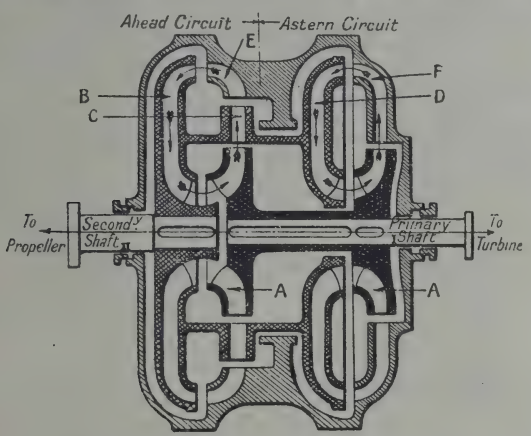

Fig. 21.—Fottinger's Hydraulic Transformer.

and the forward one, D, for astern driving. The wheels for ahead driving absorb the energy delivered to them from the water discharged by the pump wheel in two stages, the primary stage, C, being connected to the astern water turbine wheel, D. Having given up part of its energy in the primary ahead stage, the water moves in continuous compact flow through guide vanes, E, in the casing to the second stage ahead wheel, B, which absorbs the remaining energy in the water. The discharge from the second stage wheel flows back to the beginning of the circuit in the pump wheel, giving up to it the remaining energy of discharge. In the same way the astern driving wheel, D, receives its energy from the water discharged by the forward pump wheel guided into it by the stationary vanes, F, in the casing.

The vanes in the ahead and astern turbine wheels are spaced in opposite directions to each other, thereby giving the reversed motion.

A change valve, controlled by a lever, admits the water from either pump wheel to the corresponding turbine wheel to give the desired direction of rotation.

The wheels and vanes of the transformer are made of bronze, and the casings of cast iron.

The efficiency of the transformer decreases with an increase of speed reduction ratio on account of the higher velocities causing increased fluid friction.

Fresh water is used in the system, and on account of the work done upon it by friction during its passage through the vanes heat is generated. Part of this heat, which would otherwise be lost, is saved by using the water for feeding the boilers, the quantity of water in the transformer system being maintained by filling up with colder water from the air-pump discharge.

The Vulcan Diesel Hydraulic Drive.

The Vulcan gearing, fig. 22, which transmits the power of two Diesel engines to a common propeller shaft, consists of a large helical gear wheel mounted on the propeller shaft, and in which two pinions engage with gear ratio of about 3 : 1. These pinions are connected through liquid clutches to the crank shafts of two Diesel engines. The clutches, built under the Vulcan-Föttinger patents of the Vulcan Werke, each consist of a compartment for running ahead and a compartment for running astern.

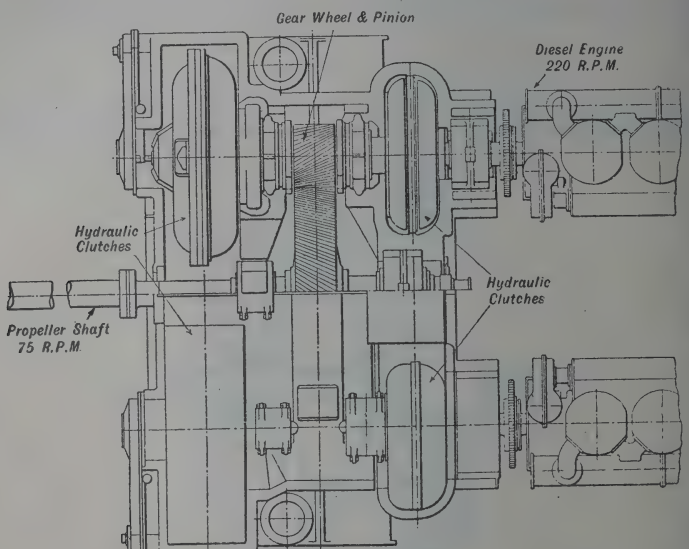

FIG. 22.

The engines are reversed by alternately filling and emptying the ahead and astern compartments by means of a reversing gear operated from the engineer's platform controlling the centrifugal pumps driven from the primary shafts. The driven pinions, and consequently the propeller shaft, run in the same or in the opposite direction to that in which the engine shafts rotate, according to whether the clutches for forward or for astern running are filled with liquid. When the propeller is reversing the Diesel engines require no attention as they run permanently in one direction.

The controlling mechanism is so arranged that the liquid or hydraulic clutches of both the Diesel engines are operated simultaneously. In the event of one of the engines requiring to be stopped during working, an arrangement is provided whereby the two compartments of its respective clutch are emptied and the engine cut out.

The efficiency of the Vulcan gearing is in normal ahead running 97 per cent. The power available for astern running is 65 per cent. of the ahead.

The gearing and the clutches are built together, forming one complete unit in a common cast-iron casing. The hydraulic clutches are of cast iron. The pinions and the wheel rim, which is shrunk on to the cast-iron body of the large gear wheel, are of special steel. The teeth are cut on a precision milling machine by the involute process. The shafts are of Siemens-Martin steel; all bearings are lined with white metal. The front bearing of the large gear wheel is constructed as a thrust bearing and takes up the thrust of the propeller shaft so that no additional propeller thrust block is required.

The liquid used for operating the clutches is lubricating oil. The bearings and teeth of the gear wheels are lubricated with the same oil by which the liquid clutches are operated. The lubricating oil and the oil which drips from the bearings of the gearing and from the clutches is

caught in a collecting reservoir placed underneath the gearing. It is drawn from this collecting reservoir by a lubricating oil pump which pumps the oil through a filter and a collector back to the bearings of the gearing and to the teeth of the gear wheels. Oil-circulating pumps attached to the Diesel engines also draw the oil from this reservoir and deliver the oil to the compartments of the clutches as required.

Driving by high-speed Diesel engines and Vulcan gearing possesses *inter alia* the following advantages over direct drive:—

(1) Less weight, lower first cost and less space, particularly in height, with consequently better utilisation of the available space in the ship.
(2) As two Diesel engines drive on to each propeller shaft, the reliability at sea is increased in consequence of this engine standby, and it is therefore a practical proposition to build ships of 5,000 s.h.p. with a single propeller shaft.
(3) Each of the engines can be disconnected from the helical gear wheel by emptying its corresponding liquid clutch. The engine is started working again by simply refilling the liquid clutch so that it is picked up and carried on by the engine, which remains running.
(4) The engines are of the single-acting, non-reversible, four-cycle type. The thermal strains due to admission of cold air to the hot cylinders are obviated, as the engines run continuously in one direction when manœuvring.
(5) The liquid clutches have the property of completely eliminating all irregularities in the turning moment of the Diesel engines not only during normal working, but also at the critical torsional speeds, as the clutches transmit a uniform turning moment, otherwise only attained by turbine drive.
(6) The vessel may be run with as low a number of revolutions of the propeller as may be desired (five to twenty revolutions per minute), which is of importance when manœuvring.

Installations are being constructed by the Vulcan Company for two 10,000-ton d.w. single-screw vessels of 4,000 b.h.p. for the Hansa and the Hamburg Australian Lines. In these instances the propelling units will be of the four-stroke cycle, single-acting type, conforming to marine practice in having crossheads, but utilising steel castings for the main structural parts of the engines, such as bedplates, columns, and cylinders. Four engines can be applied very conveniently to a single shaft.

Electric Transmission of Power for Propelling Machinery.

The application of electricity for transmitting power between the prime mover and the propeller may be divided into two classes, viz.: Turbo-electric and Diesel-electric.

TURBO-ELECTRIC.

The electrical equipment required is an alternating current generator suitable for direct coupling to a high-speed turbine, a motor of suitable speed for direct coupling to the propeller shaft, a direct current exciter or an auxiliary generator, from which direct current can be obtained, and suitable control gear. The whole can be regarded as a reduction gear having a ratio of reduction determined by the relative number of poles on the motor and generator. Thus with a two-pole generator and a sixty-pole motor the ratio of reduction would be 30 to 1, and, as with mechanical gearing, any variation in speed is obtained by varying the speed of the prime mover.

Two types of alternating current motors have been used for driving propellers:—

(*a*) Induction machines, both slip-ring and squirrel-cage types.
(*b*) Self-starting synchronous motors.

All things considered, the self-starting synchronous motor is the most suitable for this class of work on account of the large air gap, simplicity of construction, accessibility of windings, high power factor, and efficiency. When starting from rest the synchronous motor functions as a squirrel-cage motor with its field unexcited.

On account of its greater flexibility direct current is preferable for vessels up to about 3,000 S.H.P. on one shaft; beyond this power, owing to the limitations of voltage, the cables become excessively large.

Electrically driven ships in service have demonstrated their unquestionable reliability; the main driving power is transmitted magnetically across large air gaps, giving an elastic medium for absorbing shocks, and thus making it the simplest and most reliable form of speed reduction.

The turbine is of simple construction, being built in one casing and directly connected to the generator, thereby reducing the size of the seatings and eliminating distortion and mis-alignment troubles due to local straining of the ship. Bearings, shafts, shaft packings, valves and piping are reduced to a minimum, thus decreasing the friction and leakage losses. The astern turbine is eliminated entirely in an electrically driven vessel, full power astern being available without reversing the direction of rotation of the turbine.

There is an absence of vibration and noise, as the machinery is perfectly balanced, with no rubbing contacts, and the quietness of the running is a feature of great importance in a passenger vessel. Manœuvring is very efficient with this type of power transmission, so that perfect speed control in heavy seas is maintained without danger of racing.

The cost of upkeep, as has been proved by ten years' experience with electrically driven vessels, is much less than with any other type of reduction gear.

The propeller efficiency may be kept very high as the electric drive lends itself practically to any desired speed reduction between the turbine and propeller, and each may therefore be designed to operate at a speed corresponding to its highest efficiency.

DIESEL-ELECTRIC.

The Diesel electric drive will be most suitable for double purpose vessels such as fruit and meat carriers, where a large amount of power is required for operating refrigerating plant, etc., and for dredgers, cable-laying ships, self-propelled floating cranes, and vessels of similar types.

In such vessels it is possible, by the application of electricity, to use the same prime mover for both propelling and auxiliary purposes, also to have a number of comparatively small engines each driving a generator, and a single motor direct coupled to the propeller shaft, which can thus be run at the most suitable and efficient speed irrespective of the speed of the prime mover, the electrical losses being largely offset by the more efficient propeller.

The Diesel engines for electric transmission are simpler in design than those which are coupled directly to the propeller shaft, as the engine speed has no relation to the propeller speed, and as the engines run in one direction only. The large air storage tanks, also, can be eliminated.

With the electric drive accurate and constant knowledge of the power output is always obtainable from meters on the control board; and in this manner the power required at any draft or trim under all weather conditions, the effect of dirty hull on the ship's resistance, etc., can be ascertained and studied.

THE NODAL DRIVE.

The introduction of double reduction gear with high-speed turbines has produced some difficulties peculiar to this class of work.

In some cases there has been excessive noise in the engine-room, and hammering of the gears in the gear-box, followed by flaking of the gear teeth and grooving and deformation of the tooth faces, while occasional fractures of the teeth, which clearly suggest fatigue of the material, are not unknown.

Attempts to neutralise these troubles by using higher grades of steel, the broadening of the tooth faces and reduction of the transmitted loads, have not overcome the difficulty.

Accuracy of cutting of the gears and their alignment in the ship is one of the first essentials to be attained with a geared drive; nevertheless, noise, hammering, and wear have occurred with the best designs and workmanship.

The 'Nodal Drive' has been evolved after an extensive series of experiments and a complete mathematical investigation of the whole problem, the experimental work being carried out on a single-screw steamer of 2,500 S.H.P., driven by three turbines.

The investigations have shown that the troubles experienced with this gear arose from torsional oscillations of the shafts set up by the action of the propeller working in a variable wake, or from other disturbances in the system. These torsional oscillations cannot be eliminated, but they can be controlled.

The torsional oscillations of a shaft to which masses are attached has been studied very fully by various investigators, but the oscillations of a system consisting of several shafts with attached masses, connected by a train of gear wheels, is a more complicated problem.

Investigations have proved conclusively that, in the ordinary arrangement of geared drives, there is no clearly defined oscillating system. The periodicities of free vibration of the system are numerous, and synchronism, or approximate synchronism, between these critical speeds and the running speeds of any element of the system causes hammering of the gear teeth.

In the 'Nodal Drive,' as a result of accurate calculations, a suitable adjustment of the elasticities of all the shafts and the moments of inertia of the attached masses is secured, thus giving a completely defined oscillating system which has the minimum possible number of free vibration periods. These periods can be accurately determined and arranged well clear of the running speeds of the various elements of the system.

Fig. 23 illustrates the 'Nodal Drive' as installed in the experimental ship.

The original arrangement of solid primary pinion shafts, with torsionally stiff connections to the turbines, has been replaced by hollow pinion shafts with internal flexible driving shafts connecting the ends of the pinion shafts with the turbines.

The lengths and diameters of these shafts are so adjusted that the periodicities of the free torsional oscillations about the gear-box of all the shafts and their attached masses are equal.

Fig. 23A is an enlarged view of one of the hollow pinion shafts with the flexible driving shaft in position, and shows the method of supporting the driving shaft inside the hollow shaft, so as to prevent whipping action taking place. Suitable lubricating arrangements are applied to prevent wear of the supporting collars.

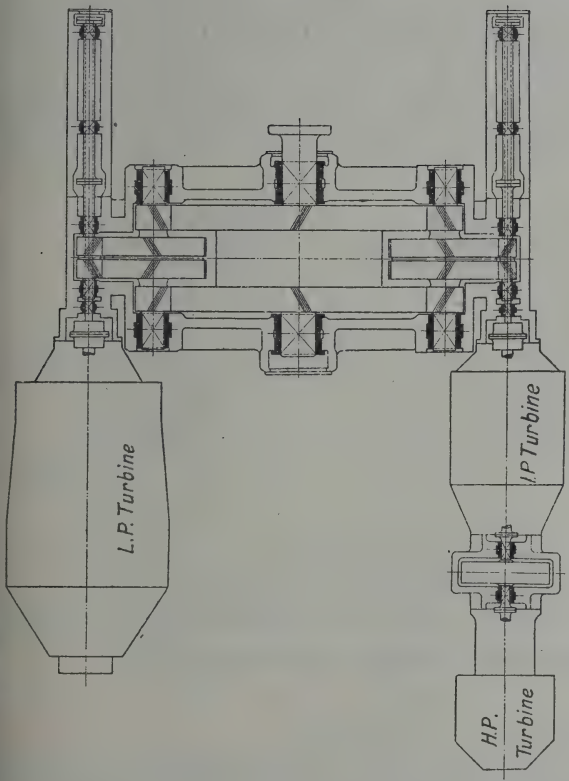

FIG. 23.

THE NODAL DRIVE.

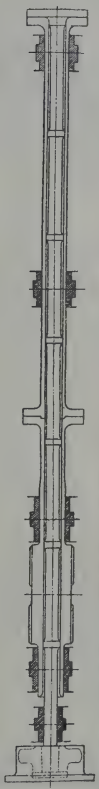

FIG. 23A.

In this experimental installation it was necessary to introduce a flywheel on the H.P. side of the drive in order approximately to equalise the moments of inertia of the two sets of turbines, and thus keep the length of the H.P. flexible driving shaft within reasonable limits. This flywheel is placed between the H.P. and M.P. turbines, and, in effect, binds all the masses in such a way as to form approximately one rigid mass.

In an entirely new design, where the 'Nodal Drive' is embodied from the start, the flywheel may not be an essential feature, since the balancing of the moments of inertia can be accomplished in the turbine design.

The 'Nodal Drive' has already been fitted to eleven steamers, and is giving complete satisfaction.

Cockburns' Geared Turbine Emergency Shut-off and Positive Control Manœuvring Gear for Saturated and Superheated Steam.

In this arrangement, fig. 24, the manœuvring valves are of the single handwheel type. Rotation in one direction from mid position opens the ahead valve, and by the opposite direction the astern valve is opened. With the arrangement shown it is impossible to have the two valves open at the same time.

The emergency valves are incorporated in the bulkhead valves and are steam operated by an automatic governor on the turbine rotors. They shut off steam completely, which, in the case of a broken shaft, prevents the turbine from being spun, as would occur with the ordinary butterfly throttle, through the quantity of steam that passes the latter valve when it is closed.

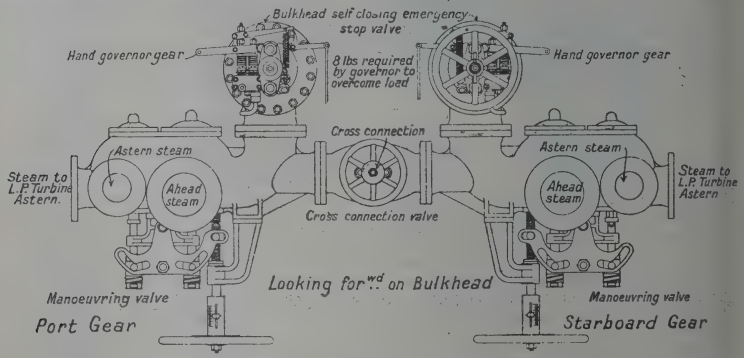

Fig. 24.

The governor gear is connected direct to the operating gear on the valves, as the governor has only to act against a resistance of 4 lbs. on each valve.

The hand emergency gear acts independently of the governor gear.

The bulkhead valves are also arranged to be controlled by the pressure in the lubricating oil system so that the steam is shut off from the main turbines in the event of failure of the oil supply.

Rules for the Dimensions of Steamship Shafts.

See p. 1079.

BOILERS.

In determining the principal dimensions of a boiler, or boiler installation, consideration must in the first instance be given to the system of draught employed, whether it is to be forced or natural draught, and since the quantity of steam which a boiler is capable of generating depends on the weight of coal consumed, it follows that the dimension which must first be decided is that of the grate area, the heating surface being proportioned from the grate area depending upon the type of boiler employed. The efficiency of the boiler largely depends on the rate of evaporation per square foot of heating surface, which should be kept as low as possible.

Coal Combustion.

The weight of coal which can be burnt per square foot of grate area per hour under varying conditions of draught is approximately :—

Natural draught . . .	. 16 to 20 lbs.	Forced draught 2 ins. air pressure	45 to 50 lbs
Forced draught ½ in. air pressure	. 20 to 25 lbs.	,, 3 ins. ,,	. 55 to 60 lbs
,, 1 ,,	. 30 to 35 lbs.	,, 4 ins. ,,	. 60 to 70 lbs

With cylindrical boilers and water-tube boilers for cruisers and battleships the maximum combustion per square foot of grate rarely exceeds 40 lbs. when working with closed stokeholds and 30 lbs. under Howden's system of forced draught; with the express type of water-tube boiler as fitted in torpedo boats and torpedo boat destroyers the combustion varies from 60 to 80 lbs. of coal per square foot of grate.

Boiler Surfaces.

The heating surface and grate area for a required boiler is determined by the method of draught employed, whether natural or forced, the kind of coal used on account of the difference in caloritic values of different varieties of coal, and the type of engine to which steam is being supplied, quadruple expansion engines, for instance, requiring less boiler surface than compound engines on account of the greater economy in steam consumption per I.H.P. of the former.

Economy in coal consumption is obtained by working the boilers easily at low rates of evaporation. Where considerations of weight and space are of importance, as in naval and fast merchant vessels, the boilers are reduced in size, and forced draught is used to increase the rate of evaporation, with corresponding reduction in efficiency. In Howden forced draught the economiser effect of the air tubes in the uptakes increases the efficiency so that this system compares favourably with natural draught and is much superior to the closed stokehold system.

The following table gives the average H.P. developed per square foot of grate, and the ratio of heating surface to grate area of different types of boilers and average consumptions of coal for various types of engines.

TABLE SHOWING PARTICULARS OF BOILERS OF VARIOUS TYPES OF STEAMSHIPS.

Draught.

The two systems of forced draught most commonly adopted are closed stokeholds and Howden's system (page 2111) with closed ashpits. In the former an air pressure is maintained in the boiler rooms by forcing in air with fans, all openings in the boiler room are closed down with doors, and air locks fitted for access purposes. With Howden's system the boiler room is open, no air locks being required, and the air is forced by fans over the surface of a nest of tubes situated in the uptakes, through which the products of combustion pass on the way to the funnel. The air is raised to a temperature of about 250°F. by contact with the hot tubes, and passes through passages on either side of the uptake into a reservoir surrounding the furnace fronts, from which reservoir the air is admitted to the furnaces by valves in the furnace fronts, at the sides and the top, to the ashpit and above the fire respectively. Valves are fitted to control the admission of air above and below the fires: these must be shut before opening the furnace door to fire the boiler, otherwise the flame would be blown out into the stokehold. The proper use of the top valve prevents excessive smoke without reducing the boiler efficiency or the amount of evaporation per lb. of coal. Special strips of twisted steel ribbon called 'retarders' are placed in each boiler tube, causing the hot gases traversing the tubes to take a spiral course and be retained longer in contact with the tubes than they otherwise would.

The latest type of furnace fronts has the side valves controlled by one handle, and is also fitted with a safety guard, so that the furnace doors can only be opened when the air valves are shut, thereby preventing the possibility of any flame coming back through furnace door when it is opened.

On account of the abstraction by the air of what would otherwise be waste heat passing up the funnel a considerable measure of increased boiler efficiency is attained compared with the closed stokehold system, and the uniform condition of furnace temperatures which Howden's system ensures tends to reduce the wear and tear of the boiler.

A more uniform efficiency of furnace can be maintained with forced draught and it may be readily controlled to suit any desired rate of combustion, being quite independent in this respect of prevailing atmospheric conditions.

The Howden-Ljungström Air Preheater.

One of the most important inventions for the reduction of fuel consumption is the air preheater, which may be considered as a development of the Howden air-tube box. By this means 70 per cent. of the heat in the waste gases from the boiler can be recovered, so that a very considerable increase in efficiency is obtained without the disadvantages of excessive weight or corrosion as in the case of feed-water heaters.

The principle involved is exceedingly simple and effective. Briefly described, a large transmission surface is assembled in a rotating part in such a way that the elements are alternately traversed by the waste gases from the boiler and by the cold air to be used for combustion. The gases give up their heat to the elements, and, as these move round into the current of cold air, the heat previously absorbed from the gases is given up to the air. The process is continuous.

In actual construction, the elements consist of thin plates of metal placed close together and corrugated in order to obtain a very large surface. They are fixed in a rotor in such a way that the passages for the gas and the air between the places are parallel with the axis of rotation. The rotor is supported upon disc rollers fixed in a stationary envelope or casing, so that the power required to drive it is very small.

The casing is provided with inlets and outlets for the gases and for the air, which are separated from each other by diametral partitions above and below the rotor. In the upper section of the casing two fans are provided, one to force the cold air through the elements which are at the moment travelling through the air side of the heater, and the other fan to suck the gases through the elements on the gas side. The two fans are mounted on one shaft which passes through the upper partition and which can be driven by an electric motor or in any convenient way, the motor drive being taken by suitable gearing.

A most important feature of the heater is the ease with which the surfaces of the elements can be kept clean. A radial pipe with steam jets is fitted below the rotor, on the gas side, and steam is discharged while the rotor is revolving, so that every portion of the elements must pass through the jets, and no part of the surface can escape the scouring action of the steam. Every particle of soot is blown away, and the efficiency of heat transmission is thus maintained constant. It is necessary to operate the jets for fifteen seconds only every few hours, so that the consumption of steam for this purpose is negligible.

Fig. 25 shows the arrangement of the air pre-heater with two cylindrical boilers, but it is also suitable for using with water tube boilers and furnaces of various types.

An arrangement in which the axis of the preheater rotor is horizontal and separate centrifugal fans are fitted has now been introduced as an alternative. In this case the fans may be situated remote from the preheater, possibly in the engine room or in a separate fan room as circumstances may decide.

The Howden Cellular Air Heater.

(Patent.)

The cellular air heater embodies all the features of the tubular air heater with the following additional advantages:—

1. The heating surface for similar space occupied is approximately double that of a tubular heater.

THE HOWDEN-LJUNGSTRÖM PATENT AIR PREHEATER.

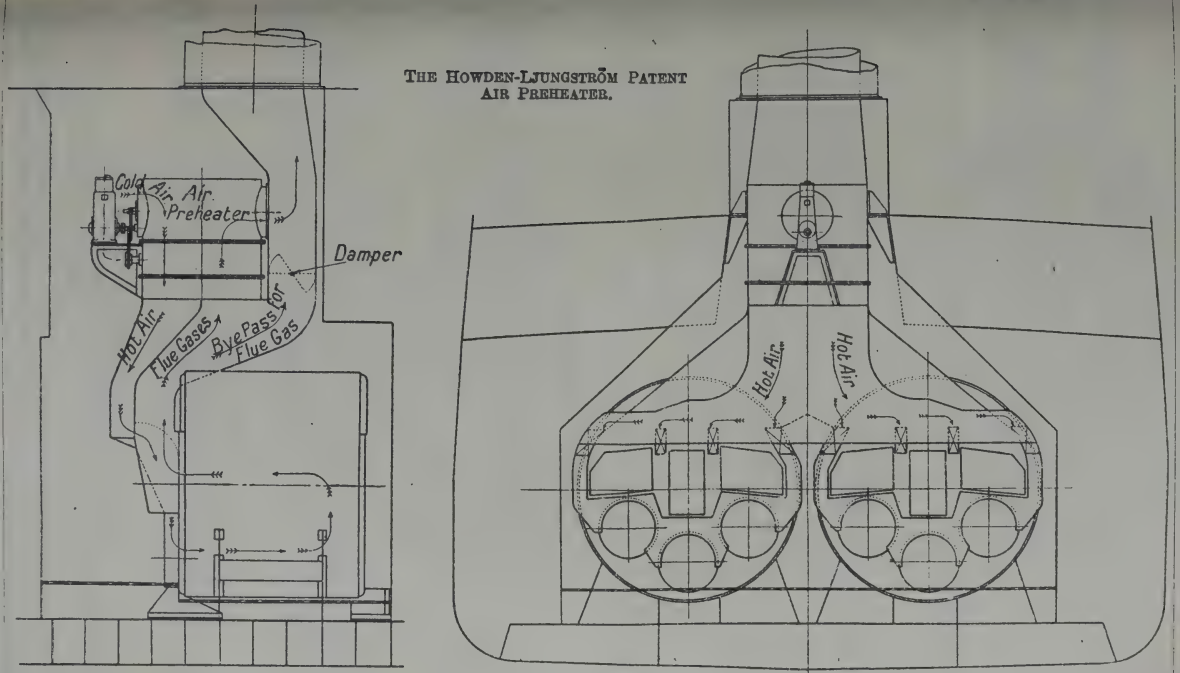

FIG. 25.

2. The gases and air travel substantially in a contra-flow direction.

3. Due to 1 and 2, a higher transfer of heat from the flue gases is obtained.

The heating elements or cells are made of mild steel plate. Each element is carefully manufactured and gauged before assembling. Special precaution is taken to prevent warping of plates and each cell is made truly parallel.

The guide vanes in the air passages are so arranged to divide the incoming air into an equal number of streams which flow directly opposite to the path of the gases on the opposite sides of the elements. These guide vanes are made of steel strips hung on to ferrules secured to the heating elements. The vanes are designed to give the air a turbulent flow. By distributing the air equally over the surface of the plates in the manner mentioned, it ensures that there can be no short circuit of air and thus avoids any part of the plate becoming overheated.

The complete heater when assembled consists of a number of portable sections securely bolted together and which can at any time be removed for repair if necessary.

Furnaces and Firebars.

If forced draught is employed it is not desirable to have firebars longer than 6 ft. on account of the tendency for large quantities of air to pass through the firebars if the fire should burn into holes. With Howden's system 5 ft. 6 ins. is the maximum length of firebar generally adopted. In naval practice with modern water-tube boilers working at full power under a moderate forced draught of 0·5 in. to 0·75 in. of air pressure, grate bars having a maximum length of 7 ft. are frequently employed; this, however, requires skilful firing, and extreme care to ensure the boiler efficiency being maintained at a maximum. For natural draught the length of grate bar should not exceed 6 ft. 6 ins., but increased boiler efficiency will be attained by using shorter bars, on account of the greater control over the fires. The diameter of furnaces for cylindrical boilers (figs. 26 and 27) should not be less than 32 ins., nor greater than 48 ins., and the number of furnaces which can be fitted in boilers of the following dimensions is :—

Boilers up to 9 ft. 0 ins. diameter	1 furnace	Boilers up to 15 ft. 6 ins. diameter	3 furnaces
„ „ „ 13 ft. 0 ins.	„ 2 furnaces	exceeding 15 ft. 6 ins.	„ 4 furnaces

The grate area of a cylindrical boiler is equal to :—Length of firebars × mean diameter of furnace × number of furnaces.

Length of Cylindrical Boilers.

The length of a cylindrical boiler is determined by the length of combustion chamber tubes or the furnace which is practically the same length as the tubes, the length of the combustion chamber and the water spaces at their backs. The combustion chamber measured horizontally should be as long as possible and usually is about 30 ins. in single-ended boilers and from 50 to 57 ins. in double-ended boilers. The water space between the back of the combustion chamber and the back end-plate of the boiler should be from 5 to 7 ins. at the bottom and wider at the top, the taper being about ½ in. per foot on the combustion chamber back.

Heating Surface.

The heating surface of cylindrical boilers consists of the external surface of the tubes, the length being measured between the tube plates, the surface of the furnaces above the firebar level, and the surface of the combustion chambers. The surface of the front tube plate on the boiler end, although in contact with the hot gases, is not usually reckoned as effective heating surface, and should not be included in the total heating surface of the boiler. The heating surface of a water-tube boiler is the total external surface of the tubes in contact with the fire and hot gases.

Diameter of Tubes for Cylindrical Boilers.

In forced-draught boilers the combustion chamber tubes are generally 2½ or 2¾ ins. diameter, and in natural-draught boilers the diameter is 3 ins. to 3½ ins., the increased sectional area being necessary to reduce the resistance to flow of the products of combustion.

Thickness of Cylindrical Boiler Shells.

The shell plates of cylindrical boilers must be of the following thickness to satisfy the requirements of the revised rules of the Board of Trade, Lloyd's, British Corporation, and Bureau Veritas.

The thicknesses shown assume the steel to have a minimum ultimate tensile strength of 28 tons per sq. in., and the longitudinal joint to have double butt straps with an efficiency of riveting equal to 84 per cent.

WATER-TUBE BOILERS.

Water-tube boilers are divided into two distinct classes, viz. :—Large-tube boilers as fitted in merchant vessels, and small-tube boilers as fitted in cruisers, battleships, torpedo boat destroyers, and launches.

The principal advantages of water-tube boilers as compared with cylindrical boilers are :—

(1) Ability to use higher steam pressures (above 250 lbs.).

(2) Rapidity with which steam can be raised.

(3) Capability to endure forcing to a great extent.

(4) Reduced weight.

(5) Reduced space occupied.

The large-tube boilers are of the Babcock & Wilcox type (fig. 28) and the Yarrow type, both of which have straight tubes, the former varying from 4 in. to $1\frac{1}{16}$ in. outside diameter, according to requirements, and the latter $1\frac{3}{4}$ in. diameter. The tubes in the Babcock & Wilcox boiler are expanded into front and rear headers, which are sinuous in form and constructed of forged steel. Opposite each tube in the headers handholes are fitted, giving access for expanding, cleaning and renewal when necessary. The front headers are connected at the top by short tube nipples to the steam drum, and by similar nipples at the bottom to the mud drum. Return tubes about 4 ins. diameter connect the rear headers to the steam space in the steam drum.

The Yarrow large-tube boiler is a development of the Yarrow express type, and is very similar in design and construction. It consists essentially of a central upper steam drum, and two smaller water drums, the latter being situated about the level of the firebars. The generating tubes are expanded into the steam drum and each of the water drums, a manhole being fitted in the front end of each drum for access when expanding or cleaning of the tubes is necessary.

WATER-TUBE BOILERS—EXPRESS TYPE.

The small tube or express type of water-tube boilers principally adopted in British naval practice are the Yarrow, the White Foster, and the Thornycroft type (fig. 29). The tubes of all these boilers are from 1 in. to $1\frac{1}{2}$ in. external diameter, and generally the two rows next the fire are at least $\frac{1}{8}$ in. larger in diameter and one wire gauge thicker.

The White Foster boiler has a similar arrangement of drums, casings, and furnace to that of the Yarrow type. The tubes, however, are bent in such a way that any one can be withdrawn and received through the manholes in the upper steam drum when required.

The modern Thornycroft boilers have one upper steam drum and two lower water drums, and are suitable for burning oil and coal, separately or combined.

The tubes are straight except for a slight curve at the lower end where they enter the water rums. The tubes can be inspected throughout the whole of their length by holding a light in the)wer barrel. The lower water pockets being cylindrical can be made of solid drawn steel,

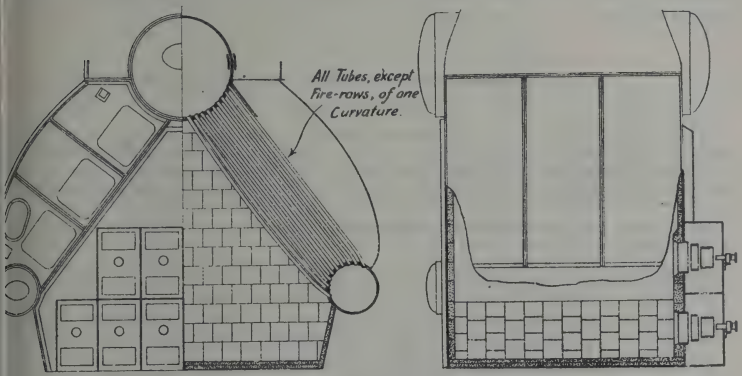

FIG. 29.

The Thornycroft Boiler.
(*Oil fuel Burning.*)

us eliminating possibilities of leakage and also making a lighter and stronger construction. The bes of any one diameter are all curved to the same radius, so that any tube will do for either w, which greatly simplifies the spares. This also allows of the lower drums being made smaller, us saving weight.

THE YARROW WATER-TUBE BOILER WITH SUPERHEATER.

Figs. 30, 31 (page 2393) show this boiler, which consists of a top steam collector, as usual, and o lower water pockets. On the left-hand side is the superheater, and on this side of the boiler ere are fewer rows of generator tubes than on the other side, where there is no superheater, it being ought desirable that the total heating surface and the resistance to the gases on both sides the boiler should be approximately the same. In one of these boilers with a total heating rface of 6,700 sq. ft., 1,265 sq. ft. consisted of superheating surface; the total heating surface the superheater side of the boiler being 3,453 sq. ft., and on the other side 3,247 sq. ft.

The superheater consists of a number of U tubes expanded into two longitudinal collectors, ıall doors being fitted so that access can be obtained to the tubes when required. The leading ature of the arrangement is that the superheater is placed on one side of the boiler only, and a mper is fitted in the up-take on the same side. If this damper is closed the whole of the gases e deflected towards the opposite side of the boiler, and no heated gases pass the superheater, e object being that if the main engines should be suddenly eased or stopped, or when raising eam, the superheater may be shut off, so as to prevent the tubes being damaged, or the steam ing superheated to an excessive extent, owing to there not being sufficient circulation of steam. this way one objection to the introduction of superheating for marine installations is overcome.

A further advantage of the arrangement is that, when the consumption of steam is suddenly duced or stopped, not only does the damper prevent the superheater tubes from being burnt, t it also greatly diminishes the output of the boiler at the time when a reduced supply of steam wanted, because only about one-half of the heating surface comes into contact with the hot gases.) avoid the possibility of the damper getting distorted through over-heating, it is provided with hollow spindle, to whch air is admitted and which passes from thence between the two plates the damper, escaping at the edge, and thus keeping the damper cool. This arrangement of mper has proved thoroughly successful under the most trying conditions.

At the maximum rate of evaporation with the damper open, namely, when burning 1·237 lb. of oil per square foot of heating surface per hour, the degree of superheat was 93·5° F.; 14·6 lbs. of water were evaporated per lb. of oil per hour, with a steam pressure of 242 lbs.

The results of other experiments indicate that in a properly designed boiler of the type described, it is possible to burn, without injury to the boiler, 2 lbs. of oil per square foot of heating surface per hour.

The Clarke-Chapman Marine Water-Tube Boiler.

(Woodeson's Patent.)

The 'Woodeson' patent marine water-tube boiler, as shown by fig. 32 (page 2394), is manufactured by Messrs. Clarke, Chapman & Co. Ltd., Gateshead-on-Tyne, and consists of two sections, each comprising steam drum, water drum, and a number of groups of tubes expanded into same; these tubes are nearly vertical and perfectly straight, and manholes are arranged on steam drums immediately over each group through which any tube can be withdrawn.

The bottom drums are absolutely hanging so that expansion and contraction can take place without causing any damage to the boiler.

In the design of the 'Woodeson' boiler, a special feature is the ease of access for purposes of examination or repairs, the time which has to be expended on the same being practically reduced to a minimum; thus in a boiler of say 6,100 square feet of heating surface, containing 456 tubes, the only work to be done to thoroughly examine the insides of this large number of tubes for their total length is the removal of the manhole doors on one end of each bottom drum, and one manhole door off each of the three steam drums: thus access can be gained to every tube, and these being perfectly straight they can be thoroughly examined for the whole of their length. The removing and replacing of the manhole doors can be done by an ordinary fireman, no skilled mechanic or complicated tools being required. There is an entire absence of screwed joints in the boiler.

Each tube being nearly vertical and perfectly straight and entering the steam drum direct without intervention of any headers, ensures a perfect steam release, and so adds to the efficiency of the boiler, as there are no sharp turns to retard the flow of the steam globules to the steam space. Also, deposits are not retained in the tubes, but are collected in the large mud-drums thus over-heating and destruction of tubes are reduced to a minimum.

The superheater consists of a number of mild-steel tube boxes, into which are expanded the tubes, which are bent to L shape and belled out.

The superheaters are provided with the necessary fittings, including specially designed by-pass valve for regulating the degree of superheat, also a large drain valve in the lowest part of the superheater for draining.

The Niclausse Boiler.

This boiler is principally adopted by the French Navy, though it is used by 15 other navies there being now upwards of 2,000,000 h.p. afloat in the Naval and the Mercantile Marine Services.

Fig. 33 (page 2395) shows the most modern design of this type of boiler, as applied to a large French cruiser of 35,000 h.p. It is the high duty type referred to in the 'Engineer' of March 13 1914, and the Institution of Mechanical Engineers' Journal of July 1914.

The tubes are either 84 or 60 mm. diameter and the boiler is therefore of the large tube type but the characteristic feature of the Niclausse inner tube gives it all the advantages of the small tube type. Its special features comprise a considerable saving of space and deadweight, and in respect of the former it will be noticed that the boilers can be located back to back and adjacent to each other, all access being entirely from the front.

Marine boilers of this type are fired by either oil or coal, or both, and excellent results are claimed by the makers, who lay more stress on average than on test efficiencies. Other features are great flexibility and overload, the cleaning facilities provided, and the ability to quickly effect the withdrawal and replacement of defective tubes, which can be done within an hour from time of stop to restart under full steaming power.

The Standard Water-Tube Boilers adopted for the United States Emergency Wooden Steamships are described and illustrated (from *International Marine Engineering*) in 'Engineering' Nov. 9, 1917.

Life of Marine Boilers.

The life of a marine boiler depends to a certain extent on the care and attention bestowed on it during the first few months of its existence, provided that the plates have been properly treated at the building of the boiler—that is, all mill scale removed and the plates kept dry and free from atmospheric corrosion. The mill scale, if not removed, has a very irritant action on the clean metal of the boiler, and is most hurtful to the plates if allowed to remain on them. The greatest care and attention is needed for the first period of working of new boilers to keep the new metal free from corrosion. It is advisable on the first voyage to put into the boilers, before closing them up, 5 lbs. of lime per 1,000 i.h.p., and afterwards for a period of about six days 2 lbs. of lime per day per 1,000 i.h.p. should be passed through the hotwell as milk of lime, and 1 lb. of lime per day per 1,000 i.h.p. during the remainder of the voyage.

Rules and Regulations with reference to Boilers of Steamships.

STANDARD CONDITIONS FOR THE DESIGN AND CONSTRUCTION OF MARINE BOILERS.

A set of rules has been framed and agreed to by representatives of the Board of Trade, Lloyd's Register of Shipping, the British Corporation for the Survey and Registry of Shipping, and the Bureau Véritas International Registry of Shipping, and recommended for favourable consideration and adoption. An abstract of these rules is given on pp. 1625–1633.

Boiler Casings.

The casings of both the Babcock & Wilcox and Yarrow boilers are constructed of light steel plates and angles, and designed to avoid distortion due to the high temperature of the gases with which they are in contact. In way of the furnaces the casings are lined with brickwork, other parts of the casings are lined with asbestos millboard or some other non-conductor, to prevent radiation of heat to the stokeholds. In the Babcock & Wilcox type of boiler, wide use is made of 'Cellinsulate,' a special form of non-conductor which possesses greater resistance to heat transmission per unit of weight than any other form of lagging.

MARINE SUPERHEATERS.

'M.L.S.' MARINE SUPERHEATERS.

(*The Superheater Company, Limited, London and Manchester; 'Schmidt' and 'Robinson' Patents.*)

The types of superheaters manufactured for marine boilers consist in principle of a series of loops or elements of solid cold-drawn steel tubing inserted in the smoke tubes of the cylindrical

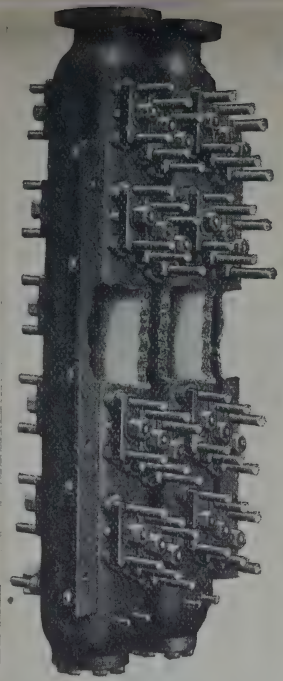

FIG. 35.—'M.L.S.' Forged Steel Header, Type 'S.'

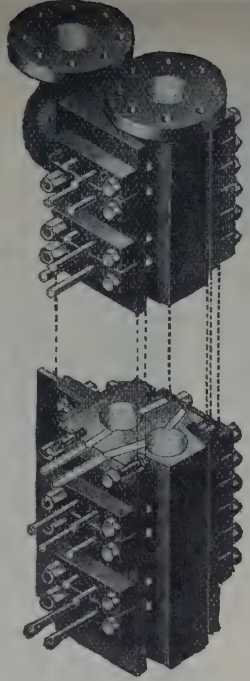

FIG. 36.—'M.L.S.' Solid Steel Header, Type 'RB.'

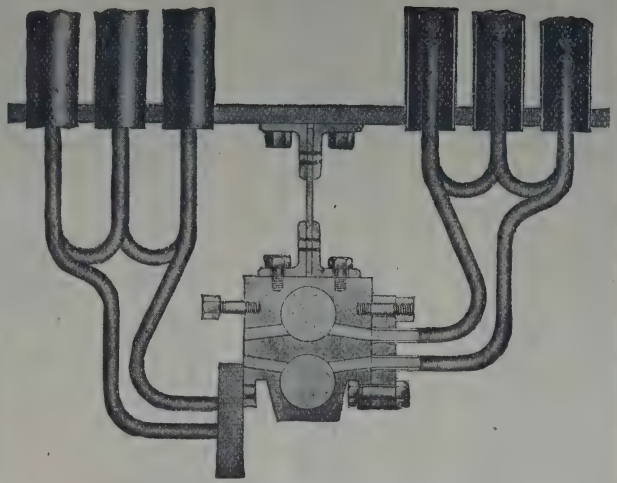

FIG. 37.—'M.L.S.' Element Attachment, Type 'RB.

steam header, the steam circulates through the elements and returns superheated to the super heated steam collector, and thence to the prime mover. The elements are, therefore, in the direc path of the gases flowing from combustion chamber of boiler to smoke-box. (See fig. 34, p. 2396.

The elements are made from solid cold-drawn steel tubing, and the return bends are made b the 'M.L.S.' Integral Machine Forged Return Bend Process, by which these bends are mad integral with the tubing itself and electric or oxy-acetylene welding avoided, thereby prolongin the life of the element and providing a clean, smooth surface, both internally and externally.

'M.L.S.' Superheater, Type 'S.'

In this type of superheater the headers or collectors, fig. 35, are pressed steel forgings; the are of plain rectangular design, with a minimum wall thickness of one inch (1"), homogenou throughout, and of uniform smooth internal and external finish, free from scale or other impurity

The saturated and superheated collectors are entirely separate; they are attached to th partition plate of the boiler smoke-box by means of angle irons.

Fig. 38 shows the method employed for attaching the superheater element ends to the heade Collars are expanded on the element ends, and these collars fit into machined recesses in th headers, where a steam-tight joint is made with a jointing ring. The collars are held in plac by a drop-forged clamp or dog, each dog securing two collars. This arrangement provides fo accessibility and easy withdrawal of elements, at the same time making a perfectly steam-tigh joint.

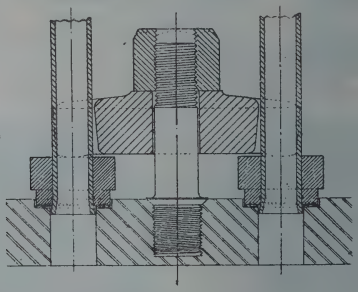

Fig. 38.—'M.L.S.' Element Attachment, Type 'S.'

'M.L.S.' Superheater, Type 'RB.'

In this design the arrangment of the superheater is similar to that previously described, bu the single superheater header embodies two longitudinal passages, one for saturated and th other for superheated steam. The header, fig. 36, is made from one solid mild steel billet, th two chambers being bored longitudinally therein; a cast steel elbow is fitted on the back an connected with one of the chambers, this elbow being for the attachment of the saturated steam pipes.

A flange is also welded on to the header to take the superheated steam-pipe outlet.

The superheater elements are expanded into flat steel flanges, fig. 37, and the sides of the and of the headers are carefully machined, so as to provide a very efficient joint.

The flanges are provided with a bolt hole at the front and a slot at the rear, and are secured to the header by a stud and bolt in such a manner that by removal of the bolt at the front and slackening the nut of the stud the elements can be easily slid in or out of position.

The elements are again made with return bends integral with the tubing itself, by the 'M.L.S.' Integral Machine Forged Return Bend Process.

'M.L.S.' Superheater, Type 'RX.'

This arrangement of superheater is similar to type 'S,' but the superheater headers are so designed that the ends of the superheater elements are expanded directly therein.

The headers are made in steel castings having transverse saturated and superheated compartments. Front openings are provided for internal examination and to allow for the expanding in and driving out the superheater elements from the side walls of the header; these front openings are closed by mild steel cover plates.

The integral superheater elements are made with return bends integral with the tubing itself, by the 'M.L.S.' Patent Machine Forged Return Bend Process.

The 'North Eastern' Superheater.

This superheater is specially designed for the Scotch (or cylindrical) type of boiler, this type being the universally adopted boiler for the mercantile marine.

The superheater, fig. 39, consists of headers arranged in pairs between the nests of boiler tubes.

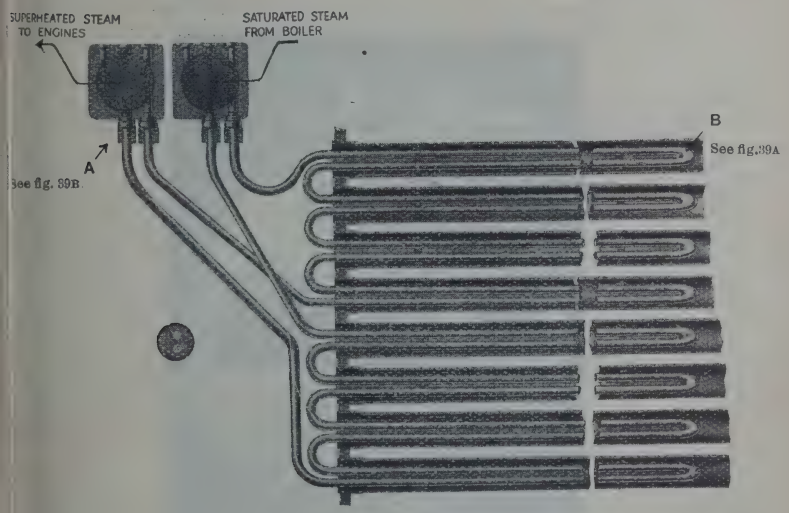

Fig. 39.—The 'North Eastern' Superheater.

These headers, which are fitted in the smoke box and attached to the boiler end, comprise saturated steam headers and superheated steam headers, the saturated being connected by pipes to the boiler stop valve, and the superheated by pipes, so as to deliver superheated steam to the engines.

THE 'NORTH EASTERN' SUPERHEATER.

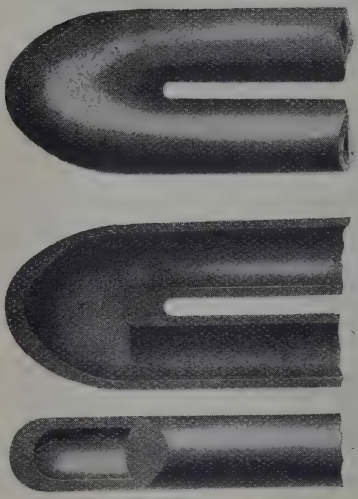

FIG. 39A.

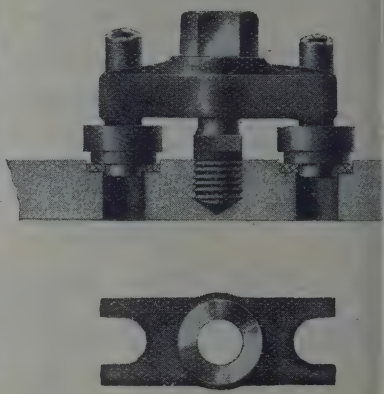

FIG. 39B.

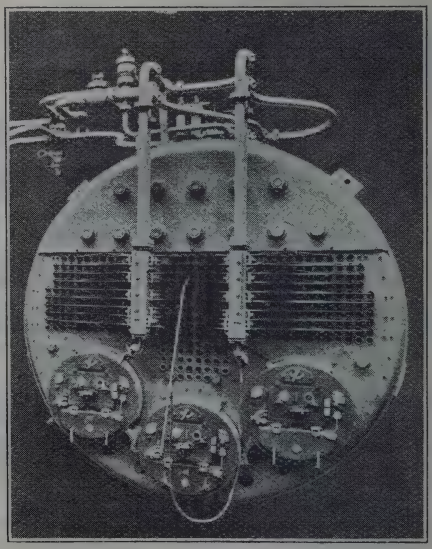

FIG. 39C.

The superheater tubes, or elements, are connected between the saturated and superheated headers and consist of a series of small steel tubes of ' U ' form carried into and out of the boiler tubes. A number of these ' U ' tubes, generally about four, are coupled in series between a saturated and its corresponding superheated steam header.

Where the ends of the elements project into the boiler tubes, and are subject to intense heat, the ends of each pair of tubes are fitted with a special steel cap, fig. 39A, welded to the tubes by oxy-acetylene welding. The end of the element where joining the header, fig. 39B, is fitted with a special form of joint, consisting of a collar fixed to the end of the tube, which collar fits into a recess in the header where a steam-tight joint is made with a jointing ring. The collars are held in place by means of special steel dogs or clamps, each clamp securing a pair of collars, and screwed down to the header by means of a stud and nut.

The general arrangement is shown by fig. 39C.

Oil Fuel.

The advantages of fuel oil as compared with coal are as follows :—

(1) Reduction in weight and space occupied by the boiler installation.

(2) Increased evaporation of water per lb. of fuel in the ratio of about 14 : 9 as compared with good quality coal.

(3) Utilisation of remote parts of the ship and of constricted spaces, such as the double bottoms, for stowage of fuel.

(4) Less manual labour and greater rapidity in stowage.

(5) No reduction in speed due to cleaning fires, difficulty in trimming coal from remote bunkers, or exhaustion of stokers.

(6) Reduced wages bill for boiler room staff, no trimmers, and comparatively few attendants for the burners being required.

(7) A prompt and effective control of the steam output due to the mechanical supply of the fuel, permitting of more rapid changes of speed than is the case with coal.

(8) Absence of smoke if air supply is properly controlled.

(9) No trouble due to accumulation of ashes ; ash expellers or ejectors are dispensed with.

(10) In the case of naval vessels, fueling can readily be carried on at sea.

Both water-tube and cylindrical boilers are now adapted for burning oil fuel, the direct-pressure system being the one most generally in use for naval and mercantile service.

Pressure pumps fitted in the boiler rooms have suctions from the oil tanks, and discharge at a pressure of from 50 to 150 lbs. per sq. in. through cold filters having fine mesh wire gauze lids; from thence the oil passes through a tubular heater, the oil being inside the tubes and heating steam outside. The temperature of the oil is raised to about 150° Fah. in the heater, and before finally reaching the burner it is passed through a second, or so-called hot, filter.

It is necessary to heat the oil in order to reduce its viscosity so that it can be atomised and forced through the fine passages of the burner, which are so designed as to give it a rapid whirling effect due to centrifugal force when liberated through tangential passages at the lip of the burner, and thus reduce it to a fine spray of conical formation. The air supply to the burner passes through directing slots cut in a steel truncated cone, 12 to 15 ins. diameter and about 16 ins. long. The burner is fitted at the centre of the entrance to the cone, and the admixture of the air passing through the slots with the oil spray from the burner produces almost perfect combustion.

In the case of naval vessels the closed stokehold system is adopted, the air pressure in the boiler rooms being controlled to suit the output of the burners. For cylindrical boilers in merchant steamers the Wallsend-Howden system (page 2148) with open stokeholds is now in extensive use. The arrangement of burners and air cones is similar to that described above, but the air supply is heated by the waste gases, as in the ordinary Howden forced draught system (page 2111) applied to coal burning. Each burner can pass from 400 to 600 lbs. of oil per hour, and it is possible to burn about 13 lbs. per cubic foot of combustion chamber. The area of the furnace front limits the number of burners which can be fitted, and it is desirable that the volume of the combustion chamber should be as large as possible.

(See also pp. 2135, 2435.)

EVAPORATORS.

For Fresh Feed Make-up Water for Boilers.*

With the high pressures of steam (usually from 150 to 200 lbs. per square inch) now carried steam boilers for use with modern triple-expansion and other engines, it is found necessary to

* Also used in connection with distilling condensers for producing fresh drinking water instead of the old way of distilling from the donkey boiler.

provide fresh feed-water for the make-up, in order to prevent the great deposit of scale on the heating surfaces which results from these high temperatures.

The quantity of auxiliary feed-water required amounts to from 1 to 5 tons per 24 hours per 1,000 h.p.

To provide this, evaporators have come into general use.

In these evaporators the sea water is boiled by the heat from steam passing through tubes

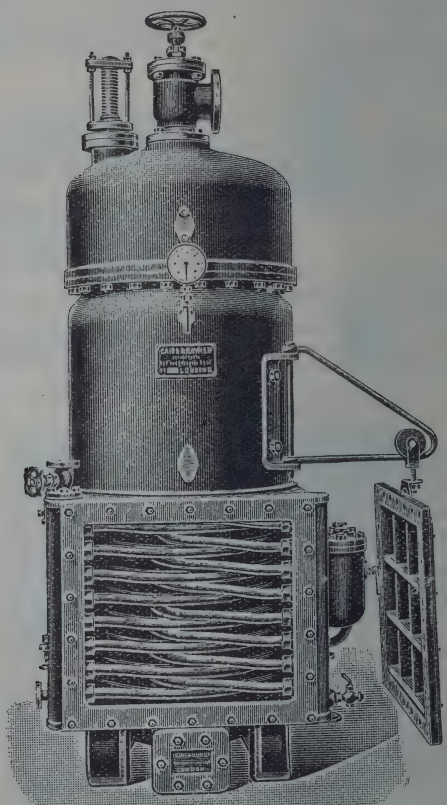

FIG. 39D.

immersed in the salt water. The condensed steam from these tubes is usually drained back t the condenser or hot-well, and so back to the boiler, and the secondary steam produced from th sea water is led to the main condenser, and is there condensed along with the exhaust steam fro the engines, and thus delivered to the boiler as fresh feed-water.

The scale formerly left in the boilers is deposited in the evaporators, which are arranged so a to be easily cleaned when necessary.

The Caird and Rayner Automatic Evaporator.

(Caird & Rayner, Commercial Road, London.)

In this evaporator, shown in general view by fig. 39D, page 2402, live steam is led from the boilers through a series of coils of solid-drawn copper-tube. Sea water being admitted to surround the coils, and automatically maintained at a constant level, is by the heat of the steam within them converted into vapour, which rises to the upper part of the evaporator, and is led hence to the condenser, where, mingling with the condensed steam from the engines, it provides the required auxiliary feed in the form of distilled water, which is pumped into the boilers by the ordinary feed pump.

The form of the heating coils is a very special feature of this evaporator, as by this their self-cleaning property is secured. The helical form gives them greater elasticity, as they expand and contract with the varying temperatures to which they are subjected in working, and especially so each time the brine is blown out and a fresh charge of cooler water admitted. This action causes the scale, which is naturally deposited on the coils, to be thrown off from time to time, and fall to the bottom of the evaporator, from which it is easily removed. This self-cleaning property of the coils, by which the heating surface is kept practically clean, secures the continued efficiency of the evaporator. The ends of the coils are connected to pockets on each side close to the front of the evaporator, so that the door can be removed, and all the joints that are subjected to primary steam pressure can be tested in full view. The pockets have suitable divisions cast in them to regulate the flow of steam through the coils suitable for the pressure of steam to be used.

An automatic feed ensures that the level of the water to be evaporated is maintained at a constant level, and also that it shall be impossible that, through any accidental neglect or carelessness, the sea water can accumulate so as to fill the evaporator and pass over into the condenser.

A series of baffle plates, specially arranged in the upper part of the shell, ensures that no priming shall take place.

In ships where there are many auxiliary engines at work, the exhaust steam from them is economically used in these evaporators on a system patented by Caird and Rayner, which has been adopted by the British Admiralty in their ships.

The exhaust steam is maintained at a pressure of about 25 lbs. by a loaded valve on the main exhaust pipe, so that any excess over that pressure can pass direct to the auxiliary condenser.

By this arrangement distilled water is obtained without any expenditure of fuel whatever.

The evaporators are usually worked under a vacuum into the auxiliary condenser, the degree of vacuum in the evaporator being regulated by a specially-designed control valve.

The evaporators will produce from 1 up to 100 tons of fresh water per 24 hours, according to size.

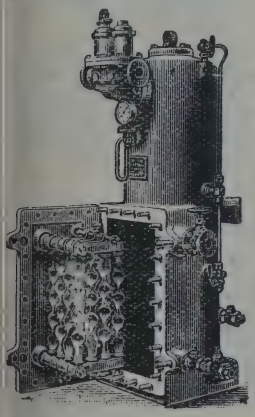

FIG. 40.—The Row Evaporator.

The Row Evaporator.

In the Row Patent Evaporator (*Royles, Ltd., Irlam, near Manchester*), the peculiar indented tube is a distinctive element in its construction. It is found that this form of tube surface casts its scale very readily and is otherwise highly efficient as an evaporating surface. Fig. 40 shows one of these evaporators open for cleaning. All the tubes are erected upon the inside surface of the door so that when this latter is opened, which is done without breaking any pipe joints, all the tube surface is accessible for cleaning. The evaporator is fitted with the usual complement of fittings, and is very compact and efficient. It is made in seven sizes, to produce from 2½ to 30 tons per 24 hours.

The Weir Vertical Type Evaporator.

(G. & J. Weir, Ltd., Cathcart, Glasgow.)

This evaporator, fig. 41, is of the vertical type. The shell and dome are of the best close-grained cast iron. The heating surface is formed of heavy solid-drawn copper tubes attached to the inlet and outlet chambers by means of hollow conical couplings. The tube space is separated from the steam space by a deflector. The arrangement of this deflector allows the steam to rise, but

throws down the water so that it is returned again to the water space. With this arrangemen it is almost impossible to make the evaporator prime under anything like reasonable limits. Th usual mountings consist of steam inlet valve, vapour outlet valve, feed check valve, brine valve drain valve, and coupling to hot-well, blow-off cock, safety valve, gauge glass fittings, pressur gauge, compound gauge, salinometer valve, and gunmetal feed pump to work off the main engin levers.

Heating Tubes.—In the latest designs the heating tubes are arranged in elements, each element consisting of a single tube coil with special hollow couplings on inlet and outlet ends in the same plane. These hollow couplings pass through a steam chamber cast on the back or side of the evaporator, and are secured in place from the outside by means of a cap nut on the ends of each coupling. The outlet opening from the tubes is of smaller diameter than the inlet, with the exception of that in the lowest or drain tube, which is the same area throughout, and through which any steam passing through the smaller outlets from the tubes is again returned through the evaporator along with the water of condensation and drained to the hot-well. By this means the pressure in the stand-pipe chamber at the outlet end is always lower than in the chamber at the inlet end, and a constant current is kept up through all the tubes, thus preventing any accumulation of air and water.

Each element or tube can be taken out separately for cleaning, and in this way the cleaning can be more expeditiously and thoroughly done.

The arrangement also provides a means of keeping two or more elements as spares. These can be quickly substituted for elements requiring cleaning, and the evaporator set to work again while the dirty tubes are being scaled. The tube attachments are strong and substantially made, and are kept tight by screwing up from the outside against a strong shoulder on the inner portion of the coupling.

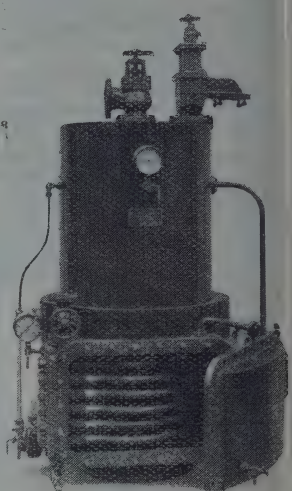

FIG. 41.

Automatic Feeding and Continuous Brining.—A water jet is so arranged as to induce the flow of brine from the evaporator and discharge the mixture overboard at any suitabl level. Sea water at a sufficient pressure is obtained by a connection from the sanitary tank, which is placed at a height sufficient to give the necessary head. As the evaporator feed is now usually obtained from the same source, to permit of automatic feeding through a feed regulator, an effective and simple combination is obtained whereby the minimum of piping i required and the feed and brining arrangements may be made integral with the evaporator.

Condensers and Water Heaters.

THE WEIR 'UNIFLUX' CONDENSER.

This design of condenser, introduced in 1909, has since become extensively adopted in thi country for naval and high-class merchant steamers, and the high vacua attainable by its adop tion when working in conjunction with the Weir 'Dual' type of combined wet and dry air pump has been an important factor in the improved efficiency of steam turbines.

The construction of the condenser introduces no novel features except as regards the pear shape of shell which has been designed with the object of causing the exhaust steam to flow ove the tubes at a uniform velocity without short circuiting, the steam inlet being arranged as fa from the air-pump suction as possible.

The 'Dual' air-pump is of the beam type having one steam cylinder and two pump barrels one pump for air and vapour and the other for water, air and vapour. Cold injection water i introduced at each stroke into the dry-air pump barrel to condense the vapour and cool the air and in order to avoid the expansion of the air present in the water filling the clearance space o the dry pump at the moment of discharge the dry-air pump is arranged to discharge below th head valves of the wet-air pumps.

The combination of improved design of air-pump and condenser in conjunction with an in creased supply of circulating water has resulted in a reduction of the condensing surface from 20 to 25 per cent. as compared with the condensing plant previously fitted.

THE WEIR DIRECT CONTACT FEED-WATER HEATER.

This system consists in taking a portion of the steam from the low-pressure receiver of the engine and utilising it to heat the feed water on its passage to the boiler. In actual practice on board ship, this steam is also supplemented by the exhaust from the auxiliary engines.

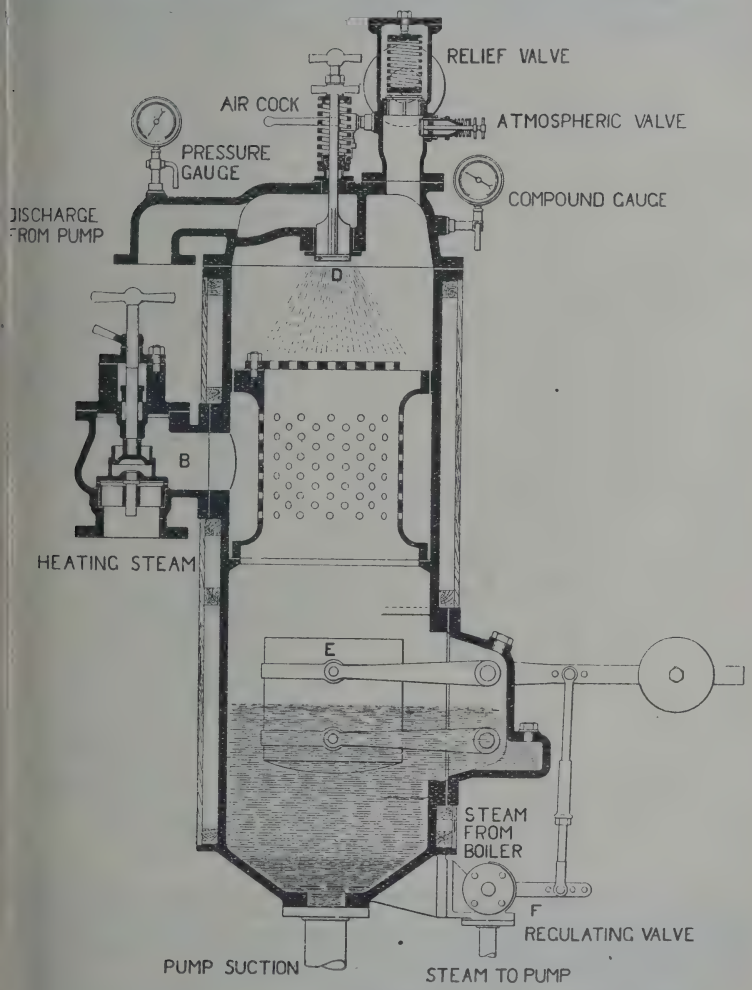

FIG. 41A.

Fig. 41A shows a sectional view of the heater. The heating steam is taken from the low-pressure casing of the main engine, and the exhaust of the auxiliary engines is also led into the heater through the non-return valve B on the side of the apparatus. A perforated cylindrical

waist piece forming an annular steam space round the heater, and surmounted by a conical spra
piece, also perforated, is fitted to ensure the uniform mixing of the steam and water. A Wei
direct-acting feed pump, or the main engine feed-pump, delivers the feed water into the heate
through the spring-loaded valve D on the cover. The feed water is forced through this valve in
thin sheet, and is instantly heated by contact with the steam. The water is further broken u
into fine spray by passing through the conical spray piece, thereby bringing the greatest possibl
surface into contact with the steam. As the pressure in the heater is generally much less tha
that of the entering water, the effect of this lowering of the pressure, and sudden heating of th

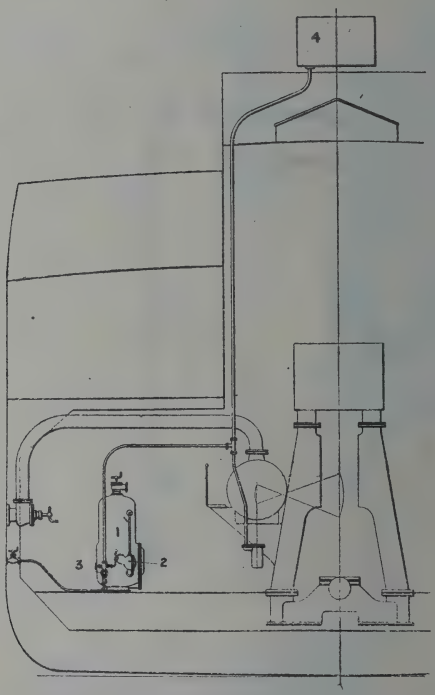

FIG. 42.—Arrangement on board ship of Evaporator with 'Weir' Feed Regulator and Brine Ejector.

1. Evaporator.
2. Feed Regulator.
3. Brine Ejector.
4. Sanitary Tank.

water, is to liberate the air in the water, and this is removed to the condenser, or to the atmospher
by a small cock K on the air vessel placed on the top of the heater. (In the case of twin-scre
vessels fitted with one feed heater, the lever cock on the heater air dome is coupled up to bot
condensers by a T piece.) The feed water is thus rendered non-corrosive, and falls to the botto
of the heater at the boiling temperature corresponding to the pressure.

The combination, fig. 42, of the automatic regulating gear with the heater is a special featu
of the Weir apparatus. The float E shown in the lower part of the heater is a pan, with wate
tight bottom and sides, but open on the top. It is suspended on two levers, so as to move up an
down with a parallel motion; the top lever spindle is carried through the door at one end, and
balanced by a lever and weight. The float is always full of water, and the weight is adjusted

balance when one-half is immersed in water. The weight lever is connected by a rod to another lever, which actuates the throttle valve F and controls the supply of steam to the pump drawing from the heater. When the water in the heater rises, the float is raised, and the throttle valve opened, and, when the water level is lowered, the float follows, and the valve is closed ; the level of the water is thus kept constant in the heater, and the pumps are completely filled with water.

When feed heaters are placed on the discharge side of the feed pump they are necessarily subjected to the boiler pressure, and must therefore be of a very substantial character. Such heaters are always of the surface type. Messrs. Weir have two special designs of heater of this class—the 'Multiflow' and the 'Uniflux.'

As affecting the engines, it is found that this system secures a fuel economy of from 5 to 8 per cent., according to the steam pressure carried, and the number of expansions in the engine.

The heater has been fitted by Messrs. G. & J. Weir Ltd. to over 4,000 vessels.

Air Pumps.

Paragon Air-Pump.

(G. & S. Weir, Ltd., Cathcart, Glasgow.)

This air-pump is a development of the well-known Dual Air-Pump, and is giving the same steadfast reliability in marine work that was characteristic of the Dual type of pump. It has been adopted by the leading steamship companies, and is shown in fig. 42A.

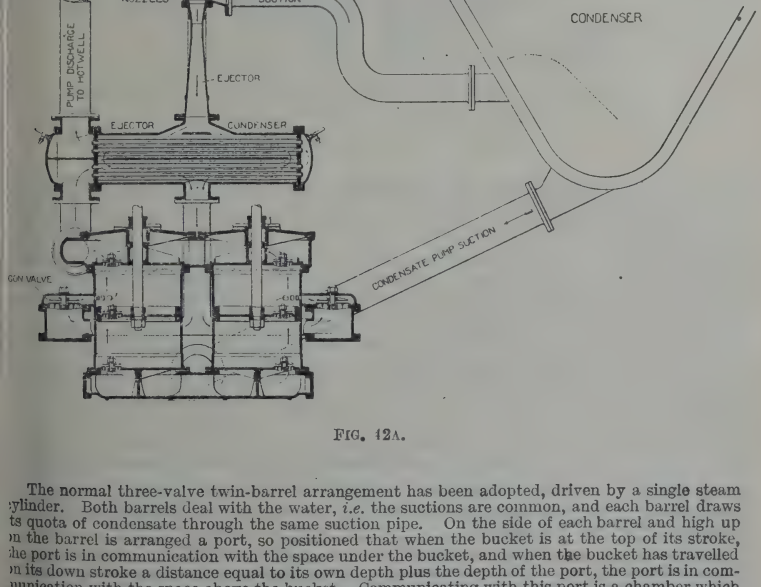

Fig. 42A.

The normal three-valve twin-barrel arrangement has been adopted, driven by a single steam cylinder. Both barrels deal with the water, *i.e.* the suctions are common, and each barrel draws its quota of condensate through the same suction pipe. On the side of each barrel and high up on the barrel is arranged a port, so positioned that when the bucket is at the top of its stroke, the port is in communication with the space under the bucket, and when the bucket has travelled on its down stroke a distance equal to its own depth plus the depth of the port, the port is in communication with the space above the bucket. Communicating with this port is a chamber which houses a non-return valve of a design similar to the pump valves. A branch pipe connects the two chambers with the augmentor condenser outlet. The augmentor condenser is of the tubular

type with brass tubes ferruled into brass tube plates. The augmentor is fitted to the top of the augmentor condenser, and discharges into same. The steam discharged by the augmentor is condensed on the outside of the tubes by the condensate, which is discharged through the tubes by the air-pump; the heat in the augmentor discharge therefore is conserved in the condensate, which results in the economy of the apparatus being good. The steam nozzles are of the convergent divergent type, similar to those fitted to the air ejector.

This pump is capable of maintaining the highest vacua, and has a large air handling capacity for the size of the pump.

Experiment has shown that on a 19 in. × 15 in. pump the fall in vacuum was only 0·4 in. Hg, when a ¼ in. diameter air leak nozzle was opened admitting air to the condenser.

Bearings.

The Michell Bearing.

Michell Bearings (thrust and journal) are largely used in modern marine practice, and are manufactured by Michell Bearings, Ltd., Newcastle-on-Tyne. There are in the British Navy alone ships aggregating over ten million horse-power fitted with main thrust blocks of this type,

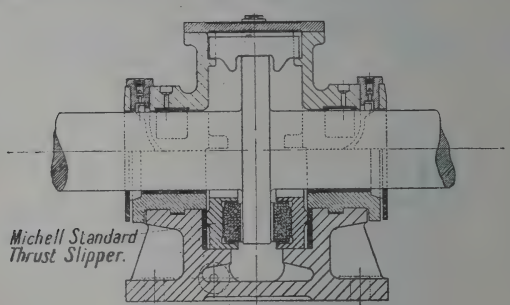

Fig. 43. Michell Slipper Type Thrust Bearing

and in passenger and merchant ships the Michell Thrust Block is commonly used, both for reciprocating engines and steam turbines.

A standard thrust block used for light craft of all kinds is shown in fig. 43. This is self-lubricating, and can be arranged upon an extension of the engine-bed or upon a separate seating immediately aft of the crankshaft coupling. The oil level in the thrust block is usually kept just above the under-side of the shaft. The bearing surfaces are lubricated by the thrust collar carrying oil upon its edge, and the oil is scraped from this by the scraper at top, thus giving a continuous cascade of oil on the pads. The pads are so pivoted that a film of oil is led into the space between pad and thrust collar, and this oil film can withstand a heavy pressure. A feature of the bearing is that as the speed increases, the pressure per square inch can be increased.

Michell thrust blocks have a single collar shaft with a series of pivoted pads arranged forward and aft, and it will be noticed from the illustration that the pads need only be in the bottom half of the bearing. Thrust blocks, however, can be designed to utilise an existing multi-collar thrust shaft.

Large engines are usually fitted with a thrust block arranged for continuous oil circulation, and in these blocks the upper as well as the lower portion of the body sustains thrust load. Oil is introduced into the space behind the pads and compelled to travel radially across the thrust faces. This oil can be cooled and used over and over. In these blocks the upper and lower parts of the body are keyed together, and liners for adjustment are fitted behind each of the rings which carry the pads.

The Michell principle is also applied to journal bearings, and fig. 44 illustrates one as fitted to a marine oil engine. When speeds are high the ring lubrication is replaced by a continuous supply of oil from a pump. It will be noticed that the oil is taken on to the shaft by means of a ring, and this ring is always kept in a central position, even if the ship pitches, as the central part of the oiling ring is guided by grooves in rollers arranged upon the shaft.

Considerable economy in length is effected by this bearing, as a pressure of about 500 lbs. per square inch projected journal area is satisfactorily carried at any speed.

The pivoting principle, upon which all Michell bearings work, ensures, perhaps, the nearest approach possible to perfection in lubrication. Astonishingly high pressures are quite safely

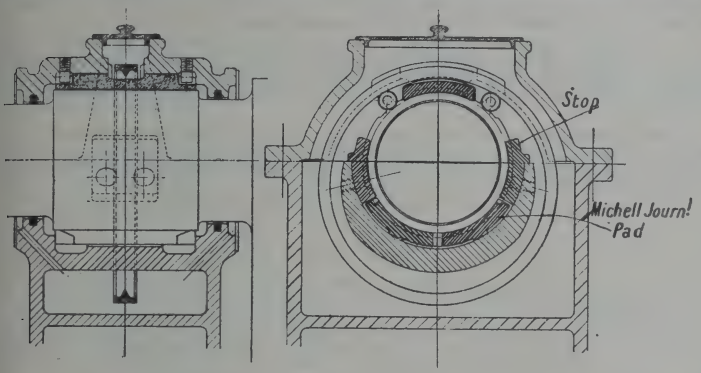

FIG. 44.—Michell Journal Bearing for Marine Oil Engine.

carried (under test as much as 5 tons per square inch has been successfully imposed), whilst speeds of any magnitude may be run by regulating the quantity of oil supplied. High speed is an advantage, inasmuch as oil film thickness increases with the speed.

MARINE DIESEL ENGINES.

Contributed by A. P. Chalkley, B.Sc., A.M.Inst.C.E.
Author of 'Diesel Engines for Land and Marine Work.'
Revised by James Thomson, M.I.N.A.

The Diesel engine as designed for marine work differs in no essential principle from the stationary type; with each manufacturing firm there are certain modifications and peculiarities of construction. On the whole the two-stroke-cycle single-acting engine is considered to have best prospects for the future, but for the very large engines for marine purposes the double-acting two-stroke-cycle motor is expected to give best results, whilst a number of firms still adhere to the four-stroke-cycle single-acting principle for moderate powers.

The superiority of the Diesel engine for marine work in certain cases is not entirely due to its fuel economy. This must always be an uncertain matter, dependent on the relative prices of the fuels. The consumption of oil with a Diesel marine engine is practically the same as for the stationary type, and, generally speaking, with oil of a net calorific value of about 18,000 B.Th.U. per lb. or 10,000 calories per kg. the fuel consumption for marine work may be taken as 0·40 lb. per b.h.p. hour for the main propelling engines. Unlike reciprocating steam engines, and steam turbines, the larger Diesel engines possess practically no advantage over smaller ones. It is usually estimated that the weight of fuel consumed by a Diesel marine engine is ½ that required for a vessel equipped with small reciprocating steam plant burning coal and about ⅓ for double-reduction geared turbines with oil fuel boilers, making allowance for standby losses, etc., and it has been found that this estimate has been well borne out in practice, although owing to the difference in efficiency between large and small steam engines and turbines it cannot apply absolutely.

The fuel consumption of large steam turbine plants with superheat and modern appliances has been reduced so much that fuel rates and first cost, etc., must be carefully considered before deciding whether Diesel or steam turbine machinery is the most suitable for the required service.

Among the most important advantages of the Diesel engine for marine work is the reduced space occupied by the propelling machinery and bunkers. This permits of greater cargo-carrying capacity, or a smaller vessel for the same cargo, with a corresponding reduction of the cost of the hull, although at the present time the cost of a Diesel engine is in excess of a steam engine and boiler plant. A vessel equipped with Diesel engines has from 10 to 15 per cent. extra cargo-carrying capacity as compared with a steam engine, and this is materially increased if the amount

of fuel carried is reckoned on the basis of the same radius in both cases, when considerable extra bunker space is rendered available for cargo in the Diesel ship. With special precautions, moreover, the fuel oil can easily be carried in the double bottom of the ship, which allows a further gain in space. In war vessels the advantage of the economy in fuel with Diesel engines will no doubt be utilised by increasing the possible radius, which may be taken at 3 times that of a steam vessel with geared turbines owing to the relative high economy at lower powers, this being a feature of the Diesel engine as compared particularly with the steam turbine.

In a Diesel ship the number of attendants in the engine room required is less than in a steam vessel, being usually in the neighbourhood of $\frac{2}{3}$. Firemen are entirely dispensed with, the handling of fuel is easy, rapid, and clean, whilst the astern power is equal to the ahead, which is not the case in turbine vessels. A list of engine room staff for various motor ships is given on page 2435.

For the same speed a single screw vessel equipped with Diesel engines usually requires slightly more power than when propelled by a steam engine for similar conditions, as the revolutions are too high for the most efficient propeller, but this does not apply to multiple screw ships when the speed exceeds 12 knots.

The weight of Diesel machinery for large powers is usually greater than steam turbine machinery.

Types of Marine Diesel Engines

There are three distinct types of Diesel marine engines, two of which have already been largely constructed and put into actual service, whilst of the third type comparatively few are in service. The first two are the single-acting engines of the four-stroke-cycle and two-stroke-cycle type respectively, whilst the third is the double-acting engine. A vessel has been completed recently with a twin screw set of vertical engines of the four-cycle double-acting type of 18,000 B.H.P.

The four-stroke-cycle motor is slightly more efficient, but the two-stroke-cycle single-acting engine has the advantage of reduced weight and space, simplicity in reversing arrangements and cheapness of manufacture. It necessitates the employment of scavenge pumps which reduce the overall efficiency of the motor. Larger powers can be developed in single cylinders, and although the limit is not yet certain, it is anticipated that 3,000 h.p. can be produced from a single cylinder. Up to the present 2,000 B.H.P. is the highest power that has been attained in a single-acting two-stroke-cycle motor per cylinder.

The reason for the employment of the double-acting two-stroke-cycle engines is to obtain the maximum power per cylinder. The chief difficulty encountered with the double-acting engine is to get rid of the heat in the cylinder, and there is also the question of the most convenient method of operating the valves in the bottom cover of the cylinder. It is stated that these troubles have now been satisfactorily overcome.

As regards the two-stroke-cycle single-acting type, the chief difference in the design of different manufacturers, apart from details of the reversing gear, is in the method of the provision of the scavenge air. In some engines scavenge valves are employed, fitted in the cylinder cover, and through these the scavenge air enters the cylinder, whilst in other types ports are provided at the bottom of the cylinder usually extending half-way round the circumference, opposite the ports for the discharge of the exhaust. Scavenging through ports presents some difficulties in regard to cleaning out all parts of the cylinders thoroughly, and various arrangements are employed to make it more efficacious, some of these being described later. With valves, the scavenging is excellent, but the valves must be large, and they add to the complication of reversing. The scavenging pumps usually work at a pressure of 2 to 6 lbs. per square inch, above atmosphere, and the power they absorb is from about 5 to 10 per cent. of the output of the engine. The power developed by a single-acting two-stroke cycle Diesel engine is about twice that of a four-stroke cycle engine of equal cylinder dimensions.

The question of reversing Diesel engines is not one of particular difficulty, the only requirement being a variation in the time of opening of the different valves. In the four-stroke-cycle engine this includes the exhaust valve, which is omitted in the two-stroke-cycle type, whilst if in the latter scavenge ports are provided, the matter is further simplified by the absence of scavenge valves. There are various methods of reversing, which, however, practically do not differ at all in principle, the arrangement being to alter the times of openings of the various valves relative to the crank shaft. In one arrangement which is commonly employed, a single cam shaft is provided on which are fixed two separate sets of cams, one for the ahead motion and one for the astern, each valve thus being capable of operation by either of the two cams. For reverse running the cam shaft can slide in a longitudinal direction, and this motion brings the astern set of cams underneath the levers operating the valves, so that the valves are thus set for going astern. Before the cam shaft can be moved, the rollers of the valve levers have to be moved clear of the cams in order to let them pass under.

A second method of reversing consists in having two separate cam shafts, on one of which the cams for ahead running are mounted, and on the other those for the reverse, and either cam shaft is set in a position for its cams to actuate the valve levers, according as it is required to run ahead

or astern. There are various other means adopted for reversing, such as by a rotation of the cam shaft relative to the crank shaft, and utilising the same cams for both directions which necessitates special setting of these cams. In another design a combination of this method and the first is adopted, whilst there are certain other special arrangements, one of which is described later.

Burmeister & Wain Type.

The engine designed and constructed by Messrs. Burmeister & Wain, of Copenhagen, and by Messrs. Harland & Wolff, may be taken as a typical four-stroke-cycle marine Diesel motor. It is built with six or eight cylinders, according to the power, the engines of the 'Glenapp' and several other boats having each eight cylinders, and developing about 2,600 i.h.p. at 115 revolutions per minute.

As is now common in most Diesel engines, and will, no doubt, be generally adopted in the future, external crossheads with water-cooled guides are employed, which, although increasing the height, are of considerable advantage in dismantling and for facility of inspection. An enclosed crank chamber is used, but at front and back there are readily removable covers.

The engine may be considered as arranged in two sets of four cylinders, which is convenient for the placing of the valve gear and manœuvring mechanism described later. The valves are fitted in the cylinder cover, as is generally the case, and each cylinder has a starting air valve, fuel inlet valve, exhaust valve, air inlet valve, and relief valve. The cam shaft carrying the cams which operate the levers controlling the valves is not situated on a level with the top of the cylinders, as is common in many four-cycle engines, but at about half the height of the engine. Each of the valves, except the relief valve, has two separate cams for its control on the cam shaft, one for ahead and one for astern running. In order to reverse the engine, the valve levers are lifted and the cam shaft moved longitudinally a distance equal to the cam width, so that, on dropping the valve levers once more, they are now immediately above the astern cams and are in a position for running in the opposite direction. The sliding of the cam shaft is accomplished by means of a disc carried on it, which moves in a slotted drum on an auxiliary shaft, the slot slanting from left to right. The auxiliary shaft can be turned by means of an air motor controlled from the starting platform, and in turning the cam shaft moves to the left or right, according to the direction of rotation of the auxiliary shaft. The actual operation of the valves from the cams is carried out by having long hollow vertical rods, whose upward and downward motion causes the rocking levers at the top to actuate the valves. It may be mentioned that, contrary to usual practice, the injection valves open inwards towards the cylinders. The drive of the cam shaft is through helical gearing and a vertical intermediate shaft, direct from the crank shaft. Sometimes a direct gear drive is adopted.

The question of the number of fuel pumps for pumping the oil to the injection valves is somewhat controversial, the majority of manufacturers preferring to have one pump per cylinder, whereas others think it desirable to minimise the number as far as possible. A small hand pump is employed for pumping the oil up to the valves when required, the usual overflow cocks being fitted.

In most Diesel engines, the governor controls the amount of fuel admitted to the cylinder by acting upon the suction valves of the fuel pump, and holding them open a longer period during the pressure stroke, if it is required to reduce the oil supply. In this engine the control is from the starting platform and a governor is fitted, which is only for the purpose of preventing the speed rising above the designed revolutions per minute, by cutting off the fuel altogether in all cylinders but one. Forced lubrication is adopted for the engine, and the oil is water-cooled and circulated continuously.

There have been some very distinct modifications with the later and larger type of motor. Eight-cylinder sets are now built developing 3,200 i.h.p., having a cylinder diameter of 740 mm. (29 ins.) and a stroke of 1,100 mm. (43¼ ins.). This is by far the largest output for a single-acting four-cycle marine motor that has yet been attained, although cylinders of greater dimensions are now being built. With an efficiency of 80 per cent. the corresponding brake horse-power is about 2,600. The speed of revolution is 115 per min., and the consumption of the engine is 0·32 lb. per i.h.p., or about 0·4 lb. per b.h.p. A vertical three-stage air compressor is driven direct off the main engine, each compressor being capable of supplying the injection air under normal conditions. A separate fuel pump is provided for each cylinder. Oil or sea-water is used for piston cooling. It may be mentioned that some designers prefer to avoid the use of sea-water for cooling purposes owing to the possibility of deposit, but the matter is largely an open question. The whole of the arrangements for operating the valves and reversing are the same as in the smaller motors, except that the camshaft, instead of being driven by two long horizontal rods, is in this case operated through spur gearing from the crankshaft, three intermediate spur wheels being provided between the crankshaft and the camshaft. It is claimed with this design that there is less likelihood of any variation in the setting of the cams due to wear and other causes.

In fig. 45 (p. 2412) a section is given of a 2,000 b.p. Burmeister & Wain motor of the latest type, whilst figs. 46, 47 (pp. 2413, 2414) give illustrations of the control arrangements for this motor.

Engines of the Burmeister & Wain double-acting type have been constructed for a twin-screw installation of 18,000 b.h.p. with chain-driven camshaft four-stroke-cycle double-acting engines, having eight cylinders in each set and working at 125 revolutions per minute. The air compressors are independent of the main engines and driven by separate Diesel engines. The main

engines are of the piston-rod type, having a gland in the cylinder bottom, and the pistons are cooled by oil. The camshafts are driven by chain drive.

Messrs. Harland & Wolff manufacture a long-stroke slow-running engine which is specially suitable for slow-speed cargo boats.

North-Eastern Diesel Engine—Werkspoor Type.

The first engine of this type was constructed by the Werkspoor Company of Amsterdam, and installed in the *Vulcanus* in 1910. North-Eastern Marine Engineering Co. was the first of British marine engine-builders to take out a licence to build this type of engine, since when engines varying from 1,000 b.h.p. up to 4,000 b.h.p. have been built, both for British and Continental owners, with very successful results.

SINGLE-ACTING ENGINES.

The motor, fig. 48, p. 2417, is usually of six cylinders, and, except for a few special features, is of the standard single-acting four-stroke type of engine.

The chief point of difference lies in the cylinder construction, the North-Eastern-Werkspoor engine having a continuous cooling surface from liner to crown of cylinder, this construction giving highly efficient cooling to the combustion chamber, there being no liner joint to interfere with the circulation. The arrangement also allows the valves to be spread further apart, giving more space for circulation between the valve ports.

The pistons and cylinders are inspected from below, a very simple arrangement being provided for this purpose.

Another point of difference lies in the arrangements for operating the valves and the method of reversing. There is one camshaft on which the cams for ahead and astern working respectively are mounted in pairs for air starting, fuel injection, induction, and exhaust. This shaft does not move in a fore-and-aft direction during reversal, but the lever which transmits the motion from the cam to the valve is mounted eccentrically on the reversing shaft. The axis of the eccentrics and the shaft on which they are mounted are not parallel, so that when the shaft is rotated through an angle of 180° the rollers are lifted from one set of cams and placed on the other.

The camshaft is driven by connecting rods from cranks on a countershaft to cranks on the camshaft, the countershaft being driven by spur gearing from the engine crank shaft. This is a totally distinct method from that already described, in which the camshaft is moved longitudinally, and illustrates the diversity of the arrangements which may be employed for reversing Diesel engines.

A light type of engine is built with the cylinders entirely supported by steel columns and diagonals, but the standard design has the cylinders supported on cast iron 'A' frames, the cylinder beam, columns, and bedplates being held together by heavy through-bolts running from top to bottom of the engine.

The main running gear has forced lubrication, and is totally enclosed in an oil-tight casing with large doors, particularly easy to remove.

The compressor is of the three-stage type, usually direct driven from the forward end of crank shaft.

DOUBLE-ACTING ENGINES.

The 'North-Eastern-Werkspoor' Double-Acting Diesel engine is a new type which has been jointly developed by Werkspoor and the North-Eastern Marine Engineering Co., Ltd.

A sectional elevation is shown in fig. 48A, p. 2417.

The upper portion of the cylinder and the arrangement of the main running gear is of normal single-acting design. A feature is the lower combustion chamber so arranged that combustion takes place in a separate chamber away from the piston rod, which therefore runs very cool and under easy conditions.

The compression pressure in the bottom cylinder is only 250 lbs./sq. in., so that this cylinder requires to be pre-heated to give the necessary compression temperature. This is done by running the engine as a single-acting unit and passing the exhaust gases from the top cylinder through the inlet valve into the bottom cylinder for about five minutes before putting the fuel on. The mean pressure on the top of the piston is about 90 lbs./sq. in. and on the bottom about 65 lbs./sq. in.

The engine is of extremely simple and accessible design, the piston being examined by lowering the bottom portion of the cylinder and thereby exposing the piston.

This engine is built in powers up to 1,000 b.h.p. per crank, the engines at present under construction having six cylinders, and are capable of maintaining 4,000 b.h.p. continuously at sea.

Sulzer Marine Diesel Engines.

Messrs. Sulzers' experience of both four-cycle and two-cycle engines has led them to adop the two-cycle engine for all marine work, and they have standard designs of 4, 6, and 8 cylinde marine engines developing from 300 to 7,200 b.h.p., the latter being a unit of 8 cylinders, or 90 b.h.p. per cylinder.

The Sulzer two-cycle engine has important differences from the other engines described Chief amongst these is the method of scavenging through a double row of ports, the upper ro of which is above the exhaust port opening and is controlled by means of a valve.

On the downward stroke of the piston, the upper row of scavenging ports is first uncovered but the valve controlling these ports remains shut and the exhaust commences to take plac only when the piston has descended further and uncovered the exhaust row of ports.

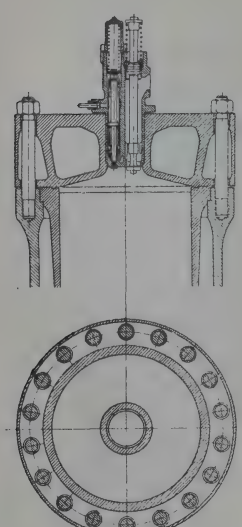

Fig. 49.

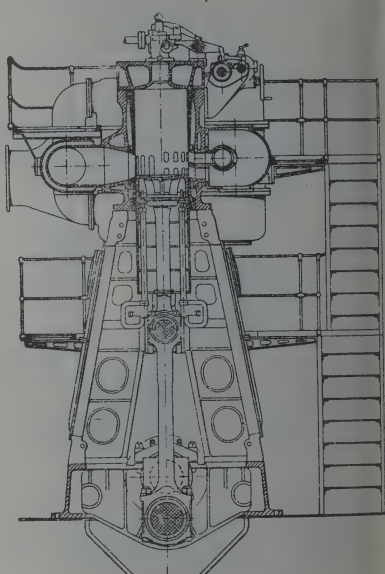

Fig. 50.

Scavenging commences as soon as the lower row of scavenging ports is uncovered and co tinues through both rows of ports, the control valve for the upper ports having been open by the pressure of the scavenging air, and air is admitted through the upper ports to the cylinde after the exhaust ports are closed, as long as the scavenge air pressure exceeds the pressure in t cylinder.

Not only is the scavenging much improved in this manner, but it will be seen that it is possib to obtain a supercharge of air, *i.e.* a slight increase above the atmospheric pressure in the cylind at the commencement of compression.

Messrs. Sulzers have found that the good combustion obtained by this method of scavengin and also the simplicity of the cylinder cover design (fig. 49) enables them to maintain with safe a higher mean pressure in their two-cycle engines than in four-cycle engines.

The power for a given size of cylinder on the Sulzer two-cycle type is more than double t power of a similar size cylinder on the four-cycle type, both being assumed to run at the sa piston speed.

The fuel consumption is also practically the same as the best four-cycle engine when worki under service conditions, *viz.* 0·42 lb. per b.h.p. hour, including scavenge blowers.

Fig. 50 shows the section through working cylinder of a standard Sulzer Marine Engine 1,350 b.h.p. running at 110 r.p.m.

F. 2419

The double row of scavenge ports and the control valve for the upper ports are seen on the ght (fig. 49), while the exhaust ports and exhaust collector are on the left. The valve shown is the rotary type, but in the latest designs automatic lift valves are used, the action being as ready described.

The engine shown is provided with a direct driven scavenging pump fitted between the h.p. r compressor at the end of the engine and the main engine cylinders.

In the latest type of engine, the scavenging pumps are in the form of independent rotary owers electrically driven. This is an advantage from the constructional point of view, and ie arrangement has the further gain that the scavenging pump may be speeded up indepen- ently of the main engine when it is desired to increase the power. This does not involve any crease in the size of the electric generating sets where electrically driven winches are installed, these latter are only running in port when the scavenging pump is idle.

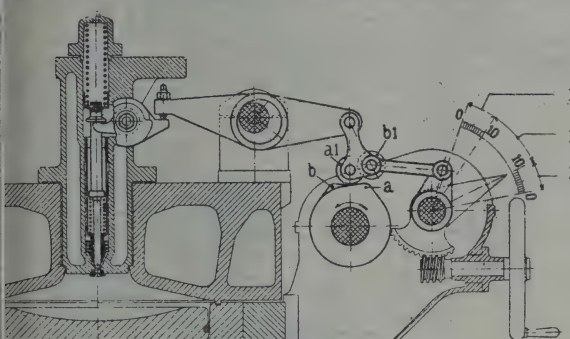

FIG. 51.—Sulzer Reversing Mechanism.

The engine illustrated, when made with separate turbo-blowers, develops 1,500 b.h.p., orking at approximately the same indicated mean pressure and piston speed as the 1,350 b.h.p. gine with reciprocating scavenge pumps.

Reversing is carried out with a minimum requirement of power, and is effected by bringing second set of rollers and cams into operation (fig. 51). Each starting and fuel valve there- re has one cam and roller, a and a^1, for running ahead, and another, b and b^1, for running astern. ie hand wheel shown in the above illustration brings a and a^1 or b and b^1 into operation in cordance with the required direction of running.

The weight complete of Sulzer Diesel Marine Engines is approximately 2 cwt. per h.p., i.e. h.p. per ton.

Submarine engines of Sulzer two-cycle type have been built developing 4,000 h.p. in 8 cylinders, ese engines being the most powerful marine Diesel engines in the world of the light type.

The first large passenger liner driven by Diesel engines is the *Aorangi*, which has engines of e Sulzer type, manufactured by the Fairfield Shipbuilding and Engineering Co., Ltd., at Govan.

THE 'DOXFORD' ENGINE.

Messrs. Wm. Doxford & Sons, Ltd., have completed a number of motor vessels, and there are w built and building an aggregate b.p. of 350,000, consisting of four-cylinder types, quadruple rew, 15,000 i.h.p., twin screw, 5,500 i.h.p. @ 95 revs., single screw, 6,000 i.h.p. @ 95 revs., and ree-cylinder types, single screw, 2,650 i.h.p. @ 90 revs., all of the opposed piston two-stroke pe operating on the Doxford system of airless injection.

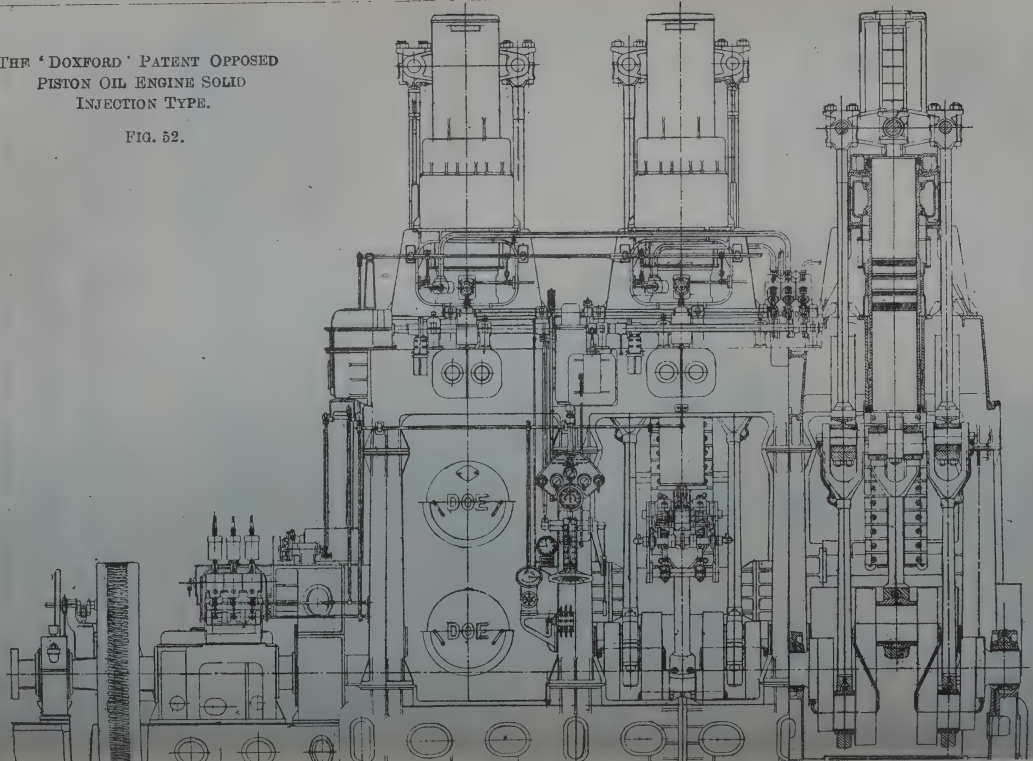
Fig. 52, p. 2420, shows the three-cylinder type of engine, in each cylinder of which there are two stons acting outwards. The lower piston is coupled by crosshead and connecting rod to a crank low the centre of the cylinder, and the upper piston acts upwards to a transverse lever above it, tending fore and aft beyond the walls of the cylinder, and coupled by two side connecting rods to o cranks, one on each side of the centre crank, but arranged in line diametrically opposite to it.

The fuel is injected between the pistons when they are close together, and when combustion kes place the pistons are driven apart, thus exerting an almost perfect turning moment on the ankshaft, without reactional load on the main bearing or the framework of the engine.

The products of combustion are exhausted through ports round the whole circumference at e top of the liner, which ports are controlled by the upper piston. At the end of the stroke, rresponding ports are uncovered by the lower piston in the bottom end of the liner, to control ie scavenging air, thus the entire cylinder is scavenged on the 'Uniflow' principle; the covering

THE 'DOXFORD' PATENT OPPOSED PISTON OIL ENGINE SOLID INJECTION TYPE.

FIG. 52.



f these ports at the beginning of the return stroke traps the containing air, which is thus com-ressed ready for the injection of the fuel and repetition of the cycle.

Fuel injection is on the Doxford ' Solid Injection ' principle, and the fuel oil is injected trans-ersely across the cylinder in the form of a fan, from each valve placed diametrically opposite, ie fan forming a curtain right across the combustion space. The air which is entrapped between he two pistons receives through suitably arranged ports a rotating motion whereby the air fed through the curtain of fuel oil, so that very efficient combustion is obtained without the il impinging on to the piston or cylinder walls. The two pistons are, moreover, hollow, and orm between them practically a complete spherical space, the surfaces of which are kept at 000° F., thus greatly assisting the burning of the heaviest grades of boiler oil.

The elimination of exhaust and induction valves, with their liability to defects, is a great dvantage, and in dispensing with the cylinder cover many defects of jointing and cooling are bviated. Also, the absence of the high-pressure compressors removes the most delicate part of Diesel engine, and the danger from possible explosions is completely avoided.

The valve gear is very simple, consisting of one camshaft in front and one at the back of the ngine. Both are driven by spur and bevel wheels direct from the thrust shaft. The front amshaft has two sets of cams for the fuel and air starting valves for ahead and astern running, ither of which is brought into operation by sliding the cam shaft by means of a hand lever. When oing ahead, the front and back fuel valves are in operation, but when going astern only the ront fuel valves come into use, giving approximately 60 per cent. of full power, which is equal o the resistance obtainable from the propeller. A hand-wheel controls the air-starting valves nd the fuel valves. By rotating the hand-wheel, the air-starting valves are brought into contact ith their cams, and air is admitted to the respective cylinders. By a further rotating of this and-wheel, the air-starting valves automatically come out of action and the fuel valves are rown into use, and by further rotating the hand-wheel, the speed and power of the engine is egulated. The small hand-wheel controls the suction valves of the fuel pump for regulating the equired fuel oil pressure.

An Aspinall governor operates the injection fuel valves, and at the same time acts upon the uel pump suction valves ; thereby racing under any condition is completely prevented.

The cylinder liners and pistons are all cooled with fresh water, and forced lubrication is employed n the crank chamber throughout.

Messrs. Doxford have run extensive trials on one of their four-cylinder 3,400 i.h.p. engines, ubmitted to the Trial Committee appointed by the Naval Arch. and Inst. of Mech. Engrs., and ave proved a consumption of ·4 lbs. per b.h.p. on ·96 British Mexican fuel oil, and a mechanical fficiency of 89 per cent. More recent test-bed results on a three-cylinder engine of 2,200 i.h.p., 90 evs., have given the fuel consumption as ·375 lbs. per b.h.p. on ·89 Anglo-Persian oil.

Messrs. Doxford claim to be the first to introduce aboard vessels centrifugal treatment of uel oil, thus enabling shipowners to burn any brand of fuel oil that may have to be taken aboard.

The Neptune Marine Oil Engine.

(Messrs. Swan, Hunter, & Wigham Richardson, Ltd., Wallsend-on-Tyne.)

The engine as shown by figs. 53 and 54 is of the reversible, two-cycle, single-acting, port cavenging type, and is arranged to be built with four, six, or eight cylinders, the scavenging umps and bilge pumps being situated at the back of the engine and driven by levers from the ngine crossheads. The compressor is driven from an extension of the crankshaft at the forward nd of the engine.

The engine embodies all the principal details of the original Neptune design in that built-p crankshafts, crossheads, guide plates, and connecting rods having double top end bearings re employed. Particular attention has been paid in this design to the accessibility of the engine, hich is, together with the above features, essential to marine engine design.

The crankshaft is designed 10 per cent. stronger than is necessary to comply with Lloyds equirements, and is of the built-up pattern in two interchangeable portions, and is drilled for onveying the lubricating oil to the top and bottom end bearings and to the guide shoes.

The main bearings are circular on the bottom, so that they can be withdrawn for examination ithout disturbing the crankshaft.

The crossheads are arranged to take the double top end bearings of the connecting rods and he links for driving the scavenging pumps. An extension on each end is provided to take the uide shoes. The ahead and astern guide shoes are arranged to have the same area of bearing urface, the reason being that in a two-cycle single-acting engine, the load from the piston is lternately on the ahead and astern faces for alternate strokes. In addition to this the position f the guide shoes makes a very open and readily accessible engine. The guide plates are il-cooled on the surface, and together with the guide shoes, are adjustable.

The piston rod is secured to the crosshead at one end, and is arranged with a flange at the other end to receive the piston.

The piston skirt is separate from the piston, and is attached to the lower part of th piston rod.

The piston is fitted with an inner casting both of which are of simple construction. The objec of this casting is to ensure an effectively cooled piston and to make the inside of the piston readil accessible for cleaning purposes.

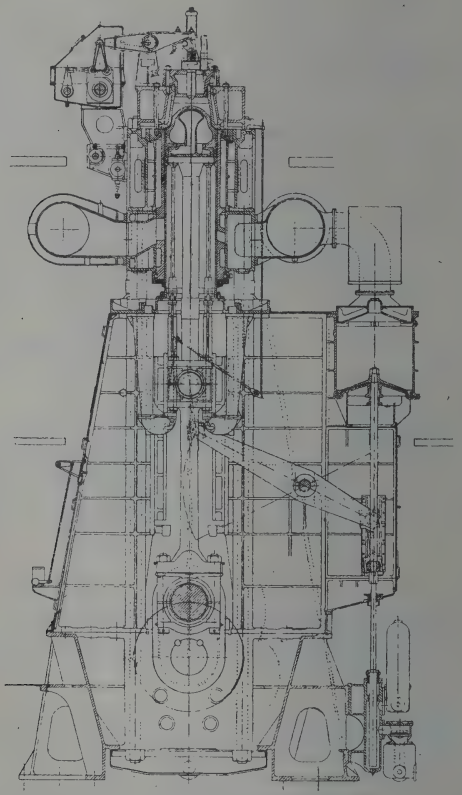


FIG. 53.—Neptune Marine Oil Engine.

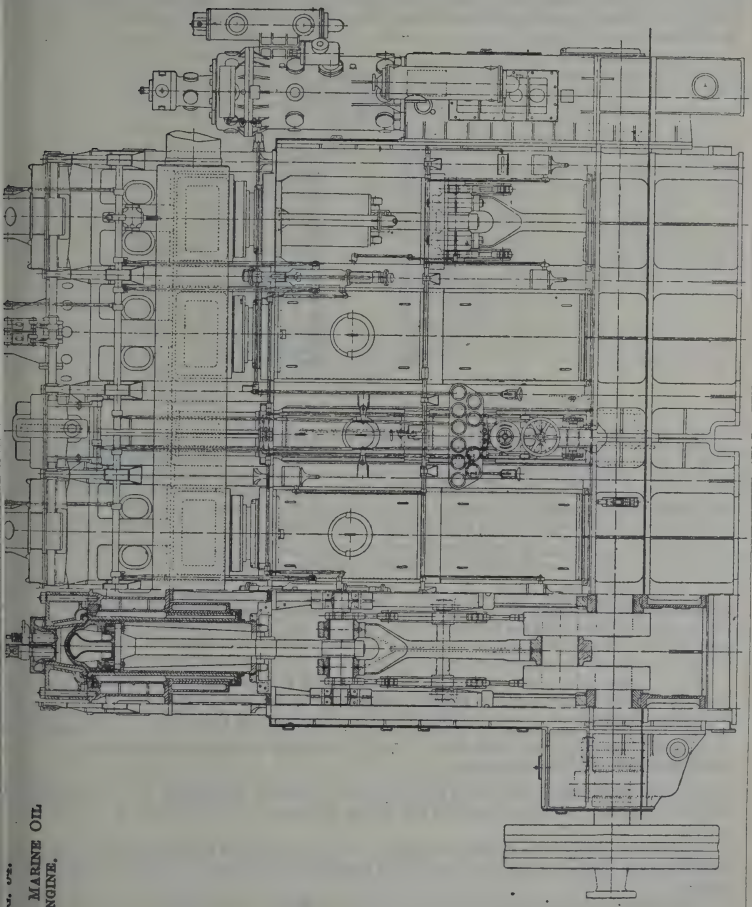
The pistons are cooled by means of sea or fresh water as required. The water is admitted t and discharged from the pistons through telescopic tubes and pipes, large air vessels being fitted t prevent water hammer. To obviate any possibility of the water leaking into the lubricating o in the crank case, the piston water service gear is provided with a double stuffing box, having drain led away to the bilge. A wiper ring and inverted funnel are fitted to the telescopic rod abov the stuffing box, in order to collect any water which may be adhering to the rod after passing th stuffing box.

As the success of two-cycle, port scavenging engines depends largely on efficient scavenging



NEPTUNE MARINE OIL ENGINE.

exhaustive experiments were carried out with various shapes of piston tops and scavenging ports, with a view to obtaining the most efficient form of scavenging possible. As a result of these experiments a symmetrical shape of the piston top and a special construction of the scavenging ports has been adopted.

The design of the cylinders and cylinder covers, as shown in fig. 55, is such as to allow all metal subject to high temperatures free expansion in every direction, and to reduce all heat stresses to a minimum. The cylinder is made in two castings, A and B. A is a beam connecting the cylinders together: it takes the load of combustion transmitted through the cover and cover casing F, and is not in any way exposed to the heat of combustion. The lower casting B, which is bolted to the beam A, contains the scavenging and exhaust passages, the latter being efficiently water-cooled.

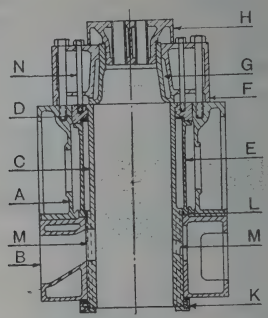


FIG. 55.

The liner C is arranged inside the two castings A and B, and is secured in position by a sandwich plate D. The sandwich plate is cast on the liner some distance below the upper flange, and is cut away to form a single ring. By this means an undesirable thickness of metal at the top of the liner, which gives rise to excessive heat stresses, is avoided, the metal being as thin as is consistent with the required strength. The sandwich plate is attached to the cover casing F by the studs N, thus making the joint between the cylinder liner C and the cover liner G.

This construction allows free expansion of the liner and makes possible a very simple design of liner in that part which is subjected to the highest temperature.

In order to avoid having a water joint in way of the ports, a water jacket E is bolted to the sandwich plate, making a joint at its lower end above the ports. A hollow collecting ring K is attached to the bottom of the cylinder liner. The circulating water passes from this ring through holes M in the ribs of the liner in way of the ports and into the cylinder jacket. This arrangement provides a very efficient means of cooling the liner in way of the exhaust ports.

The cylinder cover casing F is provided with a liner G which is free to expand in an upward direction, and is of such a design that the stresses due to heat are reduced to a minimum. It is so arranged that the liner can be easily withdrawn for cleaning purposes. The liner G has one central hole at the top, which is arranged to take the cover H, containing the necessary fuel starting and escape valves. The cover is designed to allow of free expansion of that part which is exposed to the combustion gases.

The cylinder liner, cover liner, and cover are all water cooled, the water joints being so arranged that they are not exposed to the action of the heat and pressure of the combustion gases.

Steel bolts connect the cylinders through the columns to the bedplate and take the whole of the tension loads due to combustion, the cast-iron columns being designed for compression only.

The camshaft is driven from the centre coupling of the crankshaft by means of gear wheels, eccentrics, and rods. The rods are in two sets connected by levers mounted on an intermediate shaft. All the bearings are adjustable. This gear is the usual Neptune practice and has been adopted in preference to skew gearing, owing to the unsuitability of the latter for marine purposes.

The camshaft is fitted with ahead and astern fuel and starting cams. The cam rollers are carried on links, there being one roller to each cam. Each link carries one ahead and one astern

oller. The engine can be run either in the ahead or astern direction by placing the link so that he ahead or astern rollers are in operation. These links are controlled by a handwheel at the ontrol station. The lift of the fuel valves is regulated by this gear so that when the engine is unning slowly a saving of injection air is effected. Compressed air for starting and reversing urposes is admitted to the cylinders through a valve in the cylinder cover. The fuel and starting alve levers are mounted on eccentrics, the positions of which are regulated from the control tation by means of levers operating through a servomotor. It is so arranged that the fuel valves nd starting valves cannot be in operaton at the same time. It is also arranged that when starting r reversing the engine the fuel pumps are out of operation. One half of the cylinders can be un on compressed air while the remainder are being supplied with fuel.

The fuel pumps are driven from the cam shaft driving gear, and are situated at the back of the ngine on the level of the control station. A separate pump is arranged for each cylinder. The ever used for disengaging the fuel valves is connected to the suction valves of the fuel pumps o that the pumps will be out of action at the same time as the fuel valves. A governor is fitted o operate the cut-out valves on the fuel pumps.

The control station is situated on the lower platform, and is so arranged that the engine can e easily operated by one man. In a central position are two levers for operating the fuel and tarting valves, each lever serving three cylinders. As previously stated, arrangements are ade so that it is impossible for the starting and fuel valves to be open together. The method of tarting up the engine is to admit starting air to one half of the cylinders while fuel s being supplied to the remainder. As soon as the engine is running the cylinders which were n air are put on to fuel. A reversing wheel is situated near to these levers, and arrangements re made so that the engine cannot be put over from ahead to astern or *vice versa* except when hese levers are in the ' stop ' position. Hand gear is also fitted for the control of the injection ir and fuel pumps, and, together with the telegraph and gauges, is arranged in close proximity o the starting levers.

A system of forced lubrication is arranged, the engine being entirely enclosed. A trough is tted under the bedplate to collect the lubricating oil flowing from the bearings, which is drained nto tanks situated in the double bottom of the ship. These tanks are separated from the ship's ide to prevent any possibilty of sea-water leaking into the oil.

Lubricating oil coolers, filters, and strainers are provided in the system.

The compressor is of the three-stage, single-acting type, each stage being provided with a traight tube intercooler and separator. A crosshead and guide shoe is provided to take the ide loads and to allow of the pistons being outside the crank case.

The necessary bilge and sanitary pumps are provided, and are so arranged that any one pump an be used for either purpose, and so enable one pump to be overhauled while the other is in use.

When a flywheel is provided, it is fitted at the after end of the crankshaft, the weight being aken by a special bracket which is bolted to the bedplate, and fitted with a bearing similar to he main bearings. A turning gear is provided which can be driven by a steam engine or electric notor, according to requirements.

Air for injection and starting purposes is stored in bottles situated in a convenient part of he engine-room.

The McLagan Double-Acting Sliding-Cylinder Two-Stroke Cycle Diesel Engine.

This is a three-cylinder unit engine with a cylinder diameter of 24½ ins. and a stroke of 44 ins. he designed power being 2,000 b.h.p. at 100 r.p.m., although during the trials it has been tested t 2,100 b.h.p., and could be rated at this output with a moderate and permissible mean effective ressure. The average m.e.p. at 2,000 b.h.p. is about 88 lbs. per sq. in., and the mechanical fficiency 72 per cent. The fuel consumption is ·448 lb. per b.h.p.-hour.

By the sliding cylinder design, the rubbing speed scarcely exceeds 500 ft. per minute between iston and cylinder. Not only are scavenging valves avoided and a very fine scavenging effect rovided (the scavenging air sweeps through from the top and bottom of the cylinder to the entre), but the piston rod does not pass through the bottom cylinder cover, with the result that. he fuel valve can be located centrally, and the problem of packing does not arise.

In effect, there are two separate cylinders in each line, with a space between them for the ovement of the crosshead pin. These two cylinders are joined together by ties arranged on pposite diameters, and at the top and bottom of the ties are spherical washers, so that the ylinders are free to adjust themselves independently. The actual distance moved by the cylinders about 13 ins., and they slide over the top and bottom cylinder covers. At the top the cylinder over is supported by an entablature, which itself is carried on columns extending from the

bedplate to the entablature. Below the bottom of the cylinder is another entablature, carried by brackets from the frames, and these support the lower cylinder cover, both covers being provided with gastight rings.

The scavenging air is delivered from a double-acting pump driven from the crankshaft at the after-end of the engine into the front engine columns, which are hollow and connected by piping, thus acting as receivers. Suitable branches with glands are provided, allowing the admission of the scavenging air through the pipes on the cylinder which slide within the branches mentioned. In the cylinder at the top and bottom are ports which are uncovered as the cylinder moves downwards and upwards respectively. On the downward stroke the scavenging air sweeps through the cylinder from the top to the centre, the exhaust gases being discharged through the branches and the common pipe, giving connection to the main exhaust manifold with a sliding joint and gland. There are, of course, belts of exhaust ports around the cylinder, these being uncovered by the relative movement of the piston and cylinder.

Only two valves are needed, one for fuel admission and the other for starting air. They are to the right and left of the centre-line of the cylinder respectively, each inclined at an angle of about 45 degrees with the vertical. Only one hole is required (for the fuel valve), as the starting air enters through an annulus around the inner combustion space end of the fuel valve.

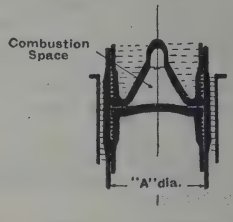

FIG. 56.

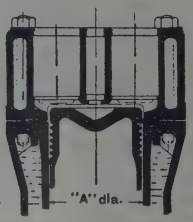

FIG. 57.

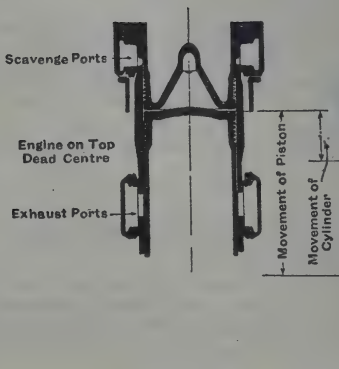

FIG. 58.

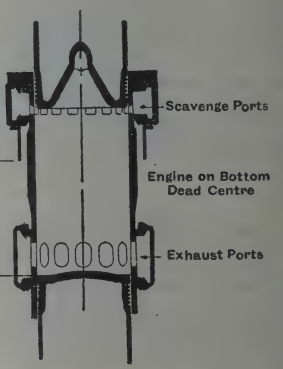

FIG. 59.

The exceptional freedom of the cylinder cover and liner to expand, and the very efficien cooling of the liner, are shown in fig. 56. Fig. 57 shows an ordinary four-cycle cover.

Figs. 58 and 59 show the relative movement of the cylinder and piston, the former being a the inner dead centre, the latter at the outer dead centre. The actual rubbing speed of the pisto rings on the cylinder is materially less than the absolute speed of the piston; at a speed of 10 revolutions per minute the rubbing speed is 508 ft. per minute, which is much less than is usuall found in large Diesel engines, and should have the effect of reducing appreciably the wear on th cylinder and piston rings.

The total length of the engine to the end of the thrust block is about 30 ft. The height from the bottom of the bed-plate is about 29 ft.

Fresh-water cooling is used for pistons, cylinders, and covers, and is to be circulated around a fresh-water cooler in the ship.

The weight of the complete engine is about 220 tons, which compares with a 2,000 b.h.p. four-cycle single-acting motor at about 370 tons for the same normal speed. It is intended to reduce the weight to 200 tons.

The Camellaird-Fullagar Engine.

Cammell, Laird & Co., Ltd., Birkenhead, have developed the Fullagar engine for marine work, and make various sizes of engines of the two-stroke cycle, opposed piston Diesel type with the oil fuel injected by compressed air.

The principal features of the design are: the elimination of the cylinder cover, the provision of a plain cylinder liner, the straight-through scavenge from end to end of the cylinder, the perfect balance of the reciprocating parts provided by the opposed pistons, one connecting-rod and one crank per cylinder.

A 1,000 b.h.p. engine is illustrated in fig. 60. There are four cylinders, in each of which the upper piston of one cylinder is connected to the lower piston of the other cylinder by external tie rods and crossheads, so that each crank receives two impulses per revolution. The horizontal component of the pull of the tie rods is taken up by guides at the top and bottom of the cylinder. The upper crossheads are enclosed and form scavenge pumps, compressing to 1½ to 2 lbs. per sq. in. The pistons uncover air and exhaust ports at opposite ends of the cylinders, and excellent scavenging is obtained.

The Fullagar design enables double the power to be produced in the same space compared with ordinary Diesel engines, and a lighter weight per h.p. As the forces and reactions are largely self-contained by the moving parts, very little load comes on to the framework of the engine, and the construction can be correspondingly light. For marine work the engines have the great advantage of being able to run at a slow speed, also they are very accessible for overhauling.

The 1,000 h.p. engine has cylinders 18½ ins. diameter by 25 ins. stroke, and the speed is 110 r.p.m. Fresh water or sea water cooling is adopted in the jackets and pistons. The starting and fuel valves are in the centre of the cylinder, between the pistons, and are operated by a horizontal cam-shaft driven by skew gearing from a vertical shaft operated by crank-shaft. Governing is effected by controlling the lift of the suction valves on fuel pump in the manner usual with Diesel engines, and to reverse the direction of rotation it is only necessary to turn the hand wheel to set the vertical shaft for the ahead or astern position.

In addition to the M.V. *Malia*, which has two 1,000 b.h.p. sets of the type just described, the following have been constructed by the firm or their licensees: two single-screw vessels engined with six-cylinder sets of 3,000 b.h.p., one with a six-cylinder engine of 1,500 b.h.p., and one with a six-cylinder set of 2,500 b.h.p. All these are now in service, and a further six-cylinder set of 2,500 b.h.p. is now being installed in a Japanese vessel.

See also p. 1948.

The 'White' Diesel Engine.

The Diesel engines made by Messrs. J. Samuel White & Co., Cowes, were first used for submarines, and they are now supplied for all marine purposes.

One of the White 450 b.h.p. two-stroke cycle engines was subjected to severe tests in order to prove its capabilities as regards power, flexibility, and endurance. A 72-hour full load trial was satisfactory, and it was proved that the engine did not require vigilant attention. The exhaust was practically invisible. At the end of this run the engine was slowed down to two-thirds speed and manœuvring trials were conducted. It was seen that 14 cubic feet of air at 700 lbs. per sq. in. was sufficient for starting and reversing the engine 42 times, the pressure of air going down to 90 lbs., which was insufficient for starting.

As an example of flexibility, the tests to determine the minimum speed consistent with smooth running of the engine are interesting. The speed was gradually reduced from 400 down to 50 r.p.m. with suitable power and without alteration to fuel pumps, etc. It was found that 50 r.p.m. could be maintained without fluctuations, and with a steady blast pressure of 630 lbs. per sq. in.

The White engines are vertical, with stepped pistons, the working piston having a clearance of about 0·024 in. and relying for gas-tightness wholly upon its rings, while the lower portion fits the cylinder liner and takes the side thrust of the connecting-rods; this lower portion is always comparatively cool, and hence is easily kept effectively lubricated. An important feature of the latest design is the rotating scavenge valves, the sleeve within which they work forming part of the reversing mechanism of the engine.

The Beardmore Diesel Engine.

Messrs. Beardmore & Co., Dalmuir, manufacture the Tosi design of Diesel engine, of which large numbers have been supplied for submarines and other work. The engines are of the four-stroke cycle type, and are very economical, the full load fuel consumption being only 0·4 lb. per b.h.p. hour.

The engines are of the enclosed design and are noteworthy for the elegance of their appearance. They are made in a number of sizes up to 4,000 b.h.p. Before standardising the four-stroke cycle engines, Messrs. Franco Tosi constructed a two-stroke cycle engine, so that they could make comparative tests. The latter engine had six cylinders and developed 1,300 b.h.p. when running at 300 r.p.m. The results of the tests showed that their eight-cylinder 1,450 b.h.p. engine was much more economical in fuel.

The outstanding feature of the Tosi design is a director valve fitted in conjunction with a combined valve in the cylinder head, which alternately admits air to the cylinder and allows the exhaust gases to escape from it, depending on the position of the director valve. In this way the cylinder valve is kept cool and free from carbon.

The latest Beardmore engines are arranged for supercharging.

Double-acting Beardmore-Tosi engines have been installed in the converted steamer *Wulsty Castle*, driving the propeller shaft at 80 r.p.m. through Vulcan hydro-mechanical gearing, the engine speed being 250 r.p.m.

See also p. 1944.

Other Types of Marine Diesel Engines.

Among the other British makers of Diesel engines for marine work are Harland & Wolff, of Belfast, the North British Diesel Engine Works, Glasgow, and Scotts Shipbuilding Co. All of these makers are well known in marine engineering and, in their manufacture of Diesel engines, uphold the high traditions of British marine practice.

There are various other types of Diesel engines, but although they differ in some details from the engines already described, the points of difference are not usually important. In the single-acting two-cycle engine of the Maschinenfabrik Augsburg Nurnberg A.G., a stepped piston is adopted, the scavenge pumps being directly below the working cylinders. This arrangement has the advantage of occupying less floor space although the height is greater. The motors are not so accessible, but the amply dimensioned gudgeon pin is kept cool, and there is a large guide surface. With the large low-speed engines of the open crosshead type, scavenge pumps are driven off the extended crankshaft, or by rocking levers. Four-cycle engines are also built by the M.A.N. Co.

A double-acting two-stroke engine of 15,000 h.p. has been constructed by M.A.N. for a land installation, and the motor liner *Augustus* is fitted with four such engines, each developing up to 3,000 s.h.p. A feature of this engine is that the scavenge ports are at the same side of the cylinder as the exhaust ports and are uncovered by the piston after the exhaust ports are fully open.

In the low-speed, two-stroke-cycle engines constructed by Messrs. Krupp, of Kiel, the general design is similar to the Carels type, except for some slight modification in the reversing gear, whilst for high-speed engines employed in submarines enclosed engines are constructed. These are made up to 1,000 h.p. and have a scavenge pump at each end and an air compressor in the centre. A section through a Krupp-Diesel slow-speed engine of 1,150 b.h.p. is shown in fig. 61.

One of the most interesting of the large Diesel engines that has been developed during the last few years is that of the F.I.A.T. Company of Turin. This is of the two-cycle type, and it is of especial interest in that after experience with two-cycle motors with valve scavenging the newer types are provided with ports in the cylinder walls for the admission of the scavenging air.

The scavenge ports are uncovered by the piston before the exhaust ports and are fitted with automatic disc valves. Marine Diesel engines of this design have been built in power up to 3,200 h.p. in six cylinders.

A development of the past year or so which seems likely to have a marked effect on the question of the manufacture of small internal combustion motors is the low-powered type of Diesel marine engine built by the Polar Company of Stockholm. It is of the four-cycle non-reversible type running at about 550 r.p.m. and is made in 1, 3, 4, 6 and 8 cylinders, each cylinder having an output of 12½ h.p. It is so far as possible totally enclosed and the construction is perfectly standardised. A reverse gear of the ordinary type has to be employed with engines of this design, since they are not made reversible as are the larger sets.

THE KRUPP MARINE DIESEL ENGINE.
(1,150 b.h.p.)

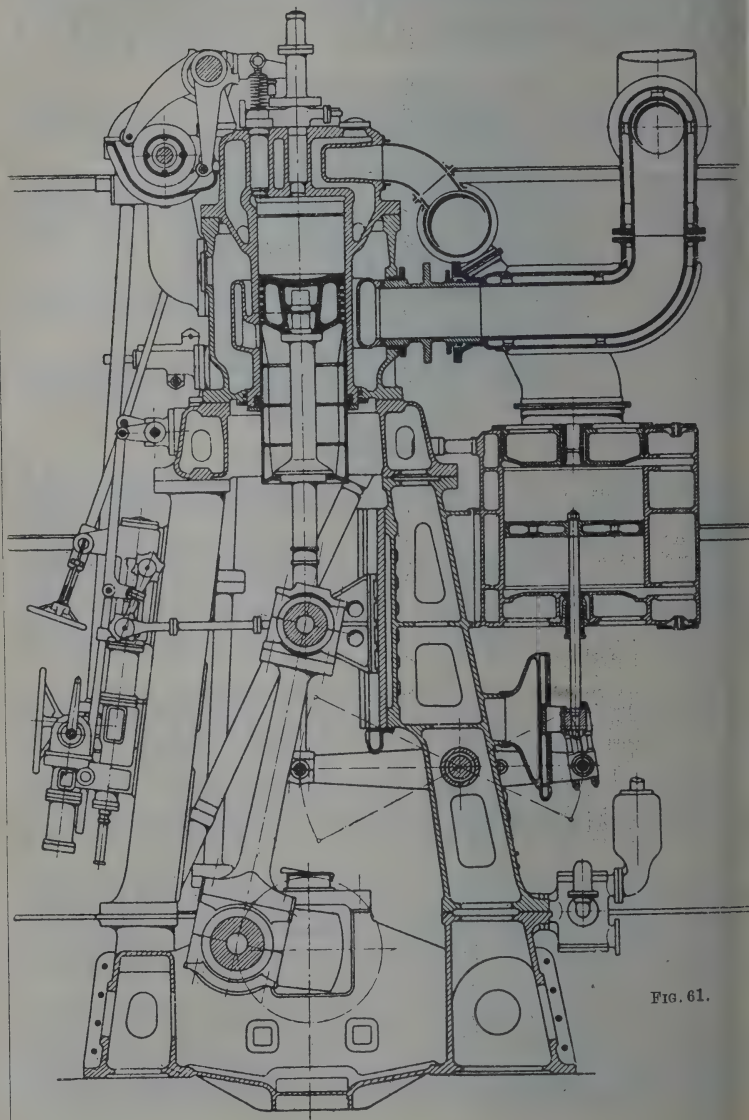

FIG. 61.

Diesel Engines for Submarines.

Practically all the European and American navies are now solely relying upon Diesel engines r the propulsion of submarines on the surface. These motors are of totally distinct type from ıose of the ordinary marine engine owing to the necessary high speed in order to reduce the eight sufficiently. They usually run at 400 to 500 r.p.m., and they are now constructed in ›wers up to 1,300 b.h.p. In the German and several other European Navies the Krupp two- ·cle engine was employed, and also that of the M.A.N. Co., which is likewise of the two-cycle ngle-acting type. The former is a six-cylinder machine with two scavenge cylinders in the ntre driven direct off the crankshaft, whilst in the latter the scavenge pumps are arranged rectly beneath each working cylinder. The air pumps for air injection are also driven off the igine, so that it is practically self-contained. The weights of these motors are low, and usually mewhere in the neighbourhood of 50 to 60 lbs. per b.h.p. For the British Navy the ickers type is usually employed, which is a four-cycle twelve-cylinder motor of about 1,200 b.h.p. ı this engine, solid injection of fuel is always adopted—that is, the injection by mechanical means stead of compressed air. The advantage of this is that no air compressor is required, which is ry desirable in a submarine. Although the engine as a Diesel engine is not quite so efficient as ith air injection, the absence of air compressor renders the overall economy about the same as in her types of motors. It is doubtful, however, whether such heavy fuel may be satisfactorily nployed as with the other engines, and Broxburn shale oil is generally used in these submarines. wo-cycle engines have also been designed for operation with mechanical injection.

Other types of Diesel engines are now used in British submarines, and one of the first of the ›o-cycle types to be employed for the purpose is the F.I.A.T., which was installed in the first bmersible built by Scott's Shipbuilding and Engineering Co. In this engine the scavenge ımps are arranged beneath the working cylinders as with the M.A.N. engine previously men- ›ned, the pistons being stepped in the ordinary manner. Other types of two-stroke Diesel otors will be installed in British submarines, if they have not already been so fitted.

In order to keep the piston speed of submarine engines within the limits which it is not sirable to exceed (from 900 to 1,100 ft. per min.), it is usual to make the ratio of the stroke to e bore very much less than with the ordinary mercantile type of motor. Frequently the stroke made equal to the diameter of the cylinders, and is very seldom more than 10 per cent. greater. this way it is possible to construct Diesel for submarine purposes almost equal from the point view of reliability to the slow-running types. High-speed engines of 1,300 h.p. have been ınstructed for installation to submarines, and others of over 2,500 b.h.p. in eight cylinders ıve been designed, and are possibly now being built for the same purpose.

A particularly important type of submarine Diesel engine is illustrated in fig. 62. This is Sulzer motor as employed in several navies, and mainly follows along the lines of the slow eed mercantile Diesel motors built by the same firm and described in the preceding pages. ıe most notable feature is that port scavenging is employed and the method of introduction an extra supply of scavenging air through valve controlled auxiliary ports is the same as the larger sets. It had been thought that the high speed of rotation (350–500 r.p.m.) might nder this system inefficient for submarine engines, but this does not appear to be the case. ›tors of this design are being built in powers up to 4,000 b.h.p. per engine.

In their latest submarine motors the F.I.A.T. Company have also adopted the port scavenging rangement, and engines of 1,300 h.p. in eight cylinders built according to this principle have ready been installed in Italian submarines.

Output, Dimensions, and Weights of Diesel Marine Engines.

The design of Diesel engines in regard to the main dimensions of cylinders, etc., is not yet a very definite or exact basis, mainly owing to the variations of mean effective pressure in e cylinders, and the uncertainty regarding the best speed of revolution. The output of a linder varies with the diameter, the stroke, the mean effective pressure, and the speed of ·olutions. In general terms it may be expressed as follows:

B.H.P. = KD^2LNn, where K = a constant; D = diameter of cylinder; L = stroke of ıton; N = revolutions per min.; n = number of cylinders.

Taking the dimensions of the cylinders in inches it is found that for four-cycle engines the lue of K varies between ·00007 and ·00009, a good average figure being

$$K = \cdot00008.$$

For two-cycle engines the value is between ·000125 and ·000155, the average being

$$K = \cdot00014.$$

As the mean effective pressure varies between 70 and 105 lbs. per square inch, and is some- ›es higher, it is evident that cylinder dimensions are no absolute criterion of the exact output a Diesel engine at a constant speed of revolution.

The piston speed in two- and four-cycle engines is approximately the same, namely, about 3 4 metres per sec., or 580 to 780 ft. per minute, with the ordinary marine motors. It does not ·an exceed these limits, except in high-speed engines of the type employed in submarines,

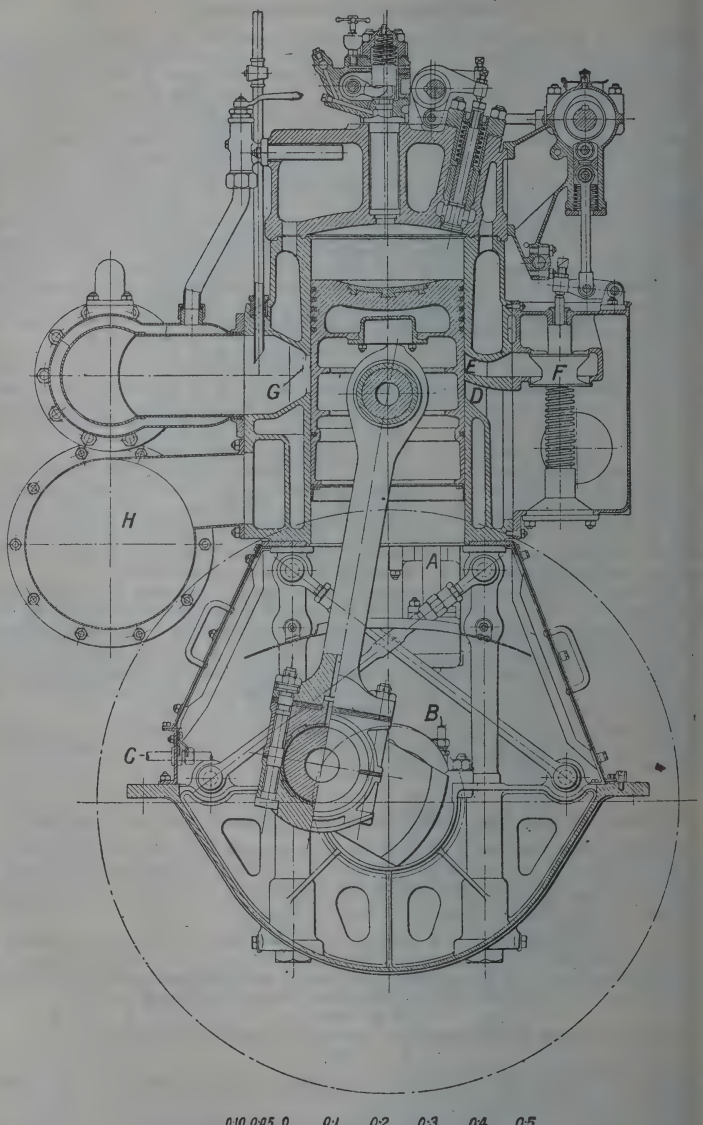

FIG. 62.—SULZER SUBMARINE DIESEL ENGINE.

when it may be as much as 1,100 ft. per minute. In the Burmeister and Wain double-acting four-cycle type the piston speed is about 1,200 ft. per minute.

The ratio of stroke to bore is a matter of wide variation, and in some cases is as low as 1·3 and others as high as 1·8. This latter figure is common in two-cycle motors with valve scavenging. Some types of four-cycle motors have a ratio of 1·4 and others 1·8.

The weight of Diesel marine engines varies as a rule between 200–300 lbs. per b.h.p., but is reduced to 60–70 lbs. per b.h.p. in submarine motors. Four-cycle engines are heavier than two-cycle, but the difference is not very marked, except in special cases, average figures being 300 lbs. and 250 lbs. respectively. This includes air compressors, scavenge pumps (in two-cycle motors) and various bilge, oil, and circulating pumps driven direct by the engine.

Weir High Pressure Air Compressors.

(G. & J. Weir, Ltd., Cathcart, Glasgow.)

Fig. 63 shows a typical Weir three-stage, single-acting, twin-crank, motor-driven air compressor, for a delivery pressure of 1,000 lbs. per sq. in. In this machine the first and second stages are formed by means of a differential type piston, the air passing from the first stage of compression through the first stage intercooler and thence to the annular space forming the second stage. After second stage compression and cooling, the air passes to the third stage situated at top of the machine, where, when third stage compression is completed, the air is delivered through the after-cooler and oil and water separator.

The coolers are of the tubular type, the air passing through copper tubes expanded into rolled brass tube plates. Arrangements for the longitudinal expansion of the tube units are provided, and all troubles associated with tube packings are completely eliminated.

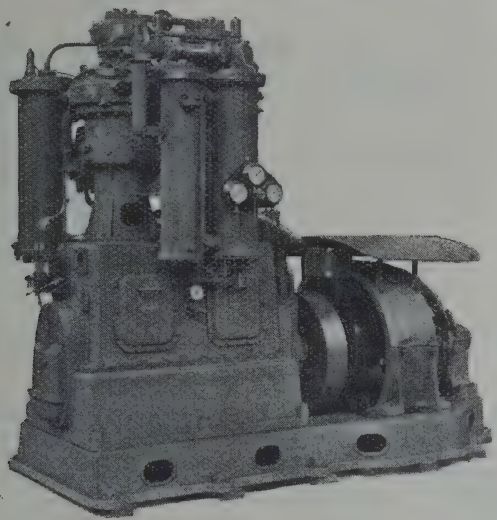

Fig. 63.

The pistons are of high-grade cast iron fitted with cast-iron rings of the Ramsbottom type. With the perfected lubricating and cooling arrangements in the Weir compressor, the wear on these cast-iron rings over long periods of running is practically negligible, the tool marks being visible after years of running.

The air valves are of special design, the valve plates being made in a steel alloy, heat-treated to obtain the correct degree of hardness. The lift of the valve is exceedingly small, preventing undue shock and noise and obtaining a high degree of efficiency. As a special precaution the valve seats are made in mild steel perforated with small holes, this type being superior to the usual cast seat with annular slots, as the former design makes it practically impossible for fragments of a broken valve to enter the cylinder with destructive effect. The assembled valve units are arranged round the cylinder heads in such a manner as to reduce the cylinder clearance to a minimum, and give a resultant high volumetric efficiency.

The motion work generally is robustly designed to meet the high stresses generated in r ciprocating air compressor machinery. The crank webs and connecting rod jaws are cut fro solid mild steel forgings and machined all over. The crosshead and piston rod are forged one piece, and tapers are provided on the rod to take the pistons.

As in best modern practice, forced lubrication is applied to all bearing surfaces, the cran case bearings being served through a special system of oil ducts by an oil pump of the oscillatin disc type. Cylinder lubrication is effected by a mechanical sight feed lubricator, feeding minu quantities of oil at the correct points on the cylinder walls, and maintaining the thin even film so necessary with comparatively high-temperature conditions.

The balancing of these compressors has received careful consideration, the weights in all cas being designed to effectively balance the forces set up by the reciprocating parts.

The circulation of the water spaces is carried out by a plunger type water-pump driven fro the compressor crankshaft. This pump is of a very compact and positive design, and has a cas iron body and gun-metal plunger with valves of the Kinghorn type.

The foregoing description is typical of compressors largely supplied for motor ship auxilia duties, viz. Diesel engine air-blast injection, manœuvring, etc.

Compressors dealing with oxygen and other industrial gases for delivery pressure ranging 6,000 lbs. per sq. in. are constructed, and may be arranged for drive either by electric moto independent steam engine, tandem steam engine, or oil engine.

Power of Diesel Marine Engines.

The following table gives details of the dimensions and powers of some of the types of Dies marine engines as now built :—

Engine.	B.H.P.	Diam.	Stroke.	R.p.m.	No. of Cy
Sulzer	4,000	28	39	110	8
Polar	800	15·7	21·25	165	6

M.A.N. (Double Acting)	7,000	27·5	47·2	125	6

Diesel Marine Engines in Service.

Motor ships have now been in operation for some considerable time, and it is possible to in what manner the chief defects have developed. At first the four-cycle engines proved m satisfactory, probably owing to the fact that more experience had been gained with this type motor previously for land work ; but the two-cycle engine is now quite as reliable in every respe due to recent developments. In the two-cycle engines the chief difficulty encountered was t cracking of cylinder covers which occurred with many engines, but the Sulzer cover is immu from this trouble, owing to the single opening for central valve. Cast steel, which was employ in some instances, has now been abandoned entirely in favour of cast iron, and with a pro mixture it is probable that the cracking of covers will in future be avoided. Air compress have in some instances given rise to difficulty, whilst in the four-cycle motors, as might ha been anticipated, the exhaust valves have required special attention.

The 1922 report of *Lloyd's Register of Shipping* devotes considerable attention to the de lopment of the Diesel oil engine. Several vessels of considerable size fitted with Diesel engi were built during the war to the Society's class by Messrs. Harland & Wolff and by Mess Burmeister & Wain, of Copenhagen. Until recently the largest Diesel engines fitted in a merchant vessel were the twin screw engines made by Messrs. Harland & Wolff, of Glasg for the motor vessel 'Glenapp,' of 7,374 tons gross, built in 1918 by Messrs. Barclay, Curle Co., Ltd. The Fairfield Shipbuilding & Engineering Co. completed a large passenger and ca vessel in 1924, with four screw engines of 12,000 b.h.p. of the Fairfield Sulzer type. The 'Aoran is 600 ft. long, with a service speed of 17 to 18 knots. This vessel is on service between Cana and Australia, and has conclusively demonstrated that the Fairfield Sulzer Diesel engine entirely satisfactory for propelling ocean liners.

The following table of typical vessels illustrates the advance which has taken place in the construction of Diesel engines :—

Name.	Tons.	Twin or Single Screw.	Date of Construction.	Cylinders.		Stroke.
				No.	Diam.	
'Vulcanus'	1,179	Single	1910	6	15½	23
'Selandia'	4,950	Twin	1912	16	20⅞	28
'Juno'	2,345	Single	1912	6	22	39½
'Siam'	5,296	Twin	1913	16	23½	31½
'Fiona'	5,219	"	1914	12	29½	43 5/16
'Panama'	5,239	"	1915	12	24 13/16	37 13/16
'Glenamoy'	7,269	"	1916	12	26¾	39 3/4
'Glenauy'	5,075	"	1917	12	24 13/16	33½
'Glenapp'	7,374	"	1918	16	29½	43 5/16
'Aorangi'	18,500	Four	1922	24	27½	39
'Asturias'	22,000	Twin	1925	—	—	—

There were recorded 2,343 motor vessels in Lloyd's Register, 1926, of which 134 have tonnages ranging from 1,000 to 2,000 tons, 128 at 2,000 to 4,000 tons, 185 at 4,000 to 6,000 tons, and 177 from 6,000 to 10,000 tons, and 15 above 10,000 tons.

Oil Fuel for Diesel Engines.

(See also FUELS Section, page 2135.)

The fuel most commonly used in Diesel engines is that known as the residual oil, which is obtained by the process of distilling the crude oil when the lighter spirits are carried over, and the residual remains. Some crude oils are, however, directly used in Diesel motors, and in particular Texas oil, which does not contain sufficient proportion of petrol and other lighter oils to warrant its distillation. The only oil fuel which is unsuitable for employment is that from an asphaltum base, and it is for this reason that Mexican fuel oil is not as a rule employed for these motors without special treatment. Besides Texas oil, that from the Californian, Persian, Trinidad, Galician, Roumanian, and Russian oilfields is satisfactory for use in Diesel motors. Tar oil, which is obtained from the distillation of tar, is also very largely utilised in Germany, where the duties on imported oils are excessive, and often render the employment of Diesel engines unprofitable. Tar oil has a higher specific gravity than the petroleum fuel (usually in the neighbourhood of unity or slightly over), and has a lower calorific value, so that the consumption of an engine using this fuel is greater than when running on the ordinary oil. It is very viscous and, therefore, often requires heating, whilst some slight modifications have usually to be made in the fuel injection arrangements in order that an engine should run quite satisfactorily on tar oil. The usual method is to allow the injection of a small quantity of a lighter fuel oil before the main body of the tar oil passes into the cylinders through the pulveriser. It is claimed, however, that some motors run without any modification whatever, but this should not be taken as a general statement.

For information relating to Diesel engines for land installations, see page 1939.

LLOYD'S RULES FOR MARINE INTERNAL-COMBUSTION ENGINES. See page 1975.

Metals for Propellers.

A properly designed bronze screw will give a very marked increase of speed (as much as *half a knot*) as compared with an iron or steel propeller, this being due to reduced scantlings, smoother surfaces, etc. Whilst the efficiency of a bronze screw continues unimpaired, that of an iron or steel propeller diminishes, through the pitting and corroding of its surface. In the case of solid screws the reduction in weight as compared with a cast-iron screw ranges from 10 to 20 per cent.

Nearly all vessels of any size or pretension are now fitted with bronze propellers. The metal has a tensile breaking strength of about 32 tons per square inch with about 20 per cent. elongation, and a transverse strength of over 7,500 lbs. per square inch. All warships as well as many merchant steamers are fitted with bronze propellers. Cast-steel propellers cost about twice as much, and bronze propellers about six times as much, as those of cast iron.

The *Bull's Metal Company* have with great success combined the study of Bronze Propeller designs with that of material, manufacture, and finish, large numbers of ordinary Bronze Propellers having been replaced with Bull's Metal propellers, giving, it is stated, a very material increase in speed on a reduced consumption of coal.

The *Delta Metal Co. Ltd.*, supply their special corrosion-resisting 'Delta' propeller bronze for casting propellers and propeller blades.

Bull's Metal Propellers

Combine the strength and toughness of mild steel with the resistance to corrosion of gun metal. Their adoption means a considerable increase in speed or saving in coal consumption. Please ask for Catalogue.

Bull's Metal Bars & Forgings

Possess the mechanical properties of mild nickel steel with extreme resistance to wear and corrosion. Please ask for Catalogue.

F. 2437

Elements of Propulsion.

If a vessel (without propeller) moving at a speed of V feet per minute experiences a total resistance of R pounds, a force R must be applied continuously by means of a thrust or tow-rope pull in order to overcome the resistance and maintain the speed. The power required is RV foot-pounds per second and is called the Tow Rope Power or Effective Power.

$$\text{Effective Horse Power, E.H.P.} = \text{R.V.} \div 33000 = \cdot 00303 \text{ R.K.}$$

If the thrust is delivered by a screw propeller working behind the ship, it is found that the action of the propeller increases the resistance. This increase is called the 'Augment of Resistance.' T, the total thrust of the propeller, must therefore be equal to R + Augment = R + A, and T − A = R. The augment of resistance can therefore be regarded as a deduction from the thrust: it is alternatively called the 'Thrust Deduction' and is written A = tT, where t is the 'Thrust Deduction Fraction.'

$$T - tT = T(1 - t) = R$$

$(1 - t)$ is called the Thrust Deduction Factor.

If a vessel is being towed at a speed of K knots, the skin friction sets the adjacent water in motion, and at the stern there will be found a 'wake' current moving in the same direction as the ship at some speed W knots. The stern, and with it the propeller, will therefore be moving at a speed K — W relatively to the wake water, and this speed is called the 'Speed of Advance.' Froude compares wake speed with speed of advance, and writes W = ω (K − W) = ωK'.

$$\text{Wake fraction} \quad \omega = \frac{W}{K - W} = \frac{W}{K}$$

$$\text{Wake factor} \quad 1 + \omega = \frac{K}{K - W} = \frac{K}{K}$$

$$\text{Wake per cent.} \quad 100\omega.$$

Taylor compares wake speed with ship speed, and writes—

$$\omega = \frac{WK}{K}$$

$$\text{Wake fraction} \quad \omega = \frac{W}{K}$$

$$\text{Wake factor} \quad 1 - \omega = \frac{K - W}{K} = \frac{K'}{K}$$

$$\text{Wake per cent} \quad 100\omega.$$

If a propeller having a pitch P and making N revolutions per minute is working behind a ship and producing a thrust T with a torque Q in the shafting just forward of the propeller, the ship's speed being K and the speed of advance of the propeller K' = K − W, the work obtained will be RK (E.H.P.) and the work expended 2πNQ, which we can call the 'Received Horse Power Behind' R.H.P.$_b$. The efficiency η is therefore $\frac{\text{E.H.P.}}{\text{R.H.P.}_b} = \frac{RK}{\text{R.H.P.}_b} = \frac{T(1 - t) \times K' (1 + \omega)}{\text{R.H.P.}_b}$.

TK' is called the 'Thrust Horse Power' (T.H.P.) and the product $(1 - t)(1 + \omega)$ the 'Hull Efficiency,' being the product of one factor $(1 - t)$ representing the effect of the propeller on the hull and another $(1 + \omega)$ representing the effect of the hull on the propeller. If we write—

$$\text{Hull Efficiency} = h = (1 - t)(1 + \omega)$$

we have

$$\text{Screw Efficiency Behind} = \eta = \frac{\text{T.H.P.}}{\text{R.H.P.}_b} h.$$

Now if the same propeller be mounted on a shaft alone, without ship or model, and run in open water at the same revolutions N, and its speed of advance adjusted until it gives the same thrust T, we can fairly assume that the speed of advance so found must be the same as the speed of advance when in place behind the ship. We are thus able to determine the wake speed. The torque is not necessarily the same as when behind the ship, though it is usually not very different, so we call the power in the shaft 'Received Horse Power in the Open,' R.H.P.$_o$, and the 'Efficiency in the Open,' $\odot$, is $\frac{TK'}{\text{R.H.P.}_o} = \frac{\text{T.H.P.}}{\text{R.H.P.}_o}$.

The ratio $\frac{\text{R.H.P.}_o}{\text{R.H.P.}_b}$ is called the 'Relative Rotative Efficiency,' r.

Finally therefore, we can write—

$$\eta = \frac{\text{T.H.P.}}{\text{R.H.P.}_b}\,h = \frac{\text{T.H.P.}}{\text{R.H.P.}_o} = \frac{\text{R.H.P.}_o}{\text{R.H.P.}_b}\,h = \odot\, rh,$$

or screw efficiency behind = screw efficiency in open × relative rotative efficiency × hull efficiency.

S.H.P., the 'Shaft Horse Power' (or B.H.P., the 'Brake Horse Power'), is the power in the shafting just abaft the engine. The shaft line efficiency l is the ratio $\frac{\text{R.H.P.}_b}{\text{S.H.P.}}$. The mechanical efficiency of the engine m is the ratio of S.H.P. to the indicated horse power (I.H.P.).

$$\therefore \quad \text{S.H.P.} = m \times \text{I.H.P.}$$

$$\text{R.H.P.}_b = l \times \text{S.H.P.} = l \,.\, m \,.\, \text{I.H.P.}$$

$l \times m$ is the 'Transmission Efficiency,' $f = \frac{\text{R.H.P.}_b}{\text{I.H.P.}}$.

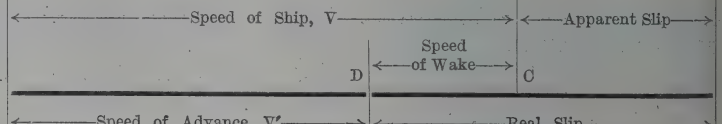
The overall propulsive efficiency or propulsive coefficient, ϵ,

$$= \frac{\text{E.H.P.}}{\text{I.H.P.}} = \frac{\text{E.H.P.}}{\text{R.H.P.}_b} = \frac{\text{R.H.P.}_b}{\text{I.H.P.}} = \eta f = \odot\, rhf.$$

η is sometimes called the 'Quasi-Propulsive Coefficient.'

A propeller having a pitch P and making N revolutions per minute would advance a distance PN if there were no slip. On account of slip, however, it actually advances a lesser distance V' called the 'speed of advance.' The difference is called slip, so that slip = PN − V', and the 'slip ratio' $s = \frac{\text{PN} - \text{V}'}{\text{PN}} = 1 - \frac{\text{V}'}{\text{PN}}$. If the thrust is T and the torque Q, the efficiency $= \frac{\text{TV}'}{2\pi\text{NQ}} = \frac{\text{TP}\,(1-s)}{2\pi\text{Q}}$.

When attached to a ship the apparent speed of advance is the ship's speed K knots or V feet per minute, where $\text{V} = 101\frac{1}{3}\text{K}$. The apparent slip is PN − V. On account of the presence of the wake stream, however, the true speed of advance of the propeller through the water surrounding it is K − W(= K') knots or V' (= $101\frac{1}{3}$K') feet per minute, and the real slip is PN − V'. Let AB represent to scale the 'Speed of the Propeller':



AC the speed of the ship V, and CD the speed of the wake.

$$\text{Then apparent slip ratio} = \frac{\text{CB}}{\text{AB}}$$

$$\text{Real slip ratio} = \frac{\text{DB}}{\text{AB}}$$

$$\text{Froude's wake fraction} = \frac{\text{DC}}{\text{AD}}$$

$$\text{Taylor's wake fraction} = \frac{\text{DC}}{\text{AC}}$$

(*W. J. Luke.*)

Law of Comparison for Model Propeller Experiments.

If a model propeller $\frac{1}{n}$th of the size of the ship's propeller is run at $\sqrt{n}$ times the revolutions and its speed of advance adjusted so that both screws are working with the same slip ratio, the thrust

of the ship's propeller will be n^3 times that of the model, the torque n^4 times, the powers $n^{3\frac{1}{2}}$ times, and the efficiencies equal.

	Model Propeller	*Ship's Propeller*
Diameter	d	$D = nd$
Pitch	p	$P = np$
Revolutions	r	$R = n^{-\frac{1}{2}} r$
Speed of Advance	v'	$V' = n^{\frac{1}{2}} v'$
Slip Ratio, s	$1 - \frac{v}{pr}$ =	$1 - \frac{V'}{PR}$
Thrust	t	$T = n^3 t$
Torque	q	$Q = n^4 q$
THP = U	$\frac{tv'}{33000}$	$\frac{TV'}{33000} = n^{3\frac{1}{2}} \frac{tv'}{33000}$
RHP = P	$\frac{2\pi vq}{33000}$	$\frac{2\pi RQ}{33000} = n^{3\frac{1}{2}} \frac{2\pi vq}{33000}$
Efficiency	$\frac{tv'}{2\pi rq}$ =	$\frac{TV'}{2\pi RQ}$
ρ_U (Rho-U)	$\frac{ru^{\frac{1}{2}}}{v'^{2\frac{1}{2}}}$ =	$\frac{RU^{\frac{1}{2}}}{V'^{2\frac{1}{2}}}$
ρ_P (Rho-P)	$\frac{rp^{\frac{1}{2}}}{v'^{2\frac{1}{2}}}$ =	$\frac{RP^{\frac{1}{2}}}{V'^{2\frac{1}{2}}}$
δ (Delta)	$\frac{dr}{v'}$ =	$\frac{DR}{V'}$

The last three functions are the same for all similar propellers working at the same slip ratio. ρ_U and ρ_P depend on revolutions, power and speed, which are given quantities in the initial stage of propeller design. The results of systematic propeller experiments are usually plotted on some function of Rho as base, since this is independent of diameter. For each of a series of pitch ratios, a curve of efficiency and a curve of some function (such as δ) involving the diameter are plotted, from which the most suitable diameter and pitch ratio can be found for the given power, revolutions, and speed of advance. Taylor has published four 'Rho-delta' diagrams obtained by combining and averaging his own propeller experiments with those of Froude, Durand, and Schaffran. These were reproduced in *The Shipbulder*, January 1925.

Metals for Marine Engines.

Delta Bronze Nos. I. and IV. alloys (see Index), Phosphor bronze, and Phosphor white lining metal No. II. are especially suitable for various parts of marine engines: the latter metal (phosphor white) has a higher fusing point than good Babbitt metal, thus allowing a bearing to heat without causing the metal to melt, a matter of some importance at sea.

Delta Bronze No. IV., a malleable bronze of great strength and tenacity, is specially adapted to replace steel in cases where a material of the highest corrosion-resisting qualities is desired. For this reason it is employed on a very large scale in the form of forgings or extruded or rolled rods, etc., for air and circulating pump rods, shafts, plungers, spindles, thrust block bolts and other parts of marine engines. For particulars of corrosion-tests, see p. 284.

Phosphor-bronze sheet is superior to copper in withstanding the action of sea-water. In a comparative experiment made at Elankenberghe, lasting over a period of six months, between the best English copper and phosphor bronze, the following results were arrived at: the loss in weight due to the oxidising action of the sea-water averaged for copper 3·058 per cent., while that of the phosphor bronze was only 1·158 per cent.

For lining bearings, crank-pin bushes, and other parts, exclusive of crosshead bushes, the following alloy has been found to give good results after extended experience in hard ocean steaming :—12 parts tin, 1 part copper, 1 part antimony, mixed in the following way : 6 parts tin alloyed with 1 part of antimony, and 6 parts tin with 1 of copper, and the two mixed together. For lining crosshead brasses the following harder alloy has been found to give good results : 85 per cent. tin, 5 per cent. copper, and 10 per cent. antimony.

The *Eyre Smelting Co., Ltd.*, who have made a special study of bearing metals for marine engines, supply a particular alloy of white metal which is stated to give good results in the big end bearings of Diesel engines. For the small end bearings the company supply a mixture of phosphor bronze, which is largely used in this country and on the Continent.

Painting Ships' Bottoms.

Ordinary oil paints are not suitable for this purpose, particularly because the drying of each coat of oil paint takes a longer time than owners can afford to allow vessels to remain in dock ; besides, these paints possess little or no power to prevent fouling. The practice, therefore, is to use what are termed ' compositions,' which are usually applied in two coats.

The composition paints have to be used in combination. The anti-corrosive, as a preservative and insulating coating, should be applied when the bottom is well scraped and dried. The anti-fouling composition contains powerful poisons and can be applied almost immediately after the primary coating, and the vessel can be floated as soon as the painting is completed, although it is desirable to allow the compositions a few hours to harden before the vessel enters the water.

It is very important to remove all rust or scale on the plates, as when such is not done corrosion is likely to continue beneath the surface and will eventually throw off any paint that can be applied. The ingredients in the best compositions are very expensive and are consequently not used to any extent in the manufacture of the cheaper brands.

The careful *stirring* up of these compositions is an essential point too often overlooked. The more valuable ingredients are heavy, and tend to form a sediment at the bottom of the drums, which requires to be carefully worked up. Much also depends upon careful painting—a thing which is unfortunately very difficult to arrange for in many of the dry docks owing to hurried and inefficient work.

Concrete Vessels.

A concrete weighing but 110 lbs. per cub. ft. and having a crushing strength after 28 days of 4,000 lbs. per sq. in., has been employed in the construction of reinforced concrete vessels of large tonnage, in America, for the United States Government. The aggregate itself, although light and cellular in structure, is not porous. The lighter quality will actually float on water, and as a test the United States Shipping Board authorities kept an amount of aggregate floating in water for some months, and it was demonstrated that the absorption was very small.

The aggregate is made from clay, calcined in kilns in a similar manner to that employed in the manufacture of bricks, the fundamental difference being that the heat (about 2,000° F.) is applied in a comparatively short time of 30 hours. This relatively sudden application of heat causes the material to swell, forming a clinker. The clay may be pressed into bricks and partially dried and stacked in kilns in the ordinary manner, care being taken to provide sufficient room around the bricks for expansion during burning. The size of the brick adopted in the United States is 8½ ins. by 4½ ins. by 2¾ ins. During burning, the bricks run together and form a solid mass of clinker, which is allowed to cool for about 3 days, in order to ensure a high degree of toughness. The cooling of the material is then completed by water, which causes the mass to split into pieces suitable for handling, and it is also found that this greatly facilitates the unloading of the kilns. The material may also be calcined in cement rotary kilns, the clay in this case being pressed into lumps of suitable size.

After burning, the product is crushed to the desired size. During the operation a proportion of the lightest aggregate is reduced to dust. This, however, is used to take the place of the sand or crushed stone in ordinary concrete, the constituent parts being carefully selected and graded. Light pneumatic hammers are used to vibrate the shuttering during ramming, materially assisting the flow of the concrete around the steel reinforcement, and producing a dense and impermeable material.

A number of reinforced light concrete oil tankers and cargo steamers of 7,500 tons deadweight have been under construction in various parts of the United States. These vessels are 434 ft. long. (*W. L. Scott, ' Engineering.'*)

When wood is used as a reinforcing material for concrete it should be impregnated with magnesium chloride, and the wood must be so placed that any change in the cross-sectional area does not affect the durability of the structure. If the latter precaution is overlooked the concrete may crack. Small strips of wood are better than larger ones, and rushes appear to be excellent for the purpose, especially for thin-walled structures such as ships.

(*Beton u. Eisen.*)

Lloyd's Rules for Ferro-Concrete Vessels.

No definite rules have as yet been formulated, but in regard to the quality and testing of steel to be used for reinforcements these are the same as given in Section 3 of the Rules of the Society, for Steel Ships. The cement should comply with the requirements of a recognised standard specification for Portland cement or the equivalent thereto. In the matter of the preparation of the concrete, the proportions of the cement, sand, and aggregate have been left to the individual constructors to submit their proposals for the consideration of the Committee, as these depend to some extent on the local facilities for obtaining sand and gravel, the quality of which varies in different districts.

In the design of vessels to be built of ferro-concrete, it is considered that concrete is incapable of withstanding any of the main tensional stresses, and the steel reinforcements embedded in the concrete must therefore be of sufficient strength to take up all the tensional stresses produced in the structure due to strain from longitudinal bending.

Lloyd's Tentative Regulations for the Application of Electric Arc Welding to Ship Construction.

(Abstract.)

Before welding, the surfaces to be joined must be fitted close to each other.

All butt and edge connections are to be lapped or strapped.

With lapped connections the breadths of overlaps of butts and seams and the profiles of the welds are to be in accordance with the following table :—

Thickness of plate. Inches.	Width of overlap seam and butt. Inches.	Throat thickness. Inches.
·40 and under	2¼	·28
·60	2½	·38
·80	2¾	·48
1·00	3	·50

Intermediate values may be obtained by direct interpolation, and for thicknesses below ·40 the throat thickness is to be about 70 per cent. of the thickness of the plate.

See also ' Electric Welding,' p. 2766.

GAS AND GASWORKS—GENERAL PRINCIPLES GOVERNING THE SIZE AND CAPACITY OF APPARATUS—COMPOSITION OF VARIOUS GASES—CONDENSATION, PURIFICATION, STORAGE—RETORTS—TAR DISTILLATION—WATER GAS—COMPLETE GASIFICATION—CYANOGEN—BENZOL RECOVERY—SULPHATE OF AMMONIA—FLOW OF GAS IN MAINS—GAS TESTS—ACETYLENE GAS—PETROL AIR GAS.

(Contributed and revised by **Alwyne Meade, A.M.Inst.C.E.**, author of '**Modern Gasworks Practice.**')

Parliamentary.

The public supply of gas in this country is governed largely by local Acts, but in general by the Gasworks Clauses Acts of 1847 and 1871, the Sale of Gas Act of 1859, and the Gas and Water Works Facilities Acts of 1870 and 1873, and most recently by the Gas Regulation Act (1920). London companies are, in addition, under the regulations of the Metropolitan Gas Act (1860). Under the Public Health Act of 1875, the local authority may become its own gas supplier, or may purchase an existing undertaking by agreement. Thus gasworks are controlled by—

(*a*) Statutory companies.

(*b*) Non-statutory companies.

(*c*) Local authorities.

The supply of gas in Scotland is, for the most part, in the hands of the local authorities. In England local authorities predominate as owners in the counties of Yorkshire and Lancashire, and in the North generally, but in the Home and Southern counties private ownership is the general rule. In addition to the Acts named above, the supply of gas in Scotland is governed by the Gas Acts of 1864 and the Burghs Gas Supply Acts of 1876 and 1893.

The obligations of the gas undertakings in the way of standards of quality were somewhat modified by an order made by the Minister of Munitions in June, 1918, as to the manufacture and production of gas, compliance with which order by the gas undertaking protected the undertaking from any forfeiture for failing to comply with its statutory obligations with regard to the illuminating power or the calorific power of the gas supplied, provided that in any event gas of a lower calorific power than 450 B.Th.U. gross was not supplied to the consumers.

It may be said that a new era in the supply of gas was marked by the introduction of The Gas Regulation Act of 1920. The commodity is no longer sold on a basis of cubic feet, but in terms of 'Therms.' In other words, the consumer now pays for the useful energy only, i.e. British Thermal Units; accordingly, the incombustible constituents in gas have no longer any commercial value. The standard 'Therm' is equivalent to 100,000 B.Th.U. Thus, if 10,000 cubic feet of gas are registered on the consumer's meter, and the 'declared' or normal calorific power of the gas is 500 B.Th.U. per cubic foot, then the number of B.Th.U. consumed is 5,000,000, or 50 Therms.

The main provisions of the Act are as follows :—

(*a*) The obligation to charge consumers on the heat unit basis.

(*b*) The adjustment of the 'standard' or 'maximum' price (on the heat-unit basis) t meet the additional expenses of manufacture and distribution arising from post-wa conditions.

(*c*) Powers are given to the Board of Trade to limit the proportion of inert constituen in the gas, if thought fit; but the committee appointed to examine the question incombustibles recommended that no limit should yet be imposed.

(*d*) There is an obligation to supply gas at 2 ins. water pressure in mains or services 2 ins. diameter and upwards.

One of the most noteworthy provisions of the Act is the latitude which is given to gas unde takings in connection with the quality of gas supplied. The old standard of illuminating powe has completely given way to calorific power, and the producer is permitted a free choice in th type of gas he distributes. He must, however, declare at what calorific power he is prepare to supply, consumers' appliances must be adjusted by him to consume the 'declared' variety gas to the best advantage, and, in order to preclude excessive fluctuations in quality, certai penalties are imposed when the heating value falls below a prescribed limit. As regards th machinery for carrying out the Act, powers are given to the Board of Trade to grant facilitie which in the past have entailed formal application to Parliament.

An important feature of the Act is that it empowers the Board of Trade to make amendin orders revising the standard or maximum price if at any time it is shown to the satisfaction the Board that the costs incidental to the production and supply of gas have substantially altere by reason of circumstances beyond the control of the gas undertakings. The effect of this wa experienced some few years ago in the London area, when on the application of the Londo County Council the standard prices of certain undertakings were substantially reduced. Mo recently, however, on the application of certain gas undertakings themselves, increases in standar prices have been approved, and in addition Bills have been introduced which permit of the pay ment of a minimum dividend irrespective of the price of gas.

The Act prescribes that the quality of the gas distributed shall be determined by a calorimete of the recording type which gives a continuous record of heating value. For some years recordin calorimeters were not insisted on, and the system of periodical spot testing is still generally i force. The Gas Referees, however, commenced to prescribe the installation of recording calor meters in certain cases as from the commencement of 1928, the two calorimeters specified for th purpose being the Fairweather and the Boys.

A non-statutory company operates as the result of established practice, or under the goodwi of the local authority. Its position is in many respects similar to that of a statutory company but before opening roads for the laying of mains permission must be obtained from the distric or county authority.

Statistics of Gas Undertakings in Great Britain and Ireland.

The following table shows the total number of gas undertakings which have existed in th United Kingdom during various years since 1901. It should be noted that the total number separate undertakings has undergone decrease during the last twenty years, this being due to th policy of amalgamation which still continues. It is noticeable, too, that while undertaking owned by private companies and individuals have undergone a decrease, those owned by loca authorities have increased, showing the tendency for the town authorities to take over unde takings from private ownership.

Year.	Owned by Companies & Private individuals.	Owned by Corporations & Local Authorities.	Total Number of Undertakings.
1901	1,349	265	1,614
1905	1,330	285	1,615
1907	1,322	297	1,629
1908	1,322	296	1,628
1909	1,330	296	1,626
1910	1,339	302	1,641
1911	1,320	308	1,628
1912	1,316	311	1,627
1915	1,281	320	1,601
1916	1,263	323	1,586
1917	1,256	322	1,578
1918	1,252	325	1,577
1919	1,252	325	1,577
1921	1,229	330	1,559
1922	1,220	321	1,551
1924	1,155	331	1,487
1926	1,134	332	1,466

The largest gas undertaking in the world is the Gaslight & Coke Co. of London. This Company distributes more energy per annum than all the public electricity supply stations in Great Britain added together. The third annual report of the Electricity Commissioners shows that the authorised electricity undertakings of the United Kingdom generated, in the year ending March 1923, 4,600 million Board of Trade units of electricity, or 15,690,600 million B.Th.U. (156·906 million therms), while the Gaslight & Coke Co. supplies its consumers annually with over 235 million therms.

The largest gasworks in the world is the Beckton station of the above company. During a year, over a million and a quarter tons of coal are carbonised at this works, and the maximum daily output of gas amounts to over 70 million cu. ft. The Beckton works were opened in 1870, and have a total area of 475 acres. There are 14 retort houses on the works, and the water-gas plant is capable of an output of 27 million cu. ft. per day. There are upwards of 50 miles of standard gauge railway on the works, and the rolling stock consists of some 14,000 wagons and 40 locomotives.

Number of Gasworks in Great Britain.

In 1927 (the last year for which statistics are available at the time of publication) the total number of gasworks in operation in Great Britain was 1,450. The total is made up as follows:

In England and Wales—	
Companies and privately owned	875
Local authorities	246
In Scotland—	
Companies and privately owned	171
Local authorities	70
In Ireland—	
Companies and privately owned	70
Local authorities	18
	1,450

Gas Made in Great Britain.

The quantity of gas made in Great Britain during 1926 was 296,082 million cu. ft. This was 4·3 per cent. in excess of that made in 1925, which again exceeded that made in 1924 by 3·1 per cent. The increase in 1926 was entirely due to the increased make of water gas, a rather smaller quantity of coal gas being made in 1926 than in 1925. Only 16,564,000 tons of coal were carbonised in 1926, as compared with 17,031,000 tons in 1925; but 1,436,000 tons of coke for water gas, and 97,703,000 gals. of oil were used in the past year, as against 1,153,000 tons and 51,383,000 gals. in 1925. The residual products in 1926 included 11,177,000 tons of coke and breeze, and 187,546,000 gals. of tar, showing reductions of 221,000 tons and 6,613,000 gals. as compared with 1925.

The total number of gas consumers throughout Great Britain is approximately 9,000,000.

The capital employed by the statutory gas undertakings alone amounts to some 150,000,000*l.*, and the total length of street mains employed runs to some 45,000 miles.

Consumption of Gas per Head of Population.

In the larger towns the average consumption of gas per head of population varies from 6,000 to 10,000 cu. ft. per annum. In smaller towns it ranges between 2,500 and 7,500 cu. ft. Gasworks statistics are, however, generally based on the consumption per consumer, which figure, for consumers through ordinary meters, approximates to 42,000 cu. ft. per annum, and 15,000 cu. ft. for those taking the gas through 'slot' meters. In addition, there will be an appreciable consumption for public lighting, and about 5 per cent. of the whole output will be written off as 'unaccounted for.' In straggling districts with long lengths of mains the latter figure may reach so much as 10 per cent. Taking the country as a whole, the average consumption per consumer at the present time works out at almost exactly 30,000 cu. ft. (say 150 therms) per annum.

Capital Expenditure on Gasworks.

This item varies considerably in accordance with the size of the installation and the price of labour and materials. In pre-war times, however, a concern promoted for the erection of a modern works with the accompanying distribution plant found it possible to complete the scheme for 600*l.* per million cu. ft. sold per annum. For smaller country works, the outlay was very much greater, varying from 750*l.* to 1,000*l.* per million cu. ft., or even more.

The following figures show the approximate capital employed (neglecting nominal additions) in 1926 in the case of representative undertakings:—

	Per million cu. ft. per annum.		Per million cu. ft. per annum.
Gaslight & Coke Company	429*l.*	Bristol Gas Company	408*l.*
Croydon Gas Company	537*l.*	Birmingham (Corporation)	266*l.*
Brighton & Hove Gas Company	429*l.*		

It is, perhaps, more accurate nowadays to rate capital expenditure on the therm basis in lieu of the cubic foot basis. As an example of how this method compares with the figures given on p. 2447 it may be mentioned that the capital of the Gaslight & Coke Company is now 1*s.* 9*d.* per therm, and that of the Croydon Gas Company 2*s.* 2*d.* per therm.

It is a somewhat surprising fact that at the present day the expenditure on the district mains, etc., is generally rather greater than that laid out in the erection of the works. Of the total outlay approximately 55 per cent. will be expended on the district, 38 per cent. on the works, and the remainder on Parliamentary, promotion, and engineers' expenses.

General Rules relating to Capacity of the Apparatus, etc.

LAND.

The area of land required for the erection of the works will amount to at least 2½ acres per million cubic feet of gas per maximum diem.

(NOTE.—The make of gas per maximum diem is calculated by dividing the total annual production by the factor of 240.)

RETORT HOUSE.

Dependent upon the size of the unit, i.e. the number of retorts set in each arch or section. The make per retort per 24 hours for different types of units is given in the following table :—

STOP-ENDED OR 'SINGLE' RETORTS.

	Therms per diem.
Length 9 to 10 ft., section 15 ins. round	15 to 20
,, 10 ft., section 16 ins. round	20 to 27
,, 10 ft., section 21 ins. by 15 ins. dee	35 to 45
,, 10 ft., section 22 ins. by 16 ins. dee	

'THROUGH' RETORTS.

	Therms per diem.
Length 20 ft., section 24 ins. by 16 ins. dee	90 to 100
,, 20 ft., section 22 ins. by 18 ins. oval	90 to 105

A later development is the short 'through' retort, 12 to 16 ft. in length, while a 21-ft. retort is now sometimes employed.

VERTICAL RETORTS.

	Therms per diem.
Woodall-Duckham type	150 to 450
Glover-West type	120 to 300
Chamber ovens	500 to 600

The gas yield from vertical retorts is extremely flexible, very much depending upon the proportion of steam admitted and the class of coal carbonised.

COAL STORAGE.

In the present day, owing to uncertainty of delivery and such causes, it is advisable for gasworks to keep in hand much larger stocks than were thought necessary some years ago. No undertaking can now afford to risk three weeks' storage, although this is a usual and sufficient allowance for that kept under cover. When ground area is available large stocks may be arranged for out in the open. The calculation of the stock of coal in hand may be performed by assuming that one ton of average gas coal occupies from 42 to 43 cub. ft. For the convenience of dealing with stocks of other materials used on gasworks the following figures are given :—

One ton of	coke occupies	85 cub. ft. (average).
,, ,,	broken coal occupies	40 ,,
,, ,,	cannel coal occupies	35 to 45 cub. ft. (varies considerably).
,, ,,	anthracite coal occupies	35 to 39 ,,
,, ,,	breeze occupies	60 to 65 ,,
,, ,,	lime occupies	42 ,,
,, ,,	oxide of iron (Dutch)	45 ,,
,, ,,	ditto (prepared)	41 ,,
,, ,,	sulphate of ammonia	47 to 48 ,,
,, ,,	ashes	50 ,, (about).
,, ,,	Portland cement	23 to 26 ,,
,, ,,	loose earth	28 to 30 ,,

CONDENSERS.

Water condensers are now largely used in preference to atmospheric types. Many of the ıtter kind are, however, still in use, and are not without their recommendations. Rules for ondenser capacity vary to some considerable extent, and there is by no means agreement on he subject. The following are given as representing the average practice :—

Atmospheric condensers.—Allow 5 sq. ft. of atmospheric condensing surface per 1,000 cub. ft. f gas made per diem.

Water condensers.—Allow 3 sq. ft. of surface per 1,000 cub. ft. per diem.

In using the first of these two rules it must be borne in mind that the figure arrived at includes in addition to the areas exposed by the actual condenser) the area of all piping between the outlet of the hydraulic main and the inlet of the condenser. In making calculations the actual urface to be considered is that with which the gas is in contact. Thus, when the gas travels nside a tube the interior surface must be taken, and when outside the exterior surface is onsidered.

Water condensers are of two distinct types :—

(*a*) Multitubular condensers.

(*b*) Water-tube condensers.

In the first type the gas passes through the tubes, which are surrounded by a water jacket. In the second type the water is within the tubes and the gas around them. As to which type s chosen depends entirely upon the conditions of working. When any deposit is likely to take place it is preferable to have this within the tubes which may be readily cleaned. Thus, when muddy water alone is available there should be no hesitation about adopting the water-tube type. On the other hand, when the gas dealt with is likely to be particularly dirty or to contain a large quantity of heavy tar vesicles the multitubular type is to be preferred. Condensers for carburetted water-gas are invariably of the water-tube type. As regards general dimensions the height of the apparatus should be from two to five times the diameter; 3-in. tubes are preferable for the larger condensers, but 2-in. pipes will suffice for those of smaller design. The ratio of the length of the tube to its diameter should be within the limits of 80 to 1, otherwise the tube loses in structural stability. In the direction of the number of tubes to be employed a good basis to work upon is that of arranging the tubes so that they occupy about 18 per cent. of the total area of the tube-plate. For water-gas condensers this may be increased to 25 per cent.

EXHAUSTERS.

In a works of from 4 to 6 million cub. ft. capacity per annum the saving to be effected by the installation of exhausters is problematical, after consideration has been given to interest on capital and running costs. Over six millions capacity the advantages of the machine are unquestionable. In the smaller works (from 15 to 20 million cub. ft. per annum) driving is nearly always carried out by means of a gas engine, the same engine providing power for operating tar, liquor, and other pumps. The effective hourly capacity of an exhauster is guaranteed by the makers. For the capacity of a four-blade machine, however, the following formula may be taken; it is not to be recommended when dealing with very large or very small exhausters :—

$$Q = 65D^2LN;$$

where,

Q = cub. ft. passed by the exhauster per hour; D = inside diameter of outer drum in ft.; L = length of drum in ft.; N = number of revolutions per minute.

This gives the gross capacity. To arrive at the nett capacity, about 20 per cent. must be deducted (for 'slip') from the figure obtained.

On the larger works it is usual to maintain a vacuum of about 4 ins. of water at the exhauster inlet. At the outlet, the pressure to be overcome varies in accordance with the resistance offered by the apparatus following and the quantity of gas passing at the time. As a general rule the total back-pressure may vary between 8 and 10 ins. on a small country works to as much as

50 ins. of water on the largest plants, but under average conditions the following pressures wi approximate to those found at the different portions of the apparatus :—

Retorts	Level gauge.
Hydraulic main	½ in. to 1 in. vacuum.
Exhauster inlet	4 ins. vacuum.
,, outlet	30 ins. pressure.
Tar extractor, outlet	26 ins. ,,
Washers, outlet	24 ins. ,,
Scrubbers, outlet	22 ins. ,,
Purifiers, outlet	9 ins. ,,
Station meter, outlet	8·5 ins. ,,
Holder, inlet and outlet	8·5 ins. ,,

It will be seen from the above that the forcing of the gas through the dry purification materia and the raising of the holder bell account for by far the greatest portion of the work agains back-pressure which the exhauster is called upon to perform.

Running Speed.

The speed at which the exhauster operates should be gauged, not by a consideration of th revolutions performed per minute, but by the peripheral speed of the tips of the blades. Thi speed should be approximately constant for all sizes of exhausters, and should lie within th limits of 650 to 850 ft. per minute.

Lubrication.

This is a point requiring the most careful attention. Much depends upon the type of lubrican made use of, the best being a mixture of refined creosote and a mineral oil. These should b admixed in the proportion of one part of creosote to three parts of mineral oil. A vegetabl oil should not be used, as this will tend to thicken the tar inside the drum.

In modern practice there is a tendency for the ordinary rotary blade type of machine to giv way to the newer high speed turbo-exhauster working on the fan principle and providing larg clearances. An advantage attached to this type of machine is that it has some considerabl volumetric capacity per unit of floor-space occupied. The construction consists of an oute case provided internally with two or more impellers which rotate on a common axis, but i distinct cells. The gas is passed from cell to cell in series until it is discharged from the machin at the requisite pressure, the pressure obtained being dependent upon the size and speed of th impellers.

WASHERS AND SCRUBBERS.

Washers.

The capacity of the wet purification plant depends very largely upon the type of apparatu employed, whether mechanical or merely static. Mechanical washer-scrubbers are now largel used, while of the static washers the well-known Livesey type has few rivals.

Rules for Capacity.—For washers of the Livesey and similar types allow one-seventh to one fifth of a cubic foot capacity per 1,000 cub. ft. of gas passed per maximum diem.

For mechanical washer-scrubbers an allowance of one-half to three-quarters of a cubic foo capacity per 1,000 cub. ft. of gas per diem may be made.

Scrubbers.

Some works are provided with scrubbers of the tower type only, and have no separate wash ing vessels. In such cases the size of the scrubbers and their number may be based on th following rule :—

Allow 10 cub. ft. of capacity per 1,000 cub. ft. of gas dealt with per maximum diem. When the scrubbers are operated in conjunction with mechanical washer-scrubbers the above allowance may be reduced to from 5 to 6 cub. ft. When Livesey and such washers are employed prior to the scrubbers, the latter should have a capacity based on 6 cub. ft. of volume pe 1,000 cub. ft. of gas per diem.

Washing and scrubbing capacity is greatly dependent upon the manner in which condensation is carried out. Extremely effective condensation will be the means towards reducing the usua wet purification allowances by nearly 50 per cent.

Horse-Power Required to Drive Washer-Scrubbers.

The following figures refer to the power necessary for the modern vertical type of machine. The horizontal machines of similar capacity will usually require one or two horse-power less :—

500,000 cub. ft. capacity per diem	4 H.P.
1,000,000 ,, ,, ,,	5 H.P.
2,000,000 ,, ,, ,,	7 H.P.
3,000,000 ,, ,, ,,	10 H.P.

It is advisable to allow a small margin (about 20 per cent.) above these figures for emergencies.

If the power employed is electricity, and this is obtainable for a halfpenny per unit, the cost of driving amounts to about 0·033*d*. per 1,000 cub. ft.

The ratio of the height to the diameter of tower scrubbers varies between 2½ and 5 to 1. In exceptional instances, however, it may be so much as 7 to 1, particularly in the case of scrubbers of small capacity. When the diameter becomes greater than 30 ft. the flat cast-iron top is inclined to sag. In such cases it may be found advisable to provide a domed top having a rise equivalent to one-sixth of the diameter, and made from steel.

As regards the material employed for packing, Livesey has given the following figures relating to the area of wetted surface exposed to the gas :—

	Sq. ft. per cub. ft. of Scrubber Capacity.
Coke	8½
Drain pipes, 3 ins. diameter	17
,, 2 ins. diameter	21
Boards on edge	31

Boards on edge, although expensive in the first instance, are to be preferred to any other type of packing. They conform to no hard and fast rule as regards size, but the following will afford satisfactory results :—

6-in. boards, ¼ in. thick, laid ¾ in. apart.
11-in. boards, ⅛ in. thick, laid ½ in. to ¾ in. apart.

WATER REQUIRED.

The amount of water required to effect wet purification depends very largely on the type of apparatus, but very variable results are found. As an average it may be taken that the water admitted to the final scrubber will vary between 10 and 13 gallons per ton of coal carbonised. It has been found that with a modern form of vertical washer-scrubber the whole of the ammonia can be removed by admitting only 3¾ gallons of water per ton of coal carbonised.

DRY PURIFICATION PLANT.

Capacity of the dry purifiers depends upon the extent to which purification is carried. Nowadays it is customary to remove sulphuretted hydrogen alone, but if lime purification (for the removal of carbon disulphide) is resorted to it is advisable to employ rather larger vessels. It is always as well, however, that the vessels should be too large rather than too small, for the first cost increases but slowly as compared with the capacity, and purification charges undergo considerable reduction as the unit capacity becomes greater. For oxide boxes the following rule may be taken :—

For a set of four purifiers allow *for each box* an area of 0·5 sq. ft. per 1,000 cub. ft. of gas to be dealt with per maximum day. If lime is to be used this figure should be increased to 0·6 sq. ft., or 0·65 to 0·7 if no catch boxes are available.

Hunt's rule for the total amount of purification space required, i.e. the combined area of all boxes, says that 20 to 30 sq. ft. per ton of coal carbonised per maximum day should be allowed.

As regards the purifying capacity of oxide of iron it may be taken that one ton will purify about two million cubic feet of gas before it is finally spent.

In order that the oxide of iron in the dry purifiers may be retained in an alkaline condition it is not advisable to remove the whole of the ammonia from the gas. The usual practice is to permit 1 grain of ammonia per 100 cu. ft. of gas to remain as a minimum.

Purifiers are invariably square or rectangular in shape and are constructed from cast-iron plates bolted together. In one or two isolated instances reinforced concrete vessels have lately been experimented with.

As regards the necessary thickness of the cast-iron plates the following figures may be taken as indicative of the general practice :—

Purifiers up to 10 ft. square	⅝ in. plates.
,, ,, 20 ,, ,,	11/16 in. ,,
,, above 20 ,, ,,	¾ in. ,,

The flanges are usually cast ⅛ to ¼ in. thicker than the body. The smallest vessels are usually 4 ft. deep, while the largest sizes vary from 6 to 8 ft. in depth. The following rule is suggested for ascertaining the required depth :—

$$\text{Depth in feet} = \sqrt[4]{\text{Total superficial area}} \times 1{\cdot}1.$$

The depth as given may be taken to the nearest foot. For smaller purifiers, i.e. up to 100 sq. ft. in area, multiply by 1·3 instead of 1·1.

PURIFIER CONNECTIONS.

The diameter of the connecting mains is most readily and accurately computed from th following formula :—

$$\text{Diameter of pipe in ins.} = \sqrt{\text{area of each box in sq. ft.}}$$

For small purifiers (up to 60 sq. ft. area) the result can be taken as it stands, but fo medium size boxes deduct 16 per cent., and for large vessels 25 per cent.

CONSTRUCTIONAL NOTES.

From the point of view of economy water-lute purifiers should be so constructed that th lute is portion of the side plate itself and not a distinct unit. This method of constructio facilitates erection and is less costly in the first place. The depth of the lute is usually half th depth of the side plate, but the depth of water obtainable must in all events be sufficient to with stand the greatest pressure which is likely to prevail within the box. The covers of purifier are invariably made from wrought iron or steel plates, usually about $\frac{1}{4}$ in. in thickness. The are either flat or slightly curved, but in either case some form of trussing or stiffening is necessary and strong curbs should be provided when the vessel is of any size. In modern purifiers the water lute principle is largely abandoned, and dry-luted covers are provided. These possess many advantages over the older method, chiefly in the direction of initial outlay, whilst they combin greater durability with increased safety. Moreover, owing to the lighter construction of th covers the lifting apparatus may be less cumbersome and costly. A gastight joint between cove and box is usually ensured by inserting a strip of rubber or tallowed hemp between the paralle flanges, the two flanges being afterwards pulled together by means of special fasteners or ordinary bolts.

For carburetted water gas purifiers the capacity allowed should be rather greater than is th case with purifiers used in connection with coal gas. A satisfactory allowance is 0·8 sq. ft. pe 1,000 cub. ft. of water gas per maximum day.

STORAGE CAPACITY.

The holder capacity necessary is somewhat dependent upon whether or not the works i provided with a water gas plant. If such a plant is available the storage allowed for need no exceed 18 hours maximum make, but if there is no water gas to fall back upon provision shoul be made for 21 to 24 hours maximum production. In years gone by it was customary to provid considerably greater storage chiefly on account of the heavy fluctuations in output. The levelling up of the hourly load-curve has, however, had a marked effect in the direction of diminishing the quantity of gas kept in hand.

PROPORTIONS OF GASHOLDERS.

Single lift height = 0·3 to 0·4 of diameter.
Multiple lift height = 0·6 to 1·0 of diameter.

In computing the capacity of a holder the volume enclosed by the crown is neglected, as th gas contained therein is not available for distribution. Accordingly

$$\text{Capacity in cub. ft.} = \cdot 7854 \times \text{diameter in ft.}^2 \times \text{height in ft.}$$

With multiple lift holders the capacity of each lift should be estimated separately by applying the above formula to each section.

DEPTH OF LIFTS.

Each lift will be approximately of equal depth.

RISE OF CROWN.

The greater the rise the stronger will be the crown. The dome should conform to a segmen of a sphere. Normally, the rise will range between $\frac{1}{15}$th to $\frac{1}{20}$th of the diameter, but when trussing is employed it may be less than when the plain crown only is used.

The cubic capacity of the crown space may be found from the following :—

$$\text{Volume in cub. ft.} = \cdot 5236 R \left(R^2 + \frac{3D^2}{4} \right)$$

where,

R = rise of crown in ft.;
D = diameter of top lift in ft.

The depth of each lift should never be less than one-seventh of its diameter, otherwise locking or tilting may occur. In general, the proportion varies between one-fourth to one-fifth of the diameter.

The crown sheeting of gasholders varies from 14 gauge to 10 gauge (about $\frac{5}{64}$ in. to $\frac{1}{4}$ in.), but much depends upon the size of the holder.

The side sheeting varies from 12 gauge to 10 gauge, but curb or cup and grip rows are thicker, $\frac{1}{4}$ in. to $\frac{3}{8}$ in. Top lift sheets are usually thicker than those of succeeding lifts, often about 8 gauge.

The thinner sheets of the bell are generally riveted up cold with $\frac{1}{2}$ in. rivets at a pitch of 1 in. to $1\frac{1}{4}$ in. All rivets above $\frac{1}{2}$ in. must be driven hot.

In the gas holder recently built for the Gartson station of the Liverpool Gas Co., wrought-iron plates are used, as these are less liable to corrode than plates of mild steel. The gasholder, which is of the spirally guided type, is 150 ft. in diameter and has a total height of 148 ft. The iron plates have a tensile strength of 21 tons per sq. in. and an area reduction of 18 per cent. with the fibre, and 18 tons per sq. in. with an area reduction of 8 per cent. across the fibre.

(*Machinery, April* 2, 1925.)

GASHOLDER TANKS.

Steel tanks have many advantages over the masonry variety, and cast-iron as a material for this purpose may now be looked upon as obsolete.

The thickness of plate required may be calculated as follows:—

$$T = \frac{PD}{2fe},$$

where,

T = thickness of the plate in ins.;

D = diameter of the tank in ins.;

f = allowable working stress (usually $5\frac{1}{2}$ tons per sq. in.);

e = the efficiency of the vertical riveted seams. This will range up to 90 per cent. for large holders. For small holders it will vary between 75 and 85 per cent.;

P = the pressure due to the water in lbs. per sq. in.

The latter may readily be found from the following:—

$$P = WD,$$

where,

W = the weight of a cub. ft. of water = 62·4 lbs.;

D = depth below the surface of the section under consideration.

As regards the apportionment of the cost of gasholders, the following figures represent normal conditions:—

	Per Cent. of Total Outlay.
Bell, complete	35 to 45
Guide framing	18 to 23
Tank (steel)	35 to 45

Single lift holders (up to about 50,000 cub. ft.) cost in pre-war days from 25*l.* to 28*l.* per 1,000 cub. ft. If of the spiral type the outlay would be reduced by 25 per cent. Two lift holders (about 250,000 cub. ft. capacity) ranged from 16*l.* to 20*l.*; or, if spirally guided, about 10*l.* per 1,000 cub. ft. capacity. Holders varying from 2 to 3 million cub. ft. capacity cost from 9*l.* to 12*l.* per 1,000 cub. ft. The large 12-million holder at the East Greenwich Works cost five guineas per 1,000 cub. ft. capacity, whilst a $10\frac{1}{2}$-million holder at Manchester worked out at 5*l.* per 1,000 cub. ft.

CALCULATION OF PRESSURE THROWN.

The pressure thrown is dependent upon the weight of the floating portion and its diameter. It may be found as follows:—

$$\text{Maximum pressure (ins. of water)} = \frac{549W}{D^2},$$

where,

W = weight of bell and water in lutes, in tons;

D = diameter of holder in ft.

When dealing with a multiple lift holder take the mean diameter.

Size of Works Mains.

No hard and fast rules are adhered to, but the following will form a guide as to the averag conditions :—

Size of Works.	Suitable Size for Mains. Ins. Diam.
3 to 4 million cub. ft. per annum.	5
6 to 10 ,, ,,	6
15 to 25 ,, ,,	8
30 to 45 ,, ,,	10
55 to 90 ,, ,,	12
100 to 150 ,, ,,	15
200 to 300 ,, ,,	18
350 to 450 ,, ,,	20 to 21
500 to 600 ,, ,,	24
600 to 900 ,, ,,	30

Composition of Various Gases.

Per Cent. by Volume.	Coal Gas.	Carburetted Water Gas	'Blue' Water Gas	Mond Gas.	Suction Gas.	Dowson Gas.
Hydrogen	49·0	35·0	52·0	26·0	16·0	20·0
Carbon Monoxide	9·0	32·0	38·0	15·0	31·0	24·0
Carbon Dioxide	2·5	4·5	4·5	12·0	3·0	6·0
Methane	27·0	13·0	1·0	3·0	nil	1·0
Heavy Hydrocarbons	4·0	10·0	nil	nil	nil	nil
Nitrogen	8·5	5·5	4·5	44·0	47·0	49·0

Calorific Power, B.Th.U. gross	550	580	300	165	160	155

Calorific Value of Various Fuels and their Cost per Therm.

The following table (compiled by G. Evetts) gives the calorific value of various fuels, and th lost per therm (100,000 B.Th.U.). The cost must only be regarded as the prime cost of a ther used in such a manner that the heating power can be developed :—

	Calorific Value B.Th.U.	Cost.	Cost per Therm Pence.
Coal	13,000–15,000 per lb.	36*s.* per ton	1·4
Coke	11,500–13,500 per lb.	30*s.* per ton	1·35
Coal Gas	400–560 per cu. ft.	10*d.* per therm	10·0
Electricity	3,440 per unit	2*d.* per unit	58·2
Petrol	19,500 per lb.	2*s.* per gall.	16·6
Fuel Oil	18,000 ,,	5*l.* per ton	3·0
Motor benzole	19,000 ,,	2*s.* per gall.	14·2
Alcohol	12,000 ,,	5*s.* ,,	62·0

Composition of Coal and Coke.

Per Cent.	Anthracite Coal.	Average Gas Coal.	Average Gas Coke.
Carbon	94·0	80·0	88·0
Hydrogen	2·5	5·5	0·2
Oxygen	0·25	8·8	traces to 3·0 (varies considerably)
Nitrogen	0·5	1·5	2·0
Sulphur	0·5	0·8	1·0
Ash	2·25	3·4	5·8
Calorific Power, B.Th.U.	15,500 per lb.	14,800 per lb.	13,500 per lb.
Volatile Matter	8 per cent.	30 per cent.	1 per cent.

Products of Distillation.

One ton of average gas coal will yield (approximately) the following products :—

Gas	13,000 cub. ft., or approximately 70 therms.
Coke	12 to 13 cwts., excluding breeze.
Breeze	1 cwt.
Tar	9 to 11 gallons.
Ammoniacal liquor	32 to 40 gallons at 8 ozs.
Sulphate of ammonia	24 to 28 lbs.
Sulphur	5 to 7 lbs.
Cyanogen (HCN)	4 lbs.
Virgin liquor	10 to 12 gallons.

The yield of gas as given above is the normal quantity of straight coal gas obtained, but it should be borne in mind that the modern vertical retort in which 'steaming' is employed will give a yield of from 85 to over 100 therms per ton of coal.

(The sulphate of ammonia is obtained from the ammoniacal liquor, and not in addition to it. The virgin liquor is included in the figure given for total yield of ammoniacal liquor. The figure given for sulphur is that which may be recovered during purification of the gas, and does not include the quantity remaining behind the coke.)

The approximate distribution of the elements of the original coal, and the manner in which each exists after the process of carbonisation, is illustrated in the following table :—

One ton of coal, consisting of :—

	Lbs.
Carbon, 1,792 lbs., distributed as—	
Coke	1,385
Breeze	107
In gas, as CO and CO_2	30
In gas, as hydrocarbons	130
In tar	122
As scurf, cyanide, etc.	18
Hydrogen, 123 lbs., distributed—	
In gas and tar	98·5
As ammonia	1·0
As water	18·5
In coke	5
Oxygen, 197 lbs., distributed—	
In gas, as CO, CO_2, and combined in tar	49
As water	148
Nitrogen, 34 lbs., distributed—	
In gas (free)	11·8
In coke	14·1
In tar (combined)	1·0
As ammonia	5·8
As cyanogen (total HCN 4 lbs.)	1·3
Sulphur, 18 lbs., distributed—	
As gaseous impurities and in liquor	6
In coke	12
Ash remaining in coke and breeze	76
Total	2,240

Amount of Coke Used as Fuel.

The quantity of coke used for heating the retort benches varies in accordance with the system of firing adopted. There are three types of firing now in common use, namely :—

(*a*) Direct-fired settings.
(*b*) Semi-gaseous settings.
(*c*) Gaseous-fired settings.

In addition, some works employ external producers, in which the producer gas is generated in a producer of special design situated away from the retorts, and forming a central source from which all the settings are supplied. At the Fuel Research Station at East Greenwich blue water gas is employed for heating a setting of vertical retorts.

The following shows the amount used :—

	Per cent. of the original weight of coal carbonised.
Direct-fired settings	28
Generator settings	15 to 18
Regenerator settings	11 to 14
Vertical retorts :—	
(*a*) Intermittent types	16
(*b*) Continuous types	11½
Outside producers	13 to 16

With modern systems it should be possible actually to sell 10 cwts. of coke per ton of coal.

See also ' Coke as Boiler Fuel,' p. 2088.

Composition of the Producer Gas.

The following is the average composition under good conditions:—

	Per-cent. by volume.
Carbon monoxide	25
Carbon dioxide	5
Hydrogen	6
Methane	1
Nitrogen	63

(Oxygen should be absent, for its presence indicates an excess of primary air.)

The analysis of the waste gases emitted from the retort setting should approximate to the following :—

	Per cent. by volume.
Carbon monoxide	19
Oxygen	0·4
Nitrogen	80·6

(The presence of carbon monoxide in the waste gases is indicative of a deficiency of secondary air, and is wasteful in firing. The oxygen, if above 0·5 per cent., denotes an excess of secondary air.)

Gasworks Temperatures.

	F.°
Retorts	1800 to 2100
Ascension pipes	200 to 300
Foul main (inlet)	140
Condensers (inlet)	125
,, (outlet)	75 to 85
Washers and scrubbers (outlet)	60
Purifiers (inlet)	60
,, (outlet)	65
Holders	60

The modern combustion chamber temperature rarely, if ever, exceeds 2800 F.° The prevailing temperature of the fuel-bed is in the neighbourhood of 1800 to 1900 F.°

Before the introduction of the regenerative system, one of the chief causes of the loss of heat arose from the escape of the waste gases of the producer at unnecessarily high temperatures. In such cases the normal temperature at which the gases are allowed to leave the settings is in the neighbourhood of 1700 to 1800 F.°, but by the transference of the sensible heat from these gases to the inflowing secondary air the temperature of the waste gases has, in the modern regenerator, been reduced to 600–800 F.° before their escape is permitted. In the ordinary way, the secondary air approaches a temperature of 1800 F.° before combustion.

Grate and Chimney Area.

The grate area of the retort bench producer must in all cases be ample, so as to ensure a steady travel for the air passing through the fuel. When the ordinary horizontal fire-bar grate is employed the recognised modern rule for grate area is as follows :

Allow one-tenth square foot of grate area for every lineal foot of retort in the setting. Thus for a through setting of ten 20-ft. retorts, this gives a total grate area of 20 sq. ft. Another

but less common rule, is that which gives the allowance as 1 sq. ft. of area for every 8 lbs. of coke consumed by the furnace per hour. As the actual consumption of coke (which is shot into the producer hot) is somewhat difficult to compute, the rule is not readily applied.

The ordinary horizontal form of bar grate is now rapidly giving way to the sloping form of grate. The original sloping arrangement consisted of a number of flat plates placed progressively in the manner of a stairway, cooling being effected by a small stream of water which was permitted to drop from step to step. The latest development is the Grille grate, which is composed of a number of independent components set together so as to form an interlocking grille. The grate is made entirely from special cast iron, and embraces a series of hanger bars, which are hung from specially shaped cross-bars. When in the working position each hanger is automatically locked, so that it cannot be displaced during the process of cleaning the fire, while at the same time, should it be necessary to remove any one of the hangers, this may readily be done by applying a slight forward movement to the lower end. The grate is employed in conjunction with a supply of steam, and the formation of clinker is practically avoided, the inert matter coming down in the form of a fine dust.

The rule given above for grate area does not apply when grates of the sloping type are employed, for, owing to the more favourable conditions of the base of the fuel bed, the circulation of primary air is uninterrupted by layers of dead matter. With the Grille type of grate the following rule may be employed :—Allow 0·6 sq. ft. of sloping superficial area per 10 lineal ft. of retort in the setting.

Flue and chimney area is calculated by allowing 1½ sq. ins. of area per lineal foot of retort in all those settings which depend upon the flues and chimney under question. Thus, if a retort bench consists of eight settings, each containing ten 20-ft. retorts, the area required would be 16½ sq. ft.

In large retort houses the height of the chimneys varies from 50 to 70 ft. The chief considerations to bear in mind are the heights of adjoining buildings, also the avoidance of down-draughts and the effect of shifting winds. It is not advisable to connect a chimney to a greater number of retort beds than ten, for above this number its dimensions become unwieldy. Circular chimneys, except for vertical retort installations, are now almost things of the past. The rectangular chimney with an external batter is most commonly employed. The batter usually varies between the limits of 1 in 36 to 1 in 40. Retort house chimneys are usually braced for their entire height; the general methods being to run angle-iron up each corner, the angles being held in position by tie bands placed at intervals of about six feet. An inspection door should be left at the base of the shaft for cleaning purposes. As regards material of construction, stock bricks may be employed for the external courses, but a lining of fire bricks in the interior is essential. Very frequently the whole chimney is constructed from fire bricks, in which case no lining is, of course, necessary. The volume of gas drawn up a chimney increases in proportion to the square root of its height; thus any increase in height produces only a comparatively small change in this respect. On the Continent it is occasionally found that a separate chimney is installed for each retort setting, but the idea is confined almost wholly to stop-ended settings. The construction of retort bench shafts should be such that the cross sectional area, in spite of the batter, is constant throughout the whole height. This may readily be arranged for by reducing the thickness of the brickwork from the bottom upwards.

Proportions of Horizontal Retort Benches.

The following normal dimensions are given as exemplifying the usual proportions of various types of retort houses and benches :—

(*a*) Single retort bench, 10-ft. retorts :—

	ft.	ins.
Width of bench	12	6
At back of bench	1	6
In front of bench	18	0
Total width inside houses	32	0

The height of the retort house to the eaves would be 20 ft., and the height of the retort bench from ground level 11 ft.

(*b*) Through retort bench, hand charging and discharging—

	ft.	ins.
Width of bench	20	0
Each side of bench, 20 ft.	40	0
Total width of house	60	0

The height of the retort houses to eaves, if house of the stage type, would be about 35 ft.; if of the subway type 8 to 10 ft. less. The height of the retort bench from base of producers to top of brickwork about 20 ft., if retorts set in three tiers.

(*c*) Through bench, mechanical charging and discharging—

	ft.	ins.
Width of bench	20	0
Charging side of bench	23	0
Discharging side	17	0
Total width of house	60	0

The height of the bench from base of producers to top of brickwork would be about 25 ft if retorts are set in five tiers. The height of the house (stage type) to eaves would be abou 40 ft. if continuous coal hoppers overhead were included. As an approximate rule for ascertain ing the height of the bench from charging floor to top of brickwork, allow 29 ins. for each tie of retorts. The width of the main setting arch will be, for two rows of retorts, from 7 ft. 9 ins to 8 ft. 9 ins.; for three rows of retorts, 8 ft. 6 ins. to 9 ft.

RETORTS.

Vertical Retorts.

Modern vertical retorts are of three types, namely, (*a*) continuous; (*b*) intermittent; (*c*) continuous-intermittent. The best known examples of the continuous type are the Woodall Duckham and Glover-West systems.

WOODALL-DUCKHAM SYSTEM.

Length of 5½ ton retorts is 25 ft. The shape of the retorts is rectangular tapered, their dimensions at the top being 4 ft. 3 ins. by 7 ins., and at the bottom 5 ft. 3 ins. by 18½ ins. Each retort will carbonise from 4½ to 5½ tons of coal per diem, and it is usual for two or four of them to be erected in one unit. The coke is extracted by a revolving rake device which makes one revolution in from 50 to 70 minutes, and the speed of extraction of the coke regulates the speed of inflow of coal at the top of the retort. The coke, after extraction, drops into a receiving hopper which is emptied about every three hours. The power required to drive the mechanical portion amounts to approximately 1·8 b.h.p. per ton of coal per maximum day. The largest type of retort made will carbonise up to 7½ tons of coal per day.

GLOVER-WEST SYSTEM.

In this system the retorts are elliptical in shape, having a taper towards the bottom. The system has recently undergone considerable development by the introduction of what is known as the 'Leigh' type of retort, which is fitted at the base with a large steaming chamber. In this way it has been possible greatly to augment the proportion of steam admitted to the retort, with the result that the yield of gas per ton of coal has been greatly increased. The retorts are set in units of 2, 4, or 8, and they are made in three sizes, the particulars in connection with which are given in the following table:—

	Type I.	Type II.	Type III.
Shape of retorts	Elliptical.	Elliptical.	Elliptical.
Breadth and width of retorts	40″ × 10″ to 46″ × 18″	33″ × 10″ to 39″ × 18″	24″ × 10″ to 30″ × 18″
Length of retorts	21 ft.	21 ft.	16 ft.
Coal throughout per diem (without steaming)	4 tons	3 tons	2 tons

ADMISSION OF STEAM.

The process of admitting steam to the base of the retort has now become the standard practice in connection with carbonisation in vertical systems. Blue water gas is thereby generated *in situ*, and besides increasing the yield of gas and therms per ton of coal carbonised, some noticeable augmentation of the liquor and tar yields has resulted. The effect of steaming is well illustrated by the following results obtained at the Fuel Research Station at East Greenwich with Mitchell Main gas coal:—

	Cub. ft. of gas per ton of coal.	Calorific Value B.Th.U. (gross).	Therms per ton of coal.
Without steaming	13,100	544	71·26
Steaming (20·53 per cent.)	22,580	460	103·86
,, (30·03 per cent.)	25,610	432	110·63

Fireclays as used on Gasworks.
See Section XX., p. 534.)

Retort Bench Fittings.

The following may be taken as giving the approximate size of ascension pipes necessary with horizontal retorts :

Works making under 10 million cub. ft. per annum . . . 5-in. pipes.
" " between 10 and 200 million cub. ft. per annum 6-in. "
" " above 200 million cub. ft. per annum . . 7-in. "

The above refer to retorts having an ascension pipe at both ends. If a single pipe is used it should not be less than 8 ins. in diameter.

Joints for Ascension Pipes.

These must on no account be made with lead. Rust joints are to be preferred to any others, although they may entail no little labour when having to be cut out. To prepare the material for these joints, cast-iron borings should be damped down with gas liquor; the mixture is then rammed well down into the joint space. When the bench is at work the heat soon hardens off the joint. If borings cannot be obtained, a serviceable joint may be made from the following :

Ewell brick dust . . . . . 1 part.
Slaked lime . . . . . 2 parts.

This is rammed into the joint dry, no moistening being necessary.

For the joints between the cast-iron mouthpiece and the fireclay retort the following may be used :—1 part of cast-iron borings to 2½ parts of fireclay. This mixture is then damped down with a solution of sal ammoniac. The amount of sal ammoniac required is about 1 lb. to every cwt. of the fireclay and borings. Ammoniacal liquor may be used in lieu of the sal ammoniac, but the latter is to be preferred, as a more complete rusting action is thereby set up.

Hydraulic Mains.

These are now of two types, i.e. :

(*a*) Distinct mains, one to every retort bench, on either or both sides.
(*b*) Continuous mains, one uninterrupted main extending over a number of settings.

The latter type have their advantages as regards initial cost, but distinct mains are otherwise to be preferred owing to the greater ease with which they are adjusted. In addition, by their use a single setting may be readily shut down and isolated.

The gas take-off from the hydraulics should be arranged from the cover of the box, rather than from the side, as is so frequently found.

Foul Main.

The size of the foul main must depend upon the combined areas of all pipes leading into it. Generally speaking, the following sizes are those prevailing, and which may be safely applied.

Capacity of Bench per 24 hours.	Size of Foul Main.	
	If one.	If two.
50,000 to 100,000 cub. ft.	6 ins. to 9 ins.	—
100,000 to 500,000 cub. ft.	12 ins. to 15 ins.	—
1 million to 1¾ million cub. ft.	18 ins.	14 ins.
2 million to 3 million cub. ft.	24 ins.	18 ins.

Another rule is that which states that the foul main (if it delivers all the gas) should be 25 per cent. of the area of the main works connections.

The modern practice is to construct the foul main from lap-welded steel plates or solid drawn tubes in lieu of cast-iron pipes. When steel is used, however, some form of expansion joint should be introduced, for the main is liable to undergo some considerable expansion when the settings are fired up from cold. With the cast-iron main, the lead joints at the spigots will be sufficient to cope with any change of length, and flange joints should therefore be avoided unless some form of expansion joint is inserted.

Tar and Liquor Removal.

The method employed for removing the tar and liquor condensed out of the gas in the hydraulic main is of extreme importance, for if an efficient principle is not employed endless trouble results in the shape of pitched-up hydraulics, stopped ascension pipes and tar mains, and considerable loss of ammonia. The tar-tower system has been regarded as one of the best methods and is a considerable improvement on the older systems. The objection to the tar-tower, however, is that it is not automatic in action, requiring periodical 'running-off,' during which process there is every possibility of temporarily unsealing the dip-pipes. One such method is the 'Reflux' system, which is entirely automatic. The system separates tar and liquor while hot, and effects the continuous circulation of hot liquor in the hydraulics, which presents many advantages from the point of view of practical working.

Retort House Governors.

The retort house governor is a more or less essential auxiliary of the modern retort house. I differs from the station governor in that, whilst the latter is employed with the object of reducin pressure, the retort house governor is interposed for the purpose of reducing the intensity c vacuum created by the exhauster. Thus the governor ensures a constant vacuum in the hydrauli main, whatever the volume of gas coming away from the coal charges may be. The intensity c vacuum required is obtained by loading the bell on similar lines to those employed with th station governor. The best place for the governor is on the top of the retort bench, as close n to the end of each section of the foul main as possible, for it is not so sensitive when interpose at the inlet or outlet of the condenser as is occasionally found. By-passes should be fitted to th governor, for it will require cleaning out about every four months.

Cost of Manufacturing Coal Gas

The cost of manufacturing towns' gas depends primarily upon the capacity of the works, it geographical position relative to suitable coalfields, and the character of the plant in use. It mus be borne in mind, too, that the actual cost of production (*i.e.* cost into gasholder) represents onl about one-half of the ultimate selling price, the remainder being accounted for by the cost of dis tribution, overhead charges, dividends, etc. In considering a normal case of an undertakin supplying about 1,000 million cu. ft. of 500 B.Th.U. gas per annum, the manufacturing cost would be approximately as follows, assuming that coal gas only was produced :—

	Cost per 1,000 cu. ft.	Cost per Therm.
Coal	26*d.*	5·2*d.*
Less Residuals	17*d.*	3·4*d.*
Net cost of coal	9*d.*	1·8*d.*
Purification	0·5*d.*	0·1*d.*
Salaries and wages	3·5*d.*	0·7*d.*
Wear and tear	7·5*d.*	1·5*d.*
Net cost of gasholder	20·5*d.*	4·1*d.*

Gasworks Conveyors and Elevators.

The formula given below may be taken as giving a useful guide as to the capacity of bucke conveyors :

$$\text{Capacity} = \frac{S \times B \times W}{96{,}768 \times P} \text{ tons per hour,}$$

where,

B = capacity of buckets in cub. ins. ;
S = speed of conveyor in ft. per minute ;
W = weight per cub. ft. of substance carried (see page 2448) ;
P = pitch of buckets in ft.

The horse-power required to operate elevators and conveyors may be readily arrived at by adopting a coefficient of friction in accordance with the conditions under which the machine is working.

Let M = the weight of material carried in lbs.
W = the weight of the moving parts in lbs.
K = the coefficient of friction.
S = the speed of the conveyor or elevator in ft. per minute,

then, for

(*a*) Vertical elevator :

$$\text{H.P.} = \frac{M \times S}{33{,}000} + \frac{K \times S(M+W)}{33{,}000};$$

(*b*) Inclined elevator :

Let a° = the angle of inclination with the horizontal, then,

$$\text{H.P.} = \frac{M \times S \times \sin a^\circ}{33{,}000} + \frac{K \times S(M W) \cos a^\circ}{33{,}000};$$

(*c*) Horizontal conveyor :

$$\text{H.P.} = \frac{K \times S(M+W)}{33{,}000}.$$

As regards the value of K, the following figures may be taken :

0·15 for metal sliding on metal ;
0·07 to 0·8 ,, ,, (well lubricated)
0·25 for wood sliding on wood.

Purification of Coal Gas.

The purification of coal gas is carried out in two stages, namely, by means of wet purification in the washers and scrubbers and afterwards in the dry purifiers. During the wet purification of the gas the alkaline ammonia is made use of for removing a portion of the acidic impurities, sulphuretted hydrogen and carbon dioxide. The two last-named are, therefore, absorbed with the formation of certain salts, which are themselves soluble in water. The resultant solution consists of water containing a certain proportion of these salts, and is known as ammoniacal liquor. In crude coal gas the ammonia content is usually in the neighbourhood of 1·5 per cent. by volume, and of this amount from about one-third to one-half will have been deposited prior to the gas reaching the wet purification plant. Hunt has given the following figures for the distribution of ammonia :

	Per cent. of total.
Ammonia removed by condensation	42·7
,, ,, first scrubber	43·3
,, ,, second scrubber	14·0

When gas containing carbon dioxide and sulphuretted hydrogen comes in contact with a solution of ammonia both acid and normal salts are formed. Thus we have :

(*a*) $2NH_3+H_2O+CO_2=(NH_4)_2CO_3$ (normal) (*c*) $2NH_4OH+SH_2=(NH_4)_2S$ (normal) $+2H_2O$
(*b*) $NH_3+H_2O+CO_2=NH_4HCO_3$ (acid) (*d*) $NH_4OH+SH_2=NH_4HS$ (acid) $+H_2O$

Composition of Gas Liquor.

The ammonia present in gas liquor is combined in two distinct ways. In the first place it is present as easily decomposible compounds, such as carbonates and sulphides, and secondly, as more stable compounds which will only undergo decomposition by heating in the presence of a caustic alkali. In general, the final mixture of gas liquor obtained consists of from 75 to 80 per cent. of the more unstable salts, i.e. 'free' ammonia, whereas the remaining 20 to 25 per cent. is made up of the more stable salts, i.e. 'fixed' ammonia. The possible constituents of gas liquor are enumerated below, although it must be borne in mind that any one sample of liquor will seldom contain all of the compounds given. In fact, some of those included are only met with on rare occasions.

Water, containing in solution:

Ammonium carbonate	'Free' ammonia.	Ammonium chloride	'Fixed' ammonia.
,, bicarbonate		,, sulphocyanide	
,, carbamate		,, sulphite	
,, sulphide		,, thiosulphate	
,, hydrosulphide		,, sulphate	
,, cyanide		,, ferrocyanide	
,, polysulphide		,, acetate	

Also phenols, amines, and other nitrogenous bodies.

The amount of ammonia in gas liquor is in reality quite small, and varies between 1·5 and 3 per cent. In general, it will be apportioned as follows :

	Per cent.
'Free' ammonia	1·2 to 1·6
'Fixed' ammonia	0·3 to 0·4

The following figures relate to sulphuretted hydrogen and carbon dioxide :

	Per cent.
Carbon dioxide in gas liquor	1·3 to 2
Sulphuretted hydrogen	0·1 to 0·6

The distribution of the total ammonia in gas liquor varies, of course, to some considerable extent. The following table, however, refers to the average solution :

	Per cent. of total ammonia.
Ammonium sulphides	6
,, carbonates	74
,, chloride	15
,, sulphocyanide	1·75
,, thiosulphate, sulphite, etc.	3
,, sulphate	0·25

The most effective manner of operating the washing and scrubbing plant is to ensure that the gas on first entering the apparatus is treated with the strongest liquor available. In each succeeding vessel the washing liquor employed becomes gradually weaker and weaker until, in the final scrubber, clean water should be employed. Where circumstances permit, it is preferable that the first washer should be operated with the liquor from the hydraulic main, for in this way both CO_2 and SH_2 may be considerably reduced.

The amount of water which must be added for the purpose of wet purification seems to vary to some considerable extent in accordance with the conditions prevailing. The writer has

found with Durham coal that the ammonia may be completely removed in ordinary coke-fille tower scrubbers by adding from 10 to 13 gallons per ton of coal carbonised. When mechanica washer-scrubbers are in use the quantity of water required will be considerably less, probably n more than 4 gallons per ton of coal.

Mr. Thos. Glover states that the liquor distributed per sq. ft. of cross sectional area of th scrubber should be 0·145 gallon per minute. This is less the quantity of clean water added t the final scrubber.

Ammonia Lost.

The quantity of ammonia lost in the direction of that permitted to go forward from the fina scrubber may be conveniently calculated as so many gallons of 10 oz. liquor.

$$\text{Quantity of 10-oz. liquor lost per week (in gallons)} = \frac{\text{Total grains of ammonia passing forward from scrubber per week.}}{1{,}522}$$

Impurities in the Gas at various stages.

	Grains per 100 cub. ft.
Outlet of condensers—	
Ammonia	200 to 300
Sulphuretted hydrogen	600 „ 900
Carbon dioxide	900 „ 1,400
Sulphur compounds	35 „ 45
Hydrocyanic acid	60 „ 80
Naphthalene	20 „ 25
Inlet of purifiers—	Grains per 100 cub. ft.
Ammonia	nil to 1·5
Sulphuretted hydrogen	450 „ 700
Sulphur compounds	35 „ 45
Hydrocyanic acid	50 „ 70
Carbon dioxide	750 „ 1,150
Outlet of purifiers—	Grains per 100 cub. ft.
Ammonia	nil
Sulphuretted hydrogen	nil
Carbon dioxide	750 to 1,150
Sulphur compounds	35 „ 45
Hydrocyanic acid	nil „ 10

(The last three named above may all be removed, or partially removed, by the employment of special processes, but in the majority of gasworks such processes are not resorted to.)

Removal of Sulphuretted Hydrogen.

Sulphuretted hydrogen is now almost universally removed by means of oxide of iron in one its forms. Natural ferric oxide (bog-ore) is still largely employed for the purpose, although i recent years various artificial preparations have found a good deal of favour, chiefly owing t their lower cost. The natural bog-ore is chiefly obtained from deposits in Holland, Belgium, an Ireland. In the dried state its composition varies between the following limits :

	Per cent.
Hydrated ferric oxide (Fe_2O_3, H_2O)	60 to 65
Organic matter	15 „ 25
Silica	3 „ 6
Alumina	1

The active material in bog-ore and artificial preparations is not actually the iron oxide, bu the oxide plus a certain quantity of water of combination, *i.e.* a hydrated ferric oxide. I addition to this moisture the material as used should contain a further quantity of water, usuall from 20 to 30 per cent. The artificial oxides are employed with a similar degree of moistur The made-up or artificial material, if of good quality, is usually rather more active than th natural product, owing to a rather higher content of ferric hydrate, which may reach so much a 70 to 75 per cent.

Reactions during the Removal of Sulphuretted Hydrogen.

The absorption of SH_2 by the active oxide occurs in two distinct ways :

(*a*) $Fe_2O_3, H_2O + 3H_2S = Fe_2S_3 + 4H_2O$.
(*b*) $Fe_2O_3, H_2O + 3H_2S = 2FeS + S + 4H_2O$.

In the first instance ferric sulphide is formed, whilst secondly the result is ferrous sulphi and some free sulphur.

When spent and inactive the material is removed from the purifier and subjected to the process of revivification, or exposure to the air, when the sulphides are oxidised to oxides and the material is ready for further use. The following are the revivifications reaction :

(*a*) $2Fe_2S_3 + 3O_2 + 2H_2O = 2Fe_2O_3, H_2O + 3S_2$.
(*b*) $4FeS + 3O_2 + 2H_2O = 2Fe_2O_3, H_2O + 2S_2$.

Oxide is generally laid in the purifiers on grids to a depth of from 8 to 10 ins. In some works, however, it is still customary to employ deep layers of as much as 30 ins. This is particularly the case in those purifiers in which hurdle grids are made use of.

A space of at least two inches should be left between the top of one layer and the base of the sieves or grids of the layer immediately above. Oxide as it becomes fouled increases in bulk, hence this precaution. Partial revivification *in situ* is nearly always arranged for in present-day systems. This is effected by admitting a small measured quantity of air to the purifiers along with the gas. The air may be taken from a small compressor and forced into the box, or may be injected by means of steam. In other cases, it is sucked in with the gas through a pipe attached to the main on the inlet side of the exhausters. When air is admitted at some point prior to the washers and scrubbers it should not be overlooked that undesirable reactions may be set up in the wet purification plant.

It is generally understood that the material in any one purifier cannot simultaneously extract sulphuretted hydrogen and undergo revivification. The assumption is not entirely accurate, but the process of sulphiding takes place at a very much more rapid rate than does the oxidation effect.

If the capacity of the purification plant is not ample the full effect of the admitted air will not be realised. For the most effective results a slight excess of air above that theoretically required (as determined from the SH_2 present) should be admitted.

When air is admitted to a purifier a rise in temperature of about 5 degrees Fahr. will usually be found as the gas passes from inlet to outlet. The air acts, of course, as a diluent, and therefore a careful check must be kept on the quantity admitted with the gas. As regards the effect of the air in this direction the following may be quoted :

Audouin and Berard found that 1 per cent. of air reduces illuminating power by 6 per cent.

	Per cent.
2 per cent. of air reduces illuminating power by . .	11
3 „ „ „ „ . .	18
4 „ „ „ „ . .	26

Würtz has stated that

3 per cent. of air causes	15·69 per cent. loss in light.
5 „ „	24·0 „ „

Dr. W. B. Davidson, in more recent experiments, has found the following results :

			Per cent.

Lime Purification.

Prior to the year 1905 lime purification for the removal of carbon dioxide and sulphur compounds other than sulphuretted hydrogen was in almost universal use. To-day, purification by this method is met with only in isolated instances.

Lime in the slaked condition is an active absorbent of sulphuretted hydrogen and carbon dioxide, and—after special treatment—is capable of removing carbon disulphide. The following reactions occur during the process of purifying by means of lime :

(*a*) Removal of carbon dioxide—

$$Ca(OH)_2 + CO_2 = CaCO_3 + H_2O.$$

(*b*) Removal of sulphuretted hydrogen—

$$Ca(OH)_2 + 2SH_2 = Ca(SH)_2 + 2H_2O.$$

(*c*) Removal of CS_2.

It must be borne in mind that slaked lime in itself has no action upon carbon disulphide. The active medium which accounts for the removal of the CS_2 is now generally supposed to be calcium hydroxyhydrosulphide. This is prepared by sulphiding the slaked lime, in other words by admitting gas containing sulphuretted hydrogen to the vessels which are destined to

remove the CS_2. Carbon disulphide certainly cannot be absorbed according to the following equation, which has been so often set down as illustrating the reaction:

$$CaS + CS_2 = CaCS_3.$$

Veley has laid down the following theory as to the actual reactions which occur:

(1) Calcium hydrosulphide is formed in the first place—

$$Ca(OH)_2 + 2H_2S = Ca(SH)_2 + 2H_2O.$$

(2) By the addition of water or oxygen the hydrosulphide is converted into hydroxyhydrosulphide—

$$(a)\ Ca(SH)_2 + H_2O = CaOH,SH + SH_2$$

or

$$(b)\ 2Ca(SH)_2 + O_2 = 2CaOH,SH + 2S.$$

(3) The carbon disulphide and hydroxyhydrosulphide then react as follows:

$$(a)\ 2CaOH,SH + CS_2 = SH_2 + Ca(OH)_2,CaCS_3$$

or

$$(b)\ 3CaOH,SH + CS_2 + H_2O = 2SH_2 + (Ca(OH)_2)_2,CaCS_3.$$

When gas is manufactured and is to be freed from the whole of its impurities it is usual to instal a system in which oxide of iron and lime are used in conjunction. Many methods of operating for this purpose are employed, but one of the most common systems is that generally known as the 'Beckton' method. It consists in the main of four sets of purifiers operated in rotation:

First Set, Lime.—These remove the whole of the CO_2 and some SH_2, which is afterwards displaced by CO_2. Some CS_2 is also absorbed.

Second Set, Oxide.—These remove the whole of the SH_2, including any which may be displaced from the lime in the previous set.

Third Set, Lime.—This lime has been previously 'sulphided' and removes the bulk of the CS_2. It will not remove the whole of this impurity.

Fourth Set, Oxide.—These vessels remove any SH_2 which is disengaged from the third set.

Cost of Purifiers.

It is difficult to give any reliable figure, based on each 1,000 cub. ft. capacity, for the cost of purifiers, for everything is dependent upon the size of the vessel. The larger the box, the lower the cost per unit of capacity. As regards the distribution of the cost, the following is illustrative of normal conditions with a medium size installation:

	Per cent. of total expenditure.
Purifying boxes	50
Covers (dry lute)	15
Lifting apparatus	4 to 6
Grids	6 to 10
Connections and valves	20 to 30

Castings for the boxes, in normal times, cost from 10*l.* to 11*l.* per ton. The covers cost from 17*l.* to 19*l.* per ton. As regards valves, it is usual to base these per inch of diameter. The following figures are approximate pre-war costs:

	Per inch of diameter.
Ordinary rack and pinion valve	1*l.*
Centre valves	9*l.*
Weck's valves, and such types	10*l.* 10*s.*

Removal of CS_2 by Hot Purification.

Owing to the uncertainty and expense of lime purification for the removal of sulphur compounds other methods of effecting the same end have recently been introduced. The most important of these is the Carpenter-Evans system of hot purification, which is now in everyday use at some works. The principle of the process consists in converting the CS_2 into sulphuretted hydrogen, and then removing the latter by means of ordinary oxide of iron purification. The gas, after being purified from SH_2 in the usual way, is passed into special chambers containing a catalyst heated to a temperature of about 800°F. The CS_2 is thereby decomposed according to the following reaction:

$$CS_2 + 2H_2 = 2H_2S + C.$$

The catalytic agent employed consists of fireclay balls about 1 in. in diameter impregnated with nickel reduced from the chloride. The free carbon resulting from the reaction is left behind in the catalysing apparatus, and after about thirty days' run it is necessary to remove it. This is carried out by the process known as 'aeration.' Air is pumped through the catalyser tubes at a definite rate thus burning out the carbon and disposing of it as carbon dioxide. The aeration

process on the larger plants usually occupies about one week, after which the apparatus is again ready for work. When starting and stopping special precautions have to be taken to ensure immunity from explosion. The effect of the process on the general composition of the gas seems to be but slight; as an instance the following figures, given by Dr. Carpenter, are quoted:

Analysis of Gas.	Before Treatment.	After Treatment.
CO_2, per cent. by volume	1·44	1·45
Heavy hydrocarbons	3·55	3·63
Oxygen	0·33	0·06
Carbon monoxide	8·16	8·03
Methane	26·85	27·26
Hydrogen	54·19	54·25
Nitrogen	5·48	5·32
Illuminating power	14·70	14·70
Calorific power (Gross, B.Th.U.)	590·0	594·40

Cost of Purification.

The present-day cost of operating the Carpenter-Evans system of purification is shown in the following table:—

	Pence per 1,000 cubic feet.
Fuel (coke @ 42*s.* 6*d* per ton)	0·2550
Conveying coke and cleaning producer	0·0240
Power	0·0129
Labour and chemical supervision	0·1180
Repairs and maintenance	0·1649
Capital charges	0·1967
Total	0·7715*d.*

Purification by means of Charcoal.

Mr. W. Gordon Adam has introduced a method for removing carbon disulphide and thiophen by passing the gas, after washing and scrubbing, through animal or wood charcoal in a granulated state. The impurities (including naphthalene) are afterwards removed from the charcoal in an unchanged condition by the application of heat, a temperature of about 300° C. being sufficient. After this treatment the charcoal is ready for further use, and is employed in a purifying vessel of ordinary construction. The prevention of ethylene absorption is effected by curtailing the quantity of charcoal used—in other words, by increasing the space-velocity above that at which ethylene is extracted.

Removal of Naphthalene.

During recent years it has become usual to employ special naphthalene solvents, to the action of which the gas is subjected before travelling to the district mains. Paraffin, water-gas, tar, and anthracene oil have all proved effective, particularly the latter. In general the gas will contain, if no special treatment is accorded it, from 6 to 12 grains of naphthalene as it leaves the works. Butterfield has pointed out that a million cubic feet of gas cooled from 68° to 50°F. may deposit about 14 lbs. of naphthalene. The introduction of carburetted water gas has to a certain extent lessened the naphthalene evil, although its effect in this direction is somewhat erratic. As regards the methods of washing with solvents, the most ready plan to adopt is that of treating the gas in a Livesey or mechanical washer just prior to its entering the holders.

Carburation with the aid of solvents was introduced by Botley, who injected, by means of a special spray, about 4 gallons of thoroughly atomised paraffin oil per million cubic feet of gas. Botley found that petroleum oil was more suitable for the purpose than spirits such as benzol. Leather made use of a creosote oil for washing the gas, but owing to the 'stripping' properties of this oil he took the precaution to pre-benzolise it first. The practice of Ferguson Bell is somewhat uncommon. The gas whilst in a warm state is washed with warm tar, and at the outlet of the wet purification plant it is further treated with a naphtha oil.

Recovery of Cyanogen on Gasworks.

Cyanogen is a subsidiary by-product which is only recovered on the largest of works. The maximum amount which can be obtained from a ton of coal is about 1½ lbs. of hydrocyanic acids or about 10,000 grains. The processes now employed recover the hydrocyanic acid either as ammonium sulphocyanide or as sodium ferrocyanide (prussiate of soda). The most readily applied method is that operating on the polysulphide principle. In this system the gas, prior to washing and scrubbing, is passed through a special vessel (of the nature of a small purifier

containing a layer of spent oxide of iron about 2 ft. in depth. Above the oxide material sprays are arranged around the box, and the oxide is periodically sprayed with water or weak cyanide liquor. The gas, containing hydrocyanic acid, passes upwards through the layer of oxide and comes in contact with the polysulphide solution trickling through the mass. The hydrocyanic acid combines with the ammonium polysulphide and yields ammonium sulphocyanide according to the following equation :

$$(NH_4)_2S_2 + HCN = NH_4SCN + NH_4SH.$$

The spent oxide used in the process should contain about 50 per cent. of sulphur, and it is a surprising fact that although sulphur is required for the completion of the reaction the spent oxide, when removed from the vessel after working for about three months shows little or no loss in sulphur, while occasionally some slight increase may be found. Accordingly, the process would be of a continuous nature were it not for the fact that the physical nature of the oxide gives rise, after a time, to excessive back-pressure, when the only remedy is the substitution of a fresh layer. Figures obtained in practice show that one ton of spent oxide is capable of removing the cyanide evolved from 350 tons of coal.

The Recovery of Crude Benzol.

While the 'stripping' of gas for the recovery of the aromatic series of hydrocarbons has been carried out in the case of coal gas produced on coke-oven works for some years, the practice has only recently been introduced in gasworks, primarily as a means of meeting the demand for certain essential war products. The coal gas, either in the semi-crude state (*i.e.* after the wet purification plant) or when completely purified, is subjected to washing with a solvent which absorbs the benzene hydrocarbons but which has no effect on the remainder of the constituents. The solvent employed consists usually of a coal-tar distillate known as 'green oil,' although other substances, such as creosote, blast-furnace oil, or crude petroleum, may also be employed. The oil, after having been in contact with the gas, is said to be benzolised, when it may contain up to 5 per cent. of benzene hydrocarbons, according to the extent to which 'stripping' is carried. The benzolised oil is then passed through a series of vessels comprising the distilling plant in which the benzene hydrocarbons, with some light naphthas and a small proportion of naphthalene, are driven off and separated from the wash-oil. The benzene vapours thus obtained are condensed and collected as a crude spirit, while the wash-oil, having been 'debenzolised,' is cooled and once more employed for treating the gas. In general, it is customary to recover from normal coal gas from 1½ to 2½ gallons per ton of coal carbonised, depending upon the amount of aromatic hydrocarbons contained in the original gas and the proportion of these which it is deemed advisable to extract. The crude spirit will vary in composition, but in general about 65 to 70 per cent. will distil over up to 120° C., and 80 per cent. up to 160° C. The portion which distils over will consist of about 80 per cent. of benzol and 15 per cent. of toluol, the remainder being xylol. The amount of wash-oil employed for extraction per ton of coal carbonised undergoes considerable variation in accordance with the taste of the responsible engineer. It may be said, however, that it should never be less than 60 gallons per ton of coal, while it may be so much as 100 gallons. Water in the wash-oil is strongly to be guarded against, and should never exceed 1 per cent. by volume if effective results are to be obtained. Temperatures play an important rôle in the process, and it may be said that the scrubber should never exceed about 70° F., and as regards the temperature of the debenzolised oil a good rule to observe is that of maintaining the oil about 5° F. above the temperature of the gas. Now that the demand for explosives has ceased many gas undertakings have discontinued the recovery of benzol.

There can be no question, however, that experience with benzol stripping has shown that a valuable effect results so far as naphthalene is concerned. On quite a number of works it has, therefore, become a common practice to wash the gas with oil, the primary object being, not the recovery of benzol, but the reduction of naphthalene. Green oil of the usual kind may be utilised for the purpose, but gas oil has in many cases been found to be superior.

Tar Distillation.

(Contributed by Harold Moore, M.Sc., A.I.C., F.C.S.)

The yield of coal tar depends very largely upon the volatile content of the coal; but, in addition, it is considerably affected by the design of the retort. Retorts in which heating is conducted gradually, and which ensure the rapid removal of the volatile products from the heat zone, yield the largest quantities of tar. The nature of the tar depends, to a slight extent, upon the type of coal used, but is much more seriously affected by the carbonising conditions. A rapid rise in temperature, with a high maximum temperature, tends to produce tar high in specific gravity, high in viscosity, rich in free carbon, and mainly consisting of aromatic hydrocarbons. Gradual heating, low maximum temperature, and rapid removal of the volatile products result in brown mobile tars, comparatively devoid of free carbon and rich in aliphatic hydrocarbons.

Horizontal retorts subject the coal to a very rapid heating with a high maximum temperature, whilst the volatile products have to pass along the heated retort walls, whereby they undergo cracking. The result is a viscous tar, rich in free carbon. Horizontal retort tars frequently

contain over 20 per cent. They possess a specific gravity of about 1·2. In continuous vertical retorts the coal is slowly passed from the cool zone into a hotter zone, undergoing gradual heating, whilst the volatiles are removed from the cooler end of the retort, and, therefore, are not so liable to undergo cracking. The resulting tar possesses a specific gravity of about 1·08, and about 1 to 8 per cent. of free carbon. Inclined retorts give products of intermediate composition; whilst coke ovens yield tars of very varied composition, depending upon the design of the ovens.

Special processes for the low-temperature carbonisation of coal, such as the Coalite and Premier Tarless systems, yield brown low-gravity tars in which free carbon is almost entirely absent. Gas works and coke ovens supply nearly all the tar produced in this country. Tar produced in gas works is accompanied by ammoniacal liquor, and requires settling out previously to distillation. The tar in distillation is usually divided into the following fractions in English distilleries:—

	Temperature.	Approx. Yield.
1. Crude naphtha	Up to 110° C.	3 per cent.
2. Light oil	110° to 200° C.	7 ,,
3. Crude carbolic oil	200° to 240° C.	7 ,,
4. Creosote oil	240° to 270° C.	15 ,,
5. Anthracene oil	270° to finish	10 ,,
6. Residuum of pitch	—	58 ,,

The finishing-point of the distillation is decided by the quality of pitch desired. The yields of the above products vary, of course, with the nature of the tars, horizontal retort tars yielding a residue of about 65 per cent. of pitch, whilst vertical retort tars give only about 50 per cent. of pitch. The benzene and toluene are mostly present in the crude naphtha fraction, the yield of benzene being about 2 gallons to the ton of tar. They are separated by distillation combined with washing with dilute alkali, which removes phenols, cresols, and other acidic bodies, followed by washing with dilute acid, which removes pyridine, quinoline, and other basic substances, and are finally refined by treatment with strong sulphuric acid, which removes certain sulphur-containing compounds and a portion of the unsaturated hydrocarbons originally present in the tar. Similar processes of refining are adopted for other fractions, though the strong acid treatment is usually applied only to the benzene, toluene, and solvent naphtha-containing fractions. The most common grades of these three distillates are sold under the names of 90*s.* benzol, 90*s.* toluol, and 90*s.* xylol. The 90*s.* benzol distils 90 per cent. of its volume at 100° C. by the tar distillers' retort test; 90*s.* toluol yields 90 per cent. at 120° C. by the same test; whilst 90*s.* solvent yields 90 per cent. at 160° C. The solvent fraction consists mainly of the three isomeric xylols. Naphthalene and anthracene are removed from the higher boiling fractions (naphthalene mainly from the carbolic oil fraction, anthracene from anthracene oil) by cooling and decantation, or by cooling and filtration.

The limiting temperatures of the fractions are liable to alteration, depending upon market conditions, whilst the distillation is frequently stopped at an earlier stage than that indicated in the above table, in order to yield a soft residue known as treated or refined tar, which is used for tar spraying on the roads. A soft finished residue is also frequently sold as pitch-creosote mixture, and used for the fuel market.

Benzol is mainly used for motor fuel, together with a considerable quantity of the toluol, though smaller amounts are employed in the synthetic chemical industry. Carbolic acid (phenol) and cresylic acid (cresols), obtained by alkali washing, both find their main market for the manufacture of disinfectants. Creosote oil is used for timber preservation and as fuel. The use of creosote as fuel is somewhat intermittent, depending upon the price of petroleum. Pitch is mainly used for road repairing, but also for many other purposes, a considerable amount being consumed for electric insulation.

WATER GAS.

Manufacture of Water Gas.

Water gas, which is employed as an auxiliary to coal gas in gasworks, is now usually of the 'blue' type, although in some instances oil enrichment has again been resorted to owing to the very considerable drop in the price of oil. The composition of these two gases has already been given on pp. 2177, 2454. The reactions occurring in the generator of the water gas plant are as follows:

$$(a)\ C + 2H_2O = CO_2 + 2H_2.$$
$$(b)\ C + H_2O = CO + H_2.$$

The carbon dioxide produced in the lower portion of the fuel bed according to equation (*a*) is then reduced to carbon monoxide on passing through the remainder of the fuel bed:

$$(c)\quad CO_2 + C = 2CO.$$

The extent to which the reaction (*b*) takes place depends largely upon the temperature prevailing in the lower part of the fuel bed.

As the above reactions are of an endothermic nature the heat of the fuel bed is gradually absorbed, accordingly this is replaced at intervals by the process of blowing. The reaction occurring during the 'blow' is of an exothermic nature, being simply as follows:

$$C + O_2 = CO_2.$$

All practical water gas plants are now operated on the intermittent principle of providing for short periods of a gasmaking 'run' and a 'blow.' In the more common carburetting plant the 'run' continues for 5 or 6 minutes, and is followed by a 'blow' extending for 3 or 4 minutes. In certain forms of plant intended entirely for the production of 'blue' gas the blowing period is generally of much shorter duration, lasting for about 70 to 90 seconds. The primary object of the 'blow' is to convert the coke direct into CO_2, thereby liberating the maximum quantity of heat, but this condition is never attained in practice, some CO being always present. The CO, in the enriching plants, is made use of for heating up the subsequent apparatus in which enriching takes place. In some of the later forms of 'blue' plants (in which no enriching vessels are required) the CO is employed for the purpose of raising the steam required during the 'run.' The average composition of the 'blow' gases issuing from the top of the generator is as follows:

Carbon monoxide	17 per cent. by volume.
Carbon dioxide	10 " " "
Nitrogen	73 " " "

Traces of hydrogen, methane and sulphuretted hydrogen may also be found. The CO is at a maximum, and the CO_2 at a minimum, during the first minute of the 'blow,' and as the period proceeds the CO undergoes reduction while the CO_2 increases in quantity.

As regards temperatures the generator should, at the commencement of the 'run,' be worked up to 2,000F.° By the time that the 'run' is completed the temperature will have dropped by from 300° to 500°. Owing to this fact the quality of the water gas undergoes gradual deterioration from the commencement of the 'run' onwards; thus at the end of the first minute of the 'run' the CO_2 content will only amount to some 2 per cent., whilst at the end of the fifth minute it may amount to from 7 to 8 per cent. The temperature of the carburettor and superheater varies in accordance with the type and quantity of oil in use at the time. Under normal conditions the following will apply:

Carburettor	1350 to 1400 F.°
Superheater	1400 to 1450 F.°

For the manufacture of carburetted water gas the materials required are as follows:

Coke	35 to 41 lbs. per 1,000 cub. ft. of gas;
Oil	about 2½ gallons per 1,000 cub. ft. of 18 candle gas;
Steam	27 to 30 lbs. per 1,000 cub. ft. of gas.

The cost of carburetted water gas is mainly influenced by the current value of the enriching oil utilised. To-day, blue water gas is a far more common and important product, so that many plants formerly utilised for producing carburetted gas are now employed for the production of blue gas only. The present-day cost of manufacturing blue gas is as follows:—

BLUE WATER GAS: COST OF MANUFACTURE (1925).

	Per 1,000 cubic feet.	Per therm.
	d.	*d.*
Coke, generator	6·0	2·0
Coke, for steam	3·0	1·0
Water, for steam	0·15	0·05
Wages	3·5	1·16
Maintenance	2·5	0·84
Purification	0·5	0·16
Establishment charges	0·75	0·25
Total	16·40	5·46

The impurities in water gas consist of carbon disulphide and sulphuretted hydrogen, which are present in the following quantities:

	Grains per 1,000 cub. ft.
Sulphuretted hydrogen	110 to 120
Carbon disulphide	10 to 15

As regards water gas tar, S. Carter has given the following analysis:

Specific gravity	1·0665
	Per cent.
Benzol	1·11
Naphtha	2·33
Creosote oil	21·35
Naphthalene	4·09
Anthracene oil	15·91
Pitch	56·70

The Complete Gasification of Coal.

Now that the choice of the quality of gas to be distributed rests with the gas engineer instead of being stipulated by Parliament, a certain amount of interest has been displayed in the process known as the complete gasification of coal. By this is meant the treatment of the coal under such conditions that no solid residue other than ash remains. Complete gasification may, of course, be carried out in two ways, namely, by treating the coal in two stages for the production, firstly, of straight coal gas, and secondly, of blue water gas in distinct plants, the two gases being subsequently mixed either in the crude or purified state. The alternative is to employ plant of special design in which the above two processes are carried out simultaneously.

From the standpoint of gas production, the two methods may be contrasted as follows:—

A. Dual Process.

	B.Th.U.
1 ton of coal yields—	
13,000 cubic feet of straight coal gas @ 520 B.Th.U. =	6,760,000
and 11 cwts. surplus coke.	
11 cwts. coke yields—	
20,500 cubic feet of blue gas @ 300 B.Th.U. =	6,150,000
Total yield in gaseous form from 1 ton of coal. =	12,910,000

B. Single Process.

	B.Th.U.
1 ton of coal yields—	
50,000 cubic feet of mixed gas @ 370 B.Th.U. =	18,500,000

The composition of the gas obtained from the modern single-stage complete gasification plant is as follows:

	Per Cent.
Hydrogen	51·0
Carbon monoxide	30·0
Methane	8·0
Unsaturated hydrocarbons	1·4
Carbon dioxide	4·6
Nitrogen	5·0
Oxygen	trace
Yield per ton of coal (cubic feet)	50,000
Calculated calorific power (gross)	370
Therms per ton of coal	185

SULPHATE OF AMMONIA.

Average commercial salt contains:

Ammonia	from 24¼ to 25¼ per cent.
Equal to	
Nitrogen	20·2 to 20·8 per cent.
Free acid	0·4 per cent.
Moisture	2 to 3 per cent.

Materials required for the manufacture of 1 ton of sulphate of ammonia:

Liquor, approximately	3,400 gallons of 8 oz. strength.
Acid "	18 cwts. at 80 per cent. strength.
Lime "	3 cwts.

The sulphate of ammonia recovered per ton of coal varies in this country between 24 ar 28 lbs.

Equation for formation :

$$2NH_3 + H_2SO_4 = (NH_4)_2SO_4.$$

Gallons of liquor × ounce strength × 0·0823 = lbs. of sulphate.

The total quantity of ammonia products (mainly sulphate of ammonia) produced in Englan Scotland, and Wales in 1923, was 425,590 tons.

CONCENTRATED LIQUOR.

The exigencies of the war were responsible for a new gasworks product in the form concentrated and purified ammoniacal liquor. This product contains about 25 per cent. ammonia, while the sulphuretted hydrogen is reduced to 0·5 per cent. by volume. The co centrated liquor is prepared by passing the ordinary liquor from the storage well through desulphurising column in which the carbon dioxide and sulphuretted hydrogen are remove the purified liquor being afterwards concentrated in a special still. With the war ended th majority of these plants have been shut down. During 1923 the quantity of concentrated liquo made in Great Britain was equivalent to 39,071 tons of sulphate of ammonia.

USEFUL MEMORANDA.

1 in. of mercury = 0·490 lbs. per sq. in. ; 1 in. of water = 0·0361 lbs. per sq. in. 1 lb. per sq. in. = 27·7 ins. of water.

A British Thermal Unit is the amount of heat required to raise 1 lb. of pure water 1° Fahr correctly, from 39·1° Fahr. to 40·1° Fahr.

A Calorie is the amount of heat required to raise 1 kilogramme of water 1° Cent. : correct from 0° to 1° Cent. This is the *large* calorie, which is the unit employed on gasworks.

1 British Thermal Unit	= 0·252 calories.
1 Calorie	= 3·968 B.Th.U.
1 Therm	= 100,000 B.Th.U.
Therms	= cu. ft. × calorific value per cu. ft. ÷ 100,00
Cu. ft.	= therms × 100,000 ÷ calorific value per cu. f

CALORIFIC VALUE OF VARIOUS GASES.

South Met. Co.	560 B.Th.U. per cu. ft.
Gas Light & Coke Co.	500 ,, ,,
Commercial Gas Co.	500 ,, ,,

200 cu. ft. of Gas Light and Coke Co's. gas = 1 therm.

CALORIFIC POWER OF VARIOUS SUBSTANCES.

	B.Th.U. per lb.		B.Th. per l
Coke-oven coke	14,436	Petrol, specific gravity 0·684	20,9
Peat, 5 per cent. water	9,900	Shale oil	18,2
Wood, pine	9,153	Blast-furnace oil	16,0
,, oak	8,316	Heavy tar oil	16,0
Petroleum, American	19,627	Coal gas tar	15,5
,, Texas	19,242	Alcohol, absolute	12,9
,, Russian	19,440		(*Lewes.*)

At normal temperature and pressure 32 cu. ft. of coal gas (14 candle power) weig approximately 1 lb.

1 cu. ft. of coal gas (14 candle power) at N.T.P. weighs ·03125 lb.
1 ,, blue water gas ,, ,, ·0376 lb.

GASWORKS TERMS.

A barrel of tar	25 gallons	A fodder of lead	19½ cwts.
A butt of liquor (Usually 8 oz. strength)	108 ,,	A hundred of deals	120 in numbe
A bushel of coal	80 lbs.	A load of lime (A bushel = 70 lbs.)	32 bushels
A bushel of coke	45 lbs.	A long thousand of slates	1,200 in numb
A chaldron of coal (Varies according to locality)	25½ cwts.	A seam of glass	120 lbs.
A chaldron of coke (Varies according to locality)	12½ cwts.	A short ton (American)	2,000 lbs.
A cord of wood	128 cub. ft.	A tonne (French)	2,204·6 lbs.
		A ton of freight	40 cub. ft.
		A truckload of bricks	About 3,300 in numb

VOLUMES OF OXYGEN AND AIR REQUIRED FOR COMBUSTION OF ONE VOLUME OF COMBUSTIBLE GAS.

Combustible Gas.	Oxygen.	Air containing 21 per cent. Oxygen.	Volume of Products of Combustion.
Hydrogen . .	0·5	2·38	1 vol. H_2O
Carbon Monoxide	0·5	2·38	1 vol. CO_2
Marsh Gas . .	2·0	9·52	1 vol. CO_2, 2 vols. H_2O
Ethylene . .	3·0	14·28	2 vols. CO_2, 2 vols. H_2O
		Incomplete Combustion.	
Marsh Gas . .	1·5	7·14	1 vol. CO, 2 vols. H_2O
Ethylene . .	2·0	9·25	2 vols. CO, 2 vols. H_2O

High Pressure Lighting.

For high-pressure lighting the cost of compressing the gas only amounts to from 2½ per cent. o 4 per cent. of the total cost of the gas consumed, which is very small when it is compared with he extra light obtained.

With a water-driven compressor, from 250 to 300 gals. water are required per 1,000 cubic feet as compressed to, say, 9 ins. pressure; with a gas-driven plant, 12·4 to 13·4 cubic feet per 1,000 ubic feet compressed to same pressure.

Compressing coal gas reduces the illuminating value until, with a pressure of 200 lbs. per q. in., the loss is 16 per cent.

(See also 'LIGHTING,' Section XXXVIII., Part III., p. 2521.)

Incandescent Burners.

The Bunsen burners used for incandescent lighting should give a flame with a green inner cone nd not a violet one, so as to show that the proportion of air used for primary combustion is as arge as possible. This ensures an intense heat in the flame, which intensity adds greatly to the ight emitted by the burner. This intensity of flame is obtained in the high pressure systems, which are now becoming so general for street and shop lighting, by increasing the pressure of this as to about 2 lbs. per sq. in., and when this is used with an inverted mantle of a much longer hape than the ordinary low pressure ones, the rush of gas at this high pressure at the nipple causes he full quantity of air required for combustion to be drawn in at the base of the burner mixing ube and so give a flame of the highest intensity. This flame only gives off the same heat per ubic ft. of gas as an ordinary Bunsen burner, but the heat is concentrated and the flame is much naller. If the quantity of air induced by the current of gas into the mixing tube is 2½ times that f the gas there will be a lilac inner cone, and the hottest part of the flame will be about 2,800°F., nd the mantle will then show about 20 candles per cubic ft. of gas consumed. If 3½ times of ir are induced, a green inner cone will be noticed, and then the flame will be about 3,000°F., and 0 candle power per cubic ft. of gas obtained.

Products of combustion must be conveyed away and not allowed to enter at the primary air ole of the Bunsen burner. The air used there should contain the full proportion of oxygen to nsure proper combustion. Mantles must fit the flame, or, inversely, the flame must fit the mantle. s then it will be in the hottest part of the flame which is at the outside where the C in the gas s combining with the O_2 of the air to form CO_2 with the evolution of the heat. As the flame is ollow, if the mantle is smaller than the flame it will be in the cooler region of the flame where the as is not being fully burned. Upright burners give their greatest light horizontally, inverted urners downwards. Shades for gas lights should be at 45° with the horizontal, not 60° or 70° s usually adopted, when very little light is reflected.

The best effects are obtained with burners which permit of the adjustment of both air and as. These burners should be adjusted from time to time. The burner should be thoroughly leaned out each time a mantle is fixed.

Incandescent Mantles.

Mantles are made from cotton, ramie, or artificial silk knitted into a 'stocking' or hose about ins. in diameter. This stocking is thoroughly washed and dried. Then it is saturated with a olution of nitrate of thorium and 1 per cent. of nitrate of cerium. After the stocking has been ashed and dried, it is either cut to proper size and impregnated with the thorium solution, or

is first impregnated and then cut to the required lengths. The impregnated stockings, after being cut and dried, are sewed at one end with asbestos thread so as to form a head provided with a loop, which serves to hold the mantle in process of manufacturing and when in use on the burner. Then the impregnated stocking is hung on a wire by the asbestos loop, and heated in a gas flame of the Bunsen type. This is done in order to burn out the thread. The next process is called the shaping. The mantle now consists only of ashes of thorium (oxide of thorium), and is carefully held over a high pressure Bunsen flame, and gradually given the right shape, at the same time being hardened. As soon as the mantle is shaped and hardened it is practically completed, but in order to protect it from breakage it is 'dipped' in a stiffening solution. There are many forms of 'dip,' but the one most used is made of soluble cotton (gun cotton) dissolved in good alcohol and acetone. To this mixture castor oil and shellac are added.

Gas versus Electricity.

The inverted incandescent gas lamp requires 47 B.Th.U. per candle-power hour obtained. The one-watt electric lamp requires 54 B.Th.U., and the ½-watt lamp 31 B.Th.U. A considerable proportion of gas burners consist of the upright type, which are less efficient, requiring 82 B.Th.U. per candle-power hour. The average may be taken at 64 B.Th.U. per candle-power hour. High-pressure incandescent burners reduced the heat consumption to 23 B.Th.U. per candle-power hour and flame arcs in electric lighting use only 15 B.Th.U. At about 75 per cent. of full load a gas engine of the ordinary type would deliver to the consumer as actual or brake horse-power 11 per cent. of the heat used at the gasworks, while an electric motor would deliver, also as brake horse-power, only 6·8 per cent. of the heat used at the electricity generating station. The efficiency of the gas power production and distribution was thus over 1·6 times that of the electricity system.
